Gastroptosis (Fig. 688).—In this condition the stomach has undergone displacement downward, the greater curvature in many cases being but little above the pubic symphysis and the lesser curvature being between the ensiform cartilage and the umbilicus. This condition is far more common in women than in men, and is especially common in women who have had many children. It may be produced by tight lacing and may follow movability of the right kidney, of the liver, or of the spleen. It is often associated with enteroptosis, mobile cecum, and prolapse of the colon, and is particularly prone to arise in the anemic and tuberculous.

Symptoms.—There may be no symptoms for a long time, but sooner or later dyspepsia arises because the stomach cannot empty itself. The stomach becomes atonic, its secretions are scanty and altered, and while the viscus may be normal in size or even shrunken, it is usually dilated. The malposition can be made out by percussion when the stomach is distended with air or with fluid, and by the *x*-rays after the patient has drunk a pint of a solution of mucilage of acacia containing subnitrate of bismuth. The bismuth lines the stomach and intercepts the *x*-rays and a radiograph shows the outlines of the stomach and hence its size and position. The pylorus descends to the umbilical region, which it does not do in plain dilatation. In dilatation the pylorus is but slightly lower than normal, but the lower border of the stomach is notably depressed.

In gastroptosis there is often a constriction a short distance from the pylorus due to a kink produced by the sagging.

When a patient with gastroptosis stands erect the bulging is most prominent in the region of the umbilicus and the epigastrium is deepened.

Gastroptosis is not infrequently associated with chlorosis and commonly with neurasthenia.

Treatment.—Lavage, regulation of diet, improvement of the general health, the wearing of an abdominal binder, and placing the patient supine for a time after each meal comprise the medical treatment. If medical treatment fails and the condition is producing grave impairment of the general health, it may be necessary to perform a surgical operation. Gastro-enterostomy is advocated by some on the ground that the unpleasant symptoms result from stagnation of gastric contents. Good results have been reported by this plan. The operation of Depage is unphilosophical. Duret's operation is objectionable (see page 1243). Beyea's operation or Ransohoff's method is preferred (see page 1243).

Fig. 688.—Gastroptosis (shown by a skiagraph).

Chronic Intestinal Stasis.—This is a term employed by Sir Arbuthnot Lane to designate such a delay in the passage of material along the gastro-intestinal tract as to permit of the absorption of so much toxin that the body cannot successfully deal with it (Lane's paper before the Derby Med. Soc., Oct. 17, 1911). Defective drainage permits absorption of poison, and absorption of poison is responsible for ill health and the lowering of vital resistance to various bacteria. Lane and his followers are of the opinion that toxemia so induced may cause chronic mastitis, rheumatoid arthritis, gastric ulcer, duodenal ulcer, appendicitis, and, by lowering resistance, may be responsible for progressive tuberculous disease. They believe that the block to drainage is brought about by kinks, and that the kinks, which tend to form in certain situations, are due to bands; in other words, the condition is due to a mechanical cause (Lane, Ibid.). Mayo regards such bands as congenital. Lane holds that faulty feeding in early life causes abnormal distention and pull on the gut, that when the erect posture is assumed the condition is exaggerated by the formation of new peritoneal bands which are formed to resist the dropping of the intestine.

In 1909 Jabez Jackson described a pseudomembrane sometimes seen over the

peritoneum of the lower ileum and colon and loosely attached to it. Sometimes it is also attached to parietal peritoneum and thus limits movements of the gut. This thin membrane is known as *Jackson's veil*, and it is probably identical with Lane's bands. Some observers regard Jackson's veil as the result of pericolitis, some as due to infantile colitis, some to chronic colitis, some to appendicitis. Isaacs ("New York Med. Jour.," Oct. 26, 1912) points out that this pseudo-membrane may be found in other regions than over the colon, and suggests calling the condition *membranous perienteritis*. He believes the membrane is formed because of ulceration or inflammation of the gastro-intestinal tract.

The large intestine is thought by many to play such a prominent part in toxin absorption that Barclay Smith (quoted in "Brit. Med. Jour.," Dec. 7, 1912), Metchnikoff, Lane, and others put under ban that portion of the gut, regard it as a useless and dangerous encumbrance, and would take it out and cast it away. Biological teaching opposes the view that the large gut is useless. It has been shown that animals like the wombat, which have come down from an antediluvian species have long large intestines. Were the theory that the large gut is useless true, these animals should have been the first to disappear.

If kinks cause stasis it is strange that the *x*-ray pictures fail to demonstrate it at the hepatic flexure or in the ascending colon (Knight, "Lancet Clinic," cxiv).

Treatment.—If a band or membrane exists, remove it, and if a raw surface is left, cover it over with peritoneum.

In partial blocking of the beginning of the large intestine or of the lower ileum some perform ileocolostomy. Lane found that in 20 per cent. of his operations impaction of the cecum necessitated a subsequent colectomy, so now he extirpates the colon and fastens the upper end of the divided ileum to the rectum. He does the same operation for rheumatoid arthritis, tuberculous joints, and other conditions—long steps on a radical road where, so far, few have gone more than a short distance.

Intestinal obstruction (**ileus** or **enterostenosis**) is a condition in which fecal movement is mechanically impeded or prevented. It may be either *partial* or *complete*, *acute* or *gradual*. *Acute obstruction* is due to a sudden narrowing or occlusion of the lumen of a portion of the intestine. *Chronic obstruction* is due to a gradual narrowing of the lumen of a portion of the intestine, and it may at any time become acute. If there is not only interference with the passage of the fecal current, but also obstruction to the blood-current in the wall of the bowel, the condition becomes *strangulation*. The primal cause is mechanical in nature, in most cases a mechanical block. In paralysis of the bowel from peritonitis there is inability of the bowel-wall to contract and force the feces onward. In all cases of unrelieved obstruction the nerves are sooner or later damaged and paralysis occurs. In acute obstruction the stagnated intestinal contents become charged with powerful poisons which act most harmfully on the musculature of the intestinal wall, and, after absorption, attack the heart and nervous system. The inaugural shock is due to the production of the block; later the increasing depression is due to absorption of poisons. Gas forms in great amount in the intestine and produces distention. Distention impairs the circulation in the wall of the intestine and embarrasses respiration by pushing up the diaphragm.

Acute Obstruction.—The worst forms of this grave condition are due to sudden and absolute blocking of the bowel with strangulation, as when a portion of bowel is caught under a band or in a hernial aperture.

As soon as strangulation occurs there is violent peristalsis. The bowel above the strangulation for a short time vainly lashes itself into effort to force intestinal material past the obstruction. The peristalsis below empties the bowel below the obstruction, leaving it empty and contracted, but not paralyzed.

Peristalsis above the obstruction soon ceases, and the bowel in this region becomes greatly distended with bloody fecal fluid and gas. The putrefaction

of the intestinal contents forms great quantities of gas: none of it can pass the obstruction and none of it can be absorbed because of circulatory disturbance in the bowel wall. It is only early in an acute obstruction that the distended bowel above the block is thin. It soon becomes congested and edematous, bleeding may occur from the mucous membrane which desquamates and may be eroded. When the mucous membrane is desquamated, bacteria pass through the bowel wall and cause peritonitis, or erosions may perforate. Miles ("A System of Surgery," edited by C. C. Choyce) points out that swelling of the gut is greatest when obstruction is in the small intestine because "secretion of a considerable amount of fluid is reflexly stimulated." The distention may ascend all the way to the stomach.

In most cases strangulation at first blocks veins; later, in severe cases, it also blocks arteries. In a very sudden and complete strangulation both arteries and veins are shut off simultaneously. Early in the case, when the veins only are obstructed, the coil of gut is purple, edematous and distended, and bloody serum may pass into the lumen of the bowel and also into the cavity of the peritoneum. Later the arteries are blocked and then gangrene soon occurs. In very acute cases when the arteries and veins are blocked simultaneously, gangrene arises promptly. In such a case the strangulated coil is not distended and is gray or greenish in color. When strangulation occurs bacteria soon begin to pass through the walls of the strangulated coil and cause peritonitis. Perforations may take place in the coil, at the seat of constriction, or even in the gut above the block.

Chronic Obstruction.—This comes on gradually. A tumor may slowly fill up the lumen of the bowel or a cicatrix or tumor in the bowel wall may constrict more and more. Pressure outside the bowel may be responsible. In regions where the feces are fluid great narrowing can occur without symptoms. When fecal passage is seriously hindered the bowel above the obstruction becomes distended and its muscular wall undergoes hypertrophy. The hypertrophy depends on the exercise of greater and greater effort to overcome the obstruction. Miles ("A System of Surgery," edited by C. C. Choyce) states that above the obstruction the bowel becomes thick, "elongated, and tortuous;" that in the small intestine hypertrophy exceeds dilatation, and in the large intestine dilatation exceeds hypertrophy.

The mucous membrane is inflamed because of irritation of retained decomposed material and ulceration may occur. Peri-intestinal suppuration may arise. Gas does not gather above the obstruction because the circulation is still active in the bowel wall and because some gas can still pass naturally. When the narrowed channel in a partially obstructed bowel suddenly and completely closes, acute obstruction arises. When it does the bowel above becomes congested and distended. An active purgative or indigestible food may be responsible for acute obstruction.

Various Causes of Intestinal Obstruction. Obstruction by Adhesions (Fig. 689).—Adhesions result from previous peritonitis. There may be a few adhesions or a multitude of them. A portion of bowel may be bent or twisted by the traction of adhesions or gaseous movement may twist a coil or bend it above an adhesion. The obstruction may be acute or chronic. Even when acute, strangulation is unusual.

Volvulus (Fig 690).—By this term we mean twisting of a loop of bowel upon its mesenteric axis. It is true that under peculiar circumstances the bowel may twist on its own long axis because of adhesions, but such a twist is not a true volvulus. Fifteen per cent. of acute obstructions are due to volvulus (Briggs, "Ohio State Med. Jour." Nov., 1912). Volvulus may occur in a hernial sac. In rare cases two coils of intestine twist together. It is not limited to the pelvic colon, but, in a very large majority of cases, it is this portion of bowel which suffers. The twist may be partial, a complete turn, or even two or three complete

turns. This very dangerous condition occurs particularly in adults. A colon loaded with feces predisposes; so does a long mesocolon and a mesocolon with a narrow base, and so may adhesions. Rotation may be caused by straining at stool, by a sudden shift in position, by lifting, by a blow upon the abdomen, or by peristalsis induced by an active purgative. In most cases the twist is tight enough to occlude the blood-supply of the loop. The loop becomes plum colored and edematous, bloody serum flows into the bowel and into the peritoneal cavity, and immense distention of the loop occurs. The colon above the obstruction also distends. Peritonitis occurs early. Perforation may occur and is most apt to take place above the loop.

Intussusception (Figs. 691, 692).—By this term we mean the invagination of a portion of bowel wall into the lumen of an adjacent part of the gut. In nearly all cases an upper segment invaginates into the lower. One-third of all cases of obstruction are due to this cause (Treves). In young children it usually causes acute obstruction; in an adult, chronic obstruction, ending perhaps in an acute attack. Most cases of obstruction in children are due to intussusception. Pitt reports that in St. Thomas's Hospital, from 1875 to 1900 inclusive, there were 115 cases of intussusception, and every patient was under fifty years of age. Gibbon's patient was fifty-eight. Rutherford Morrison had a case due to polypus, and the patient was sixty-two years of age. Males are twice as liable as females. During the performance of peristalsis a localized circular constriction forms and the invagination takes place through the constricted area. The great relative frequency of intussusception in childhood is due to the greater mobility and irritability of the child's bowel (Treves). The irregular and localized spasm is due to bulky or irritant material within the gut, and, according to Rushmore ("Annals of Surgery," August, 1907), the starting-point of invagination is obstruction. Were peristalsis alone the cause the condition would be far more common than it is in the diarrhea of children. There are four chief varieties: the *ileocecal*, in which the ileum and the ileocecal valve pass into the cecum and colon; the *colic*, in which the large intestine is prolapsed into itself; the *ileal*, in which the small intestine alone is involved; and the *ileocolic*, in which the ileum prolapses through the ileocecal valve. Other forms are *diverticular* (with a diverticulum), *retrograde* (due to reversed peristalsis), *of Meckel's diverticulum, ileo-appendiceal*, and *cecal*. The first variety is vastly the most common. In Rushmore's table ("Annals of Surgery," August, 1907) the location was definitely stated in 237 cases: 140 of these were ileocecal and 31 were ileocolic.

The *intussusceptum* consists of the entering tube and the returning layer.

The *intussuscipiens* is the sheath or receiving tube. As the intussusceptum grows longer and longer the mesentery is drawn between the entering tube and the sheath. The mesentery becomes curved and draws the involved intestine toward the back and left side. The dragging, twisting, and squeezing of the mesentery impairs the blood-supply of the intussusception. The invaginated portion, especially the returning tube and apex, becomes congested and swollen, the mucous membrane secretes profusely, and blood passes into the bowel. From this source come the blood and mucus passed by the bowel. An intussusception tends to become irreducible by adhesion of its walls and by engorgement, particularly of the apex. An intussusception may cause complete obstruction eventually, strangulation may take place, gangrene may occur, peritonitis may arise.

Foreign Bodies, Gall-stones, and Enteroliths ((Fig. 693).—Foreign bodies include, besides certain substances that have been swallowed, gall-stones and enteroliths or intestinal calculi. Foreign bodies are apt to lodge in the lower portion of the ileum or in the cecum, and they may cause ulceration at the seat of lodgment. If a gall-stone is sufficiently large to cause obstruction, it cannot have passed the duct, but must have ulcerated into the bowel from the gall-

bladder. About three-fourths of the cases of gall-stone intestinal obstruction occur in women. The stone is arrested at some point because either local spasm or paralysis of the bowel has developed. It may be arrested high up, but is most apt to be in the lower ileum. A stone under 1 inch in diameter ought to pass. A. W. Mayo Robson ("Brit. Med. Jour.," May 1, 1909) points out that all cases of obstruction due to gall-stones are not the result of mechanical obstruction by a large stone which entered the intestinal canal by ulceration, but that there are three other possible conditions, viz.: Local peritonitis in the gall-bladder region causing paralysis of the bowel; volvulus of the small intestine due to biliary colic or to ulceration of a gall-stone into the gut; obstruction coming on "after the original cause has disappeared" and due to adhesions without or obstruction within the gut.

Enteroliths (fecal concretions) are usually deposits of salts from the feces, especially apt to be formed when the patient has long suffered from catarrhal inflammation of the bowel. The nucleus may be a hair-ball in a woman who swallows hair, or the stone of a fruit. A gall-stone may have a concretion form about it. Food residues mixed with salts may constitute concretions. So may insoluble materials taken frequently as medicine or from habit (chalk, bismuth, magnesia). An enterolith increases in size up to a certain point, but seldom becomes enormous.

Internal Herniæ (Fig. 695).—These include: (1) retroperitoneal hernia, (2) diaphragmatic hernia, and (3) other intraperitoneal hernia.

A hernia may pass into one of the fossæ about the duodenum, one of the fossæ about the cecum, the intersigmoid fossæ, or through the foramen of Winslow into the lesser peritoneal cavity. Pringle reported a case of hernia into the paraduodenal fossa ("Glasgow Med. Jour.," 1916, lxxxvi). Intersigmoid retroperitoneal hernia is one of the rarest of lesions and only three cases have been reported (John B. Murphy's Clinics, August, 1914). The appendix may be strangulated in a pericecal fossa and cause obstruction. Diaphragmatic hernia is described on page 1302. An internal hernia may become strangulated just as an external hernia.

Obstruction by Bands and Abnormal Openings (Fig. 696).—Briggs considers adhesions, bands and abnormal openings responsible for 40 per cent. of cases. The band may be a portion of the great omentum which has taken on an unnatural attachment, a Meckel's diverticulum, omphalomesenteric remnants, an appendix attached at its tip, a broad band or cord-like peritoneal adhesion, a retroperitoneal pouch or an abnormal opening in the diaphragm. The obstruction in these cases is apt to be acute and is commonly accompanied by strangulation. It usually involves the ileum, sometimes the colon. There may be an abnormal opening, congenital or acquired, in the omentum, the mesentery, or the mesocolon. The bowel may slip through such an opening and be caught and strangulated.

Obstruction may take place by *Meckel's diverticulum* (Fig. 694) (see page 1122), a structure due to persistence of the vitelline or omphalomesenteric duct, coming off from the ileum from 12 to 36 inches above the ileocecal valve, and present in about 2 per cent. of persons. The vitelline duct should be obliterated in the eighth week of fetal life. If it persists the individual possessing it is in constant and serious danger. The mortality of a series of cases of obstruction due to Meckel's diverticulum is enormous. A Meckel's diverticulum usually has no mesentery, is from 3 to 10 inches long, and arises from the convex side of the gut. It may hang free or may be attached to the umbilicus by its tip or by a fibrous cord formed by the obliterated tip. In some cases it remains open at the umbilicus (see page 457). In other cases a cord runs from the umbilicus to the gut or the tip of the diverticulum or is adherent to another portion of the intestine. The diverticulum may become gangrenous with or without strangulation, may enter a hernial sac, may ulcer-

ate or perforate like an appendix. (W. Sheen, in "Bristol Medico-Chir. Jour.," Dec., 1901, gives an admirable account of "Some Surgical Aspects of Meckel's Diverticulum;" see also article on "Obstruction of the Bowels by Meckel's Diverticulum," by James E. Moore, in "Jour. Am. Med. Assoc.," Oct. 4, 1902 and on "Abdominal Crises Caused by Meckel's Diverticulum by Miles F. Porter, in "Jour. Am. Med. Assoc.," Sept. 23, 1905.) Strangulation of the diverticulum may take place beneath an adherent appendix, a Fallopian tube, a portion of mesentery, or the pedicle of an ovarian tumor, or it may take place in an omental or a mesenteric aperture. Gangrene, inflammation, or twisting may occur. Obstruction may be due to invagination of the diverticulum into the bowel. H. Tyrrell Gray collected 39 cases of invagination and added 1 of his own, 40 in all ("Annals of Surgery," Dec., 1908).

Cicatricial Stricture.—This is not a common cause. I have operated on 1 case due to the scar of a typhoid ulcer. The obstruction occurred gradually and became acute years after the fever. Any healed ulcer may be responsible. Tuberculosis is the most common cause. Syphilis or dysentery may be responsible. A contusion or wound of the bowel may be causal.

Tumors of the Bowel.—They are uncommon in the small intestine. Adenoma, lipoma, fibroma, and myoma may occur. They may cause obstruction from blocking or may be responsible for intussusception. Sarcoma is seldom met with, but more often in the small bowel than in the large gut. The patient's general health is much impaired, and a tumor can be palpated before obstruction occurs, and obstruction may never occur. Carcinoma of the upper bowel is rarely met with. Cancer of the small bowel is more common than benign tumors and sarcoma, but less common than cancer of the large bowel. Cancer of the small intestine is most common in the lower ileum, and arises from columnar cells. It causes constriction and stenosis and usually ulcerates. In the large intestine fibroma, lipoma, adenoma, myoma, or sarcoma may arise. I removed an adenoma from the sigmoid which had produced obstruction. Apparently it has not recurred after four years. A great number of adenomata may be present (*multiple adenoma of Virchow*). Obstruction is rare from innocent tumors. In sarcoma symptoms are absent until the growth attains a large size and obstruction may be the first symptom. Sarcoma of the intestine causes glandular involvement as does cancer. The colon is a common site for cancer. It is usually primary, but may be secondary. It produces chronic obstruction. The growth is columnar celled, and may be scirrhous, encephaloid, or colloid. A tumor causes obstruction by a block, a kink, a volvulus or an intussusception.

Obstruction by Tumors, etc., Outside the Bowel.—Among the causes of such obstruction are retroflexion or retroversion of the womb, especially in pregnancy, cysts or tumors of the kidneys, mesentery, ovaries, uterus, etc., movable kidney, enlarged spleen or diverticulum of the bowel (sigmoid or small bowel). Obstruction from any of the above causes takes place in the rectum, the sigmoid flexure, or the colon above the sigmoid.

Obstruction from Fecal Accumulation.—Fecal impaction resulting from prolonged constipation is quite common. Obstruction sometimes, but seldom, occurs. When obstruction follows upon impaction it is usually brought about by rotation of a loop of bowel (volvulus) or angulation of a segment, but may be due to abolition of peristalsis because of paralysis. In impaction the fecal mass is usually soft, but may be hard. There may be one large mass or numerous smaller ones. The mass may reach from the rectum even into the transverse colon and may even be mistaken for a neoplasm. It usually begins to form in the pelvic colon (Miles, "A System of Surgery," edited by C. C. Choyce). The weight of such a quantity of feces may cause a packed loop of gut to sink into the pelvis and may stretch and narrow the mesocolon. Ulcerations of the mucous membrane may form (*stercoral ulcers*).

Postoperative Obstruction.—Obstruction may come on a day or two after, several or many days after, or weeks or even months after an abdominal operation. We deal here with early obstruction.

Obstruction may be due to a mechanical cause at the seat of operation (adhesion of the bowel to a raw surface, volvulus, catching of the gut under a band, etc.). It may be due to a mechanical cause distant from the seat of operation (bands, adhesions, displacement of the intestine, etc.) It may be due to thrombosis of the mesenteric vessels. Although any one of the above conditions may arise after an operation, there is nothing special and peculiar in it when it does. Such conditions are considered under special headings (bands, adhesions, etc.). Again, postoperative obstruction may be due to the pressure upon the gut of gauze-packing or of a drainage-tube. It may be due to paralysis of a loop of gut because of local sepsis (as after an operation for appendicitis), or it may be a paralytic ileus from widespread sepsis (general peritonitis).

What we really mean by postoperative obstruction is a condition arising from gaseous distention. Gas begins to accumulate soon after the operation. The patient cannot expel it. He tries, but the straining efforts fail and may burst the belly wound. More and more gas gathers and annoyance becomes torture. The overdistended bowel finally becomes paralyzed and paralytic obstruction occurs. This true postoperative obstruction is particularly apt to arise if evisceration has been practised, if the intestines have been squeezed and handled and not protected from chill, and if the operation has been prolonged.

Embolism or Thrombosis of the Mesenteric Vessels.—The arteries may be the seat of embolism or thrombosis; the veins, of thrombosis. A large artery may be blocked by an embolus or occluded by a thrombus or a large vein may be blocked by a thrombus or filled by the extension of a thrombus from a radical of the portal system (especially from the region of the appendix). The section of bowel, large or small, from which the blood is kept undergoes paralysis. Gangrene and peritonitis soon follow. This very fatal condition manifests itself in most cases as a paralytic obstruction arising suddenly in an individual who has cirrhosis of the liver or valvular disease of the heart, or who has had ulcerative endocarditis.

Reflex Obstruction of Renal Origin.—This condition may occur as a result of Bright's disease, renal calculi and infections and the stomach may dilate as well as the intestine (see Daniel N. Eisendrath, in "Surgery, Gynecology, and Obstetrics," June, 1916). This reflex paralysis is made manifest by distention, sudden obstruction, vomiting (which does not become feculent early), pain and abdominal rigidity. The condition appears to be due to splanchnic inhibition (Eisendrath, Ibid.).

Pseudo-obstruction or Spasm of the Intestine.—In this condition a limited portion of the bowel undergoes spasmodic contraction, which lasts for several hours or even for a day and then passes quickly away. This contraction is usually in the pelvic colon. In many cases a swelling can be made out. It is due to a loop of distended gut and disappears when the patient is under ether. Such a swelling is known as a *phantom tumor*. These attacks occur in neurotic women, especially those with catarrh of the colon. Besides the causes of obstruction above mentioned we should refer to shrinking of the mesentery.

Symptoms of Acute Obstruction.—The onset is marked by pain, shock, and vomiting. The tighter the constriction, the more sudden is the attack; the more bowel there is involved, the greater the shock. This element of shock often makes the diagnosis uncertain, and we may suspect abdominal hemorrhage or perforation when the real lesion is strangulation. The pain is violent and continuous, with fierce exacerbations. The continuous pain is due to the constriction; the exacerbations, to the colic of peristalsis. If the small intestine is involved the continuous pain is about the umbilicus. If the large

intestine or duodenum is the seat of trouble the continuous pain is located about the lesion. The pains of peristalsis are generalized throughout the abdomen. The higher up the constriction, the tighter it is, and the more bowel there is caught, the greater the pain. Later, when paralysis of the gut occurs or perforation takes place, the pain for a time abates, to recur again with peritonitis. Early in the case there is neither rigidity nor tenderness; as paralysis begins tenderness develops. Early in the case pressure may actually afford some relief. When tenderness exists tapping is more apt to cause pain than is pressure; in peritonitis pressure causes more pain than tapping (Battle). When peritonitis arises, of course tenderness becomes acute and rigidity develops.

Vomiting comes on soon after the development of pain, but does not give any relief. It is accompained by nausea and violent retching, continues practically without cessation, and whether food and drink are taken or not.

The vomited matter consists first of the contents of the stomach, next of quantities of bilious matter, and finally of brown or yellow stinking fluid, which was long believed to be feces. Vomiting of this character is called *stercoraceous vomiting*. Vomiting of genuine feces may occur, but is rare. In stercoraceous vomiting the fluid gushes up in quantity and by regurgitation rather than efforts of vomiting. This sort of vomiting can occur even when the obstruction is in the upper jejunum or duodenum.

A notable characteristic of obstruction is total inability to pass gas or feces. It is necessary to remember that in the very beginning of the case there may have been a bowel movement, due to peristalsis emptying the intestine below the seat of lesion. A single movement early is no proof that the condition is not obstruction. It is only in cases of strangulation in the pelvic colon that the patient has a strong desire and makes frequent attempts to move his bowel. If an enema is given it is usually retained, or else leaks away without bringing fecal matter with it. Distention from gas (*tympanites*) is always soon present. The lower the obstruction, the more widespread is the distention. Early in the case the abdomen is flat and relaxed, but this condition is very temporary. We may be able to gain information by studying the distention. If both flanks bulge, the block is in the pelvic colon. If the left flank is flat and the right distended, the block is in the colon well above the pelvic colon. If only the small intestine is distended, the block is on the proximal side of the ileocecal valve. As the case progresses distention increases and causes great embarrassment to respiration by pushing up the diaphragm. In thin patients, early in the case, we may occasionally see waves of peristalsis above the obstruction. We can sometimes feel them even when they are unrecognizable by the eye. In many cases of intussusception and in a number of cases of chronic obstruction which have become acute they can be felt.

Cases of intestinal obstruction tend to pass into collapse. This condition is due to the absorption of poisons from the decomposing matter above the obstruction, and is aggravated by vomiting and sweating which abstract quantities of fluid from the blood. When collapse has come on the temperature is subnormal; the extremities cold; the pulse very rapid and weak, often a mere thread or trickle; the respirations are rapid and shallow, and the face *Hippocratic* (eyes, cheeks and temples sunken, eyes dull and often turned upward, lids drooping, nostrils thin and drawn, features pinched, the nose pointed, the malar bones prominent, ears retracted and cold, jaw often drooped and mouth perhaps open, lips blue or blanched, skin livid or deadly pale). The amount of urine passed is very small. The higher the obstruction, the less the amount passed. During or after the second day indican is usually present in the urine. It results from putrefaction of proteids brought about by anërobic bacteria and the formation of indol in the intestine. In obstruction there is leukocytosis, the

white count being from 15,000 to 30,000 (Bloodgood, in "Johns Hopkins Hospital Reports," vol. vii).

The mortality from acute obstruction is very high. According to Elsberg, gangrene occurs in 13 per cent. of cases. Seldom can a mass be felt. It can often be felt in intussusception; it can sometimes be palpated when there is a fecal concretion or other foreign body. Obstruction during pregnancy is very dangerous. If the uterus is not emptied by operation most cases will abort or miscarry. The diagnosis is usually made disastrously late because the pain of obstruction is thought to be the pain of parturition.

Symptoms of Chronic Obstruction.—The symptoms come on gradually. There are periods when great constipation exists, alternating with periods of comfort or perhaps with seizures of fluid diarrhea. After a time the attacks of constipation become painful and accompanied, it may be, by vomiting after eating. The patient feels abdominal discomfort most of the time and is much annoyed by gas in the intestine. It is very difficult to expel the gas from below. All the time the constipation is growing more obstinate and the patient is resorting to stronger and stronger purgatives and obtaining less and less response. Finally, a strong purgative may fail utterly, only serving to cause severe colic and perhaps vomiting. It may also cause pain at the seat of the lesion. Patients in this condition may develop attacks of diarrhea, small amounts of feces mixed with mucus being passed. This condition is due to colonic catarrh, is called the "diarrhea of constipation," and affords no mitigation to the discomfort and pain.

During the progress of the case the bowel above the block distends. Because of the hypertrophy of the muscular wall of the gut and of the loss of flesh painful peristalsis (which can be felt and seen) is often noted above the obstruction. This sign is detected far oftener in chronic than in acute obstruction. The distended intestine showing peristaltic contraction is a strong suggestion of chronic obstruction. The painful peristalsis is often productive of rumbling and gurgling noises (*borborygmi*). By noticing the portion of gut distended we may be able to locate the seat of stenosis (see page 1118). This method is more valuable in chronic than in acute obstruction. On digital examination of the rectum the rugæ may no longer be felt and the rectum is greatly distended because of paralysis. This is known as *rectal ballooning*.

The above-described condition may cease to intermit or even remit, all the symptoms may grow progressively worse, constant nausea being present, vomiting ensuing on taking food, and the breath being horribly foul. Such a patient is being poisoned to death by putrefactive toxins. He may perish from exhaustion, from perforation, or from peritonitis. At any time during the progress of chronic obstruction acute obstruction may develop. The sudden complete block may be due to a plug of hardened feces or some foreign body. It not unusually follows the taking of a strong purgative. It may be due to volvulus or to bending.

In some cases of chronic obstruction a tumor may be palpated, in some intussusception can be made out, in some there is a history of antecedent peritonitis, in many there are evidences of malignant disease.

Diagnosis.—*The determination of the seat of lesion* requires abdominal and rectal examination. An intussusception may sometimes be felt by a finger in the rectum and can often be felt by palpation of the abdomen. Vaginal examination may be demanded. Pain is apt to arise at the seat of obstruction or to radiate from there. Abdominal palpation may detect a tumor. Rectal insufflation of hydrogen may locate the obstruction by causing great distention below it. Entire suppression of urine, early vomiting, absence of abdominal distention, and rapid collapse mean obstruction in the duodenum or in the jejunum. Early vomiting, a rapidly progressive case, with great distention of the umbilical region, means obstruction of the ileum or the cecum.

Distention of the entire abdomen and of the flanks, linked with tenesmus, with less violent symptoms, less rapidity of progress, and less diminution of urine than in the above-cited forms, means obstruction low down in the colon or in the rectum. An old test for obstruction in the adult large intestine is an injection by a fountain-syringe: if 6 quarts can be introduced, there is no obstruction in the large intestine; if less than 4 quarts can be introduced, there is probably obstruction in the large intestine. This test is unreliable. The passage of a sound in the rectum is generally useless and is often unsafe. In many cases the seat of the lesion and the cause of the obstruction can be determined by exploratory laparotomy only.

The *determination of the causative condition* is always difficult and is often impossible. *Intussusception* may arise in child or adult. It is the common cause in children. Intussusception may induce acute or chronic obstruction. In the child acute obstruction is far more common than chronic obstruction. In most cases the child has been previously healthy except for constipation or diarrhea. The attack begins with a violent seizure of colicky pain and vomiting, but although the patient be pale, there is seldom shock at this stage. The vomiting may be occasionally repeated, but it is not forcible retching and very rarely becomes stercoraceous. The bowel below the obstruction is often emptied in this stage. After a time pain abates or disappears, to recur again and again. Between the seizures of pain the patient often appears to be in good condition, with a normal temperature and an almost normal pulse. Tenesmus soon arises in most cases, bloody mucus in small quantities being passed frequently. The source of the bloody mucus is the squeezed and congested intussusceptum. A sausage-shaped mass can usually soon be felt somewhere over the large intestine. It may be in the right iliac fossa or in the left iliac fossa, but usually over the region of the transverse colon. Osler reports that a mass was palpable in 66 of 93 cases, and in over one-third of these cases it was noted the first day. It has been felt as early as three hours after the onset of pain. It becomes rigid during a pain. It may shift its position hour by hour, and it may disappear after having been obvious. It may be detected only when an anesthetic is given. Rectal examination gives no information in early cases or in cases involving the small bowel only. In late cases a mass may perhaps be felt in the rectum. The abdomen is rarely rigid, distended, or tender until late in the case, and at this period there may be shock r sepsis. In chronic intussusception in a child the condition may progress very slowly. The stools contain bloody mucus, there are attacks of abdominal pain, a lump may be felt along the colon or through the rectum, and peristalsis may be visible. If an abdominal lump is detectable it will harden during colic and will change its position from day to day.

Acute intussusception in the adult seldom presents characteristic features unless the sausage-shaped lump can be detected.

Chronic intussusception in an adult causes sudden attacks of vomiting and of abdominal colic which last a short time and pass away as suddenly as they arose. Later they may linger longer. A lump can usually be made out. There may be constipation or mucous diarrhea, and blood may be passed with the mucus. Acute obstruction usually arises.

Obstruction from adhesions is chronic obstruction which may become acute. There is a history of antecedent peritonitis. A local distention of the intestine is often noted. In *obstruction from bands* there is a record of antecedent peritonitis, of a traumatism, of a violent effort, or of pelvic pain. The attack is sudden in onset, is fierce in character, and is usually excited by violent exercise or the taking of food. Vomiting is early and intractable, and it soon becomes stercoraceous; pain is violent; peristalsis above the obstruction is forcible for a time; tympanites and abdominal tenderness appear after the attack has lasted for some little time; obstruction is complete, not even gas being passed;

collapse soon arises; no tumor can be detected, and rectal examination is negative. *Volvulus*, which is usually located in the pelvic colon, is far commoner in men than in women, in the middle aged than in those at the extremes of life. It is usually preceded by constipation. The symptoms come on with explosive suddenness and rapidly attain great severity. Obstruction is absolute; vomiting is late and is rarely stercoraceous; no tumor can be detected; rectal examination is negative; abdominal distention is early and pronounced, and may become enormous; peristalsis above the volvulus is seldom discovered; collapse is not so rapid nor so grave as in obstruction from bands and internal hernia. There is severe continuous pain with frequent exacerbations. The pain is about the umbilicus and in the left iliac region and left loin. Tenderness is soon manifest and is ominous, as it means peritonitis. If unrelieved, death will occur in from forty-eight to seventy-two hours. Cases of incomplete obstruction by volvulus are rarities. *Obstruction by a foreign body* may sometimes be inferred from the history of some such body having been swallowed. The obstructing body may occasionally be felt during palpation or may be discovered by the *x*-rays. Abdominal distress may exist for days or weeks before obstruction occurs. Vomiting is late and is rarely severe, but pain, tenderness, and distention are marked. In *obstruction from gall-stones* the victim is elderly and usually stout. There may be a history of one or more attacks of hepatic colic, but often the only history is of what was supposed to be painful chronic indigestion. When the stone is ulcerating into the bowel it causes localized pain and tenderness. As it slowly descends along the intestine it may be arrested again and again, causing attack after attack of blocking. When the gut becomes really blocked pain is early and acute, and vomiting is invariable and usually becomes stercoraceous. There is seldom much tenderness. Rigidity is not common. Shock is seldom present at the onset. Distention is not marked. In rare cases the stone can be palpated.

In *obstruction by an enterolith* the patient may give a history of many attacks of supposed enteritis or colitis, followed after some time by temporary attacks of obstruction. The calculus in rare cases can be palpated. The *x*-rays will show it.

In *obstruction from fecal impaction* the subject is usually of advanced years, and more often a woman than a man. There is a long history of constipation, flatulent indigestion, abdominal annoyance, painful straining at stool, and of repeated attacks of the diarrhea of constipation (small fluid movements, which bring no relief because the solid masses remain agglutinated to the wall of the bowel). The colon is distended by a mass of feces, usually dough-like, but sometimes hard, which is appreciable by palpation. Sometimes hardened or putty-like masses can be touched by a finger in the rectum. In such a subject acute obstruction may at any time arise. It is characterized by severe colic, great distention, and often by vomiting, but the vomiting is not violent and is seldom stercoraceous. Collapse soon begins. *Obstruction from stricture* or *from pressure* comes on acutely after a prolonged period of disturbance, during which period attack after attack of temporary obstruction, complete or partial, has taken place. A history of blood or pus in the stools suggests *tumor of the bowel;* a history of *blood* or pus having been absent would suggest pressure from without. In *pseudo-obstruction* or *spasm of the bowel* there is sudden apparent obstruction occurring in a neurotic subject, especially a female. It is most apt to arise in a victim of old colitis, or in one who has very recently been subjected to an abdominal operation. There is severe pain, vomiting, distention, and inability to pass gas or fecal matter. The attack is transitory, lasting a few hours or, at most, a day or two, and ceasing as suddenly as it began. Sometimes a limited swelling can be detected. It is due to a loop of distended bowel and results from a contracted segment of gut. It disappears under ether, and is called a *phantom tumor*.

The presence of an *internal hernia* is not thought of until strangulation takes place and seldom then. In duodenal hernia the patient has long suffered from pain of a colicky character. There is "a circumscribed globular swelling, resembling a movable cyst, except that it is resonant on percussion and yields intestinal sounds on auscultation. Owing to the compression of the inferior mesenteric vein at the neck of the fossa, the patient usually suffers from piles which bleed freely" (Alexander Miles, in "A System of Surgery," edited by C. C. Choyce). When strangulation occurs shock is early and overwhelming, and vomiting is early, violent, and persistent. Obstruction from pericecal or intersigmoid hernia is not diagnosticated as to cause.

In hernia into the foramen of Winslow the pain is violent and epigastric, and in this region there is a swelling which gives a dull note on light and a tympanitic note on deep percussion. Diaphragmatic hernia is considered on page 1302.

Obstruction due to embolism or thrombosis of the mesenteric vessels is announced by colicky abdominal pain, but early in the case there is no tenderness, no rigidity, and no distention. Rigidity comes on and is usually general. There is usually paroxysmal abdominal pain but the pain may be constant. It is most acute at the seat of lesion and there is tenderness at that point. As the damaged loop is not unusually in the pelvis tenderness may be found by rectal examination (Elliot and Jameson, in "Annals of Surgery," Nov., 1915). Pain in the loin and back is often complained of (McArthur, "Annals of Surg.," vol. xxxiii). Moderate vomiting may occur and there may be blood in the vomitus. There is great restlessness and usually collapse. There may be free fluid in the peritoneal cavity. Leukocytosis is noted, the polymorphonuclear leukocytes being increased. In one group of cases there is absolute obstruction. About 60 per cent. of the cases are of this type. In another group of cases there is watery diarrhea which may be bloody. Even when bloody diarrhea does not occur blood may perhaps be found in bowel washings. Cardiac disease can usually be demonstrated and albuminuria is common.

In *true postoperative obstruction* (see page 1117) as the pulse mounts the abdomen distends, usually vomiting comes on, and there is an almost continuous regurgitation of brownish putrid fluid. It may cease for an hour or two, when there will be a great gush of the fluid. The regurgitated matter may contain blood. There is seldom pain or rigidity, the temperature is subnormal, the extremities are cold, and the face is Hippocratic (see page 1118). The condition resembles acute gastric dilatation. The cause is intestinal paralysis. The symptoms of *postoperative thrombosis of the mesenteric vessels*, according to A. E. Maylard,[1] are as follows: Abdominal pain, perhaps colicky in character, gradual or acute in onset, and, as a rule, constant. Early in the case there is no abdominal tenderness, no distention, and no rigidity. The pulse is rapid, the patient is extremely restless, there may be vomiting, but it is never violent, as in acute obstruction; often there is diarrhea, and sometimes bloody diarrhea. These symptoms become particularly significant if there be cardiac or vascular disease.

Obstruction from Meckel's diverticulum is usually acute, but is sometimes chronic, and occurs particularly in young adults and children. It has been stated that other and visible deformities are usually present, but in a study of 69 cases by A. E. Halstead[2] this was true of but 1 case, in which harelip existed. In obstruction from Meckel's diverticulum there is often a history of former mild attacks (Ibid.). Halstead sums up the symptoms as follows: As the obstruction is high up, the abdomen has the shape of an inverted cone; early in the attack there is often local meteorism, especially under the costal arch of the right side, but there is no distention in the flanks. Early, active peristalsis may be visible. The tenderness is just to the right of the umbilicus,

[1] "Brit. Med. Jour.," Nov. 16, 1901.
[2] "Annals of Surgery," April, 1902.

on a level with it or below it. In most cases there is early fecal vomiting. Gray ("Annals of Surgery," Dec., 1908) describes invagination of the diverticulum into the bowel. The average age for those attacked is fifteen years. Such cases give a history of previous abdominal crises due to twisting, inflammation, or slight invagination. The acute attack is apt to begin while the patient is active. Gray says that about 30 per cent. of the patients pass blood; that the pain is umbilical and usually very violent; that tenderness is seldom acute unless there be peritonitis; that there may be an abnormal umbilical cicatrix; that in a minority of cases there is a palpable abdominal mass, and that the mortality after operation in acute cases is nearly 60 per cent.

Differentiation of Intestinal Obstruction from Other Diseases.—Always examine for a strangulated hernia at every hernial outlet. If obstruction is complicated by an irreducible hernia above the seat of lesion, the hernia, if it contains gut, will always enlarge and become tender because of accumulation of feces. Functional obstruction may attend peritonitis or may follow the reduction of a hernia. In this condition, if peritonitis be absent, there is no pain, no tenderness, no tumor, no tendency to collapse, but simply absolute constipation, distention, and perhaps non-stercoraceous vomiting. Appendicitis with peritonitis may cause symptoms similar to those of obstruction; but there is fever, a history of pain in the right iliac fossa, and the vomiting is not stercoraceous. Acute pancreatitis produces symptoms so similar to those of intestinal obstruction that a diagnosis cannot always be made (see page 1197). We must consider in the diagnosis perforation of a gastric or duodenal ulcer, rupture of an extra-uterine pregnancy or a pus tube, strangulation of the pedicle of an ovarian tumor, renal colic, and hepatic colic. Poisoning by ptomain, arsenic or by corrosive sublimate should not be confounded with intestinal obstruction.

Prognosis.—Without surgical interference most cases of acute intestinal obstruction die within ten days—usually within seven days. In volvulus death may occur in forty-eight or seventy-two hours. It may occur as early in obstruction by a band, in internal hernia, or mesenteric blocking. Death may be due to shock, to exhaustion, to perforation, to peritonitis, or to obstruction of respiration and circulation by tympanites. Recovery occasionally, but very rarely, happens by the formation of a fistula externally or into another portion of the bowel. In acute obstruction from foreign bodies the obstructing body occasionally passes. Volvulus and strangulation by bands are almost invariably fatal unless an operation is performed. In intussusception recovery occasionally follows the sloughing away of the prolapsed gut, but stricture almost inevitably results from this rare event. Functional obstruction gives a good prognosis. The mortality is from 40 to 50 per cent. Deaver and Ross ("Annals of Surgery," 1915, lxi) give the statistics of 276 cases of acute intestinal obstruction. The mortality was 42 per cent. The earlier the diagnosis and the more prompt the operation the less the mortality. In the table of Deaver and Ross (Ibid.) the mortality of strangulated hernia was 33.5 per cent. Obstruction from postoperative adhesions had a mortality of 49.3 per cent. The mortality from intussusception was 40 per cent. The prognosis of chronic obstruction depends upon the causative lesion. It does not threaten life immediately to anything like the degree that acute obstruction does.

Treatment.—In any abdominal case in which the diagnosis is uncertain and the patient is shocked give an enema of brandy and hot water, wrap the patient in blankets, surround him with hot-water bottles, and study the development of symptoms and signs. In half an hour, as a rule, reaction will be brought about and a probable diagnosis may be made (Greig Smith). In acute obstruction it is usually customary to empty the stomach by lavage and to evacuate the rectum by means of copious injections given while the patient is in the knee-chest position. The emptying of the stomach is imperative if stercora-

ceous vomiting has been going on, for vomiting of a quantity of such material while a patient is taking ether may cause death by drowning, the fluid flowing in enormous quantity into the bronchi. In very severe cases a general anesthetic cannot be given and the belly must be opened under cocain. Hutchinson's method of taxis and massage is uncertain, and is as liable to inflict harm as to confer benefit. Some surgeons apply constant compression to the abdomen by means of straps of adhesive plaster. Puncture of the intestine by an aseptic hypodermatic needle (introduced obliquely) to relieve gaseous distention is a decidedly dangerous proceeding. The passage of a small tube from the anus as high as possible will empty the colon of gas if no obstruction intervenes. In intussusception it is the custom of some surgeons to give no food by the stomach; administer opium and belladonna to arrest peristalsis, wash out the rectum with copious injections, give an anesthetic, and insufflate hydrogen gas or carbonic-acid gas in order to distend the bowel. Other surgeons treat intussusception by forcing air into the rectum by means of an ordinary bellows, and others inject water by a fountain-syringe, the reservoir being at a height of 3 feet. D'Arcy Power believes in the value of hydrostatic pressure in intussusception in children. He states that the child should be anesthetized and the large intestine filled *gradually* with hot saline fluid, the reservoir not being raised more than 3 feet above the patient. The fluid should be retained for ten minutes. My own feeling is that whereas it may be justifiable to try to reduce intussusception by gaseous or hydrostatic pressure during the first twenty-four hours of the attack, early operation, except in newborn infants, gives a better prognosis and is safer and more certain. Without opening the abdomen it is impossible to know the condition of the intestine. Gangrene may occur early (it has been found in less than four hours after the onset of symptoms), and if gangrene exists gaseous distention or hydrostatic pressure will cause death. Rushmore's reported case shows that there may be "no systemic symptoms to indicate the presence of gangrene" ("Annals of Surgery," August, 1907). Another point against conservative treatment is the common uncertainty as to whether complete reduction has been accomplished. Vomiting may continue for hours after genuine reduction and the bowels may not move for some time. Waiting to be sure that reduction has been accomplished will probably be responsible for death if reduction has not been obtained. After the first twenty-four hours it is never justifiable to use gaseous or hydrostatic pressure because of the great risk that ulcer or gangrene may exist. Pressure cannot be accurately regulated, and if the bowel is much damaged, may lead to rupture. If the case is not seen until after the first day, or if injections have been used and have failed, all surgeons believe that laparotomy should be performed.

Frederick Holme Wiggin has made a study of the reported cases of laparotomy for infantile intussusception, and considers that operation done within the first forty-eight hours will give a mortality of 22.2 per cent.[1] (see Operation for Intussusception). In very young infants the mortality of laparotomy is very high, and it is a fair question if on them immediate laparotomy should be advised without a trial of conservative methods, if the case is seen during the first twelve or twenty-four hours. The mortality of operation is very large on those under eighteen months of age. But even in those under six months of age Wiggin thinks the mortality after operation is not above 22.2 per cent., if operation is done within forty-eight hours, and my personal feeling is that operation should be the method of treatment even in the case of a young baby.

I agree with Rushmore that operation done during the first twelve hours would greatly reduce the mortality, perhaps to the figures he expects would follow such a practice, viz., 12.5 per cent.

In obstruction of the main mesenteric vessels operation is of no avail. In obstruction of branches it may be possible to resect the involved region of

[1] "Med. Record," Jan. 18, 1896.

bowel, a region which is found to be gangrenous or becoming so. Reich in reporting upon 91 cases operated upon by resection and anastomosis, records 18 recoveries (quoted by Elliot and Jameson, in "Annals of Surgery," Nov., 1915).

Some surgeons advocate resection, sewing of the divided ends in the wound and the subsequent performance of end-to-end suture. This shortens the primary operation and saves the patient from the great danger of leakage at the point of anastomosis because of spread of the thrombosis (Jackson, Porter and Quimby, in "Jour. Am. Med. Assoc.," 1904).

Obstruction in pregnancy is very fatal. The uterus should be emptied before the obstruction is attacked. Some advise vaginal others abdominal section. Then the obstruction should be relieved surgically. In most cases it is due to bands.

In obstruction from fecal impaction use large rectal injections and give small repeated doses of salines or of castor oil. If there are signs of inflammation, do not give cathartics, even in small doses, but give opium and belladonna to arrest vomiting and to relax spasm. Impactions in the rectum can be removed by the use of a spoon. In acute intestinal obstruction do not delay, but open the abdomen, if possible, before collapse comes on, and find the cause of the obstruction. If it is a gall-stone or enterolith, try to crush it without opening the intestine; if this fails, push it up a little distance, incise the bowel, remove the stone, and close the incision with Halsted sutures. Pilcher[1] collected 40 cases operated upon for gall-stone obstruction, with 21 deaths. If there is fecal obstruction, break up the masses by pressure and push the fecal plug down without opening the bowel. If there is intussusception, reduce the prolapse and shorten the mesentery; but if reduction be impossible, perform a resection and enterorrhaphy, or make an artificial anus. In volvulus untwist and shorten the mesentery; but if this be impossible, treat as an irreducible invagination. In obstruction from adhesions try to separate them and straighten out the bowel, stitching healthy peritoneum over each raw spot to prevent recurrence. In obstruction by a band, free the loop and, if it be gangrenous, resect or follow the plan of Mikulicz (see page 1126). Anastomosis may be necessary. In flexion separate the intestines, remove the flexion by a V-shaped incision, and suture the wound in the bowel. In chronic obstruction it is often advisable to perform an exploratory laparotomy, discover the condition, and determine what is to be done to correct it. Some tumors external to the bowel may be removed. Growths in the bowel wall may be removed by resection of the involved portion of intestine, or an anastomosis may be performed, or it may be necessary to make an artificial anus. In obstruction from Meckel's diverticulum that structure may be found twisted, the gut near it may be kinked or twisted, or the diverticulum may act as a band, the bowel being caught under it or kinked over it. Intussusception of the gut below it sometimes occurs; so does invagination of the mucous membrane of the diverticulum; so does chronic inflammation and cicatricial narrowing of the diverticulum or gut (Halstead). The diverticulum may be gangrenous, perforated, or cystic. In internal hernia the constriction must be divided and the bowel removed from the fossa. Any gangrenous gut should be resected if the patient's condition justifies it, or Mikulicz's plan should be followed (see page 1126).

After opening the abdomen the surgeon must be guided by conditions. The diverticulum should be removed, just as the appendix is removed in appendicitis, and complications relating to the gut must be dealt with.

The mortality after operations for acute intestinal obstruction is very high (from 40 to 50 per cent.). If the diagnosis were made earlier, operations would be done earlier and the mortality would be much less. Nine out of 10 of these cases that I see in hospital work are gravely shocked and practically dying on

[1] "Med. News," Feb. 8, 1902.

admission. If a patient with obstruction be very gravely shocked, I usually follow Moynihan's plan, of simply opening the bowel and draining it in its most distended coil without any search being made for the lesion. The object is to drain the poisons from the intestine, poisons which are the active agents in killing the patient. The abdomen is opened under cocain, the incision being small. A distended coil of intestine is sutured to the peritoneum about the abdominal incision, every care being taken that the stitches do not penetrate the mucous membrane of the gut (Moynihan). A purse-string suture is now inserted so as to enclose an area of the exposed gut; an incision is made into the gut in this enclosed area, and gas and feces flow out. Paul's glass tube (see Fig. 804) is passed into the gut and the purse-string suture is tied. Instead of Paul's tube we may use a rubber tube sutured as is the tube in Kader's gastrostomy (Elsberg, in "Annals of Surgery," May, 1908). The obstruction is thus temporarily relieved, and if the patient recovers, the causative lesion may be subsequently sought for and attacked. If a fecal fistula follows the enterostomy and refuses to close, it may be closed by operation. If Elsberg's plan is followed a persisting fecal fistula will be rare. My colleague, Professor Francis T. Stewart, has devised a method by which the bowel can be drained without any risk of infection of the peritoneal cavity, a risk which always exists in using Paul's tube. Stewart places a clamp at either extremity of the loop of bowel and surrounds it with gauze. One-half of a Murphy button is inserted into the empty loop through a small incision. The other half of the button is squeezed into a rubber tube the diameter of which is somewhat smaller than the flange of the button. The two parts of the button are then clamped, and the clamps are removed from the loop of bowel. The intestine is sutured to the wound margins and the feces drain into a receptacle on the floor. Fig. 697 shows Stewart's operation. In any case of intestinal obstruction if gangrene exist the temptation to do immediate resection is strong. I have done it a number of times with a very large mortality. Of late I have been following the plan of Mikulicz and results have been far better. The gangrenous loop is brought outside of the abdomen, it is fixed parallel to the wound, and enterostomy is performed above it. The loop is dealt with later. If a fecal fistula forms it is subsequently closed by appropriate methods. Postoperative obstruction coming on soon after a surgical operation is often not recognized for a time, and

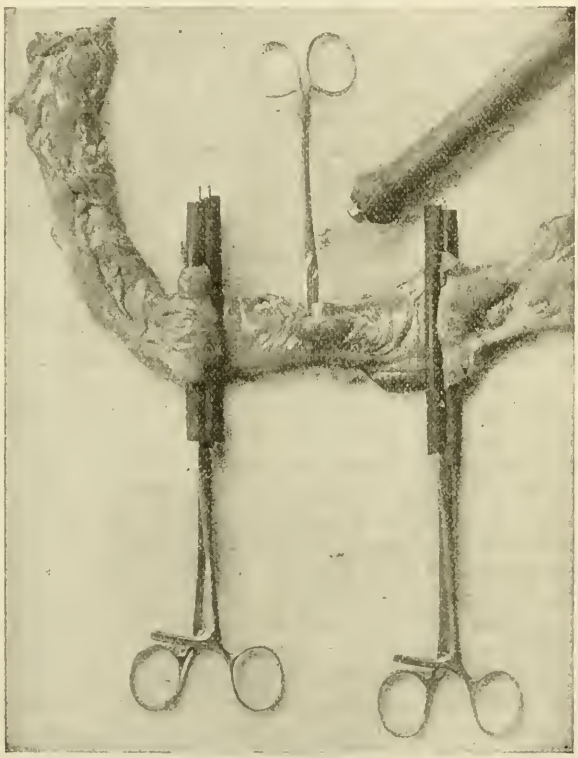

Fig. 697.—Stewart's method of enterostomy.

the surgeon will be in doubt as to whether he is dealing with peritonitis or intestinal paresis or both. When distention becomes evident after an operation we should wash out the stomach with warm salt solution, administer salines in small doses frequently repeated, and employ enemata. Many surgeons give two or three doses of atropin hypodermatically at intervals of two hours. Each dose should be $\frac{1}{200}$ gr. Atropin is given with the idea that it increases peristalsis and contracts blood-vessels. It is probably merely sedative, relaxes spasm, and is useless if strangulation exists. Eserin stimulates the muscular coat of the intestines. There seems to be no doubt that eserin given soon after an operation tends to prevent distention. A better plan than the administration of atropin is to give hypodermatically $\frac{1}{30}$ gr. of eserin (physostigmin salicylate) and $\frac{1}{40}$ gr. of strychnin every hour until four doses have been taken. During fifteen minutes of this period carry the heated Paquelin cautery to and fro over the abdomen, not touching the skin, but near enough to it to cause distinct reddening. The intestinal tract should be gone over systematically with the cautery, first, the stomach and small intestine, then the large intestine. Pituitrin is an extract of the posterior lobe of the pituitary gland. When given intravenously or subcutaneously it raises blood-pressure, is a diuretic, and stimulates involuntary muscle fiber. It is useful in cases of flatulent distention. It comes in ampoules each of which contains 1 c.c. The dose is one to two ampoules, repeated in two hours. I have seen electricity succeed. A continuous current battery is used and it must be able to furnish 50 milliamperes. The patient lies upon the back and a flat electrode covered with chamois damp with salt solution is fastened to the negative pole and is placed upon the belly. The rectal electrode is fixed to the positive pole and inserted in the rectum. This electrode is tunneled and through the tunnel salt solution is introduced into the rectum. This solution protects the mucous membrane and diffuses the current. The current is now turned on. At first the galvanometer should register 10 milliamperes.

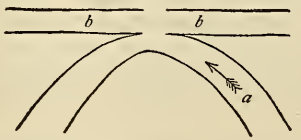

Fig. 698.—Fecal fistula: *a*, Direction of fecal flow; *b*, *b*, belly wall.

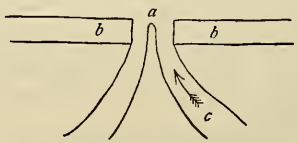

Fig. 699.—Artificial anus, showing spur: *a*, Spur; *b*, *b*, belly wall; *c*, direction of fecal flow.

The current is slowly increased to 30 or 40 milliamperes. Every five minutes the place of the abdominal electrode is changed and the current is reversed, the galvanometer being brought to zero while effecting reversal. It is common for gas to escape and then feces. If the salt solution should be expelled more must be introduced. Fecal matter may appear. The current may be used for fifteen minutes and the procedure may be repeated in three or four hours (the above directions are from a valuable book, rich in practical surgery, viz., Stewart McKay, on the "Preparation and After-treatment of Section Cases.")

If these measures are not soon followed by the passage of flatus or feces, open the abdomen; never wait for the advent of stercoraceous vomiting.

Fecal Fistula and Artificial Anus.—A fecal fistula is an abnormal opening in the intestine through which gas or a portion of the feces escapes (Fig. 698). If all the intestinal contents escape through the opening, it is called an *artificial anus* (Fig. 699, Senn). A surgeon may make a fistula deliberately (*intentional fistula*). A fistula may be the product of disease or injury (*accidental fistula*). Senn enumerates the following causes of accidental fistula: wounds, injury of the intestines, intestinal ulceration, intestinal strangulation, foreign bodies in the intestinal canal, malignant tumors, actinomycosis, pelvic

and abdominal abscess, appendicitis, injury of the bowel during an abdominal operation, the application of ligatures, catching by sutures, and the employment of drainage-tubes.

Treatment.—Many fistulæ close spontaneously. This can be hoped for only if the opening is quite small, if the general health of the patient is good, if the cause has passed away, if the fistula is not lined with mucous membrane, and if there is no spur (spur is shown at *a*, Fig. 699). In most cases of fistula not high up it is well to give Nature a chance to effect a cure, and not to be in a hurry to operate. Most fistulæ in the large bowel heal spontaneously. The part is cleansed frequently with peroxid of hydrogen, the patient is kept recumbent, food is given which does not leave much residue, pads of gauze are applied with pressure, and the bowels are kept regular.

If the track be lined with granulations, it may be touched with lunar caustic; if it be lined with mucous membrane, the actual cautery should be applied. Any collection of pus which exists should be drained. If these methods fail, an operation must be performed. The fistula may be sutured by extraperitoneal manipulation (Greig Smith); it may be covered with skin (Dieffenbach); the spur may be removed by means of a clamp, or resection may be performed. In most cases it is best to incise a button of skin around the opening, temporarily suture the fistula, open the peritoneal cavity, deliver the bowel, and suture carefully (Senn's method). In some cases partial exclusion of the fistulous part is necessary, the bowel being divided above the fistula, the end near the fistula sutured, and the other end anastomosed to the bowel below the fistula. In other cases complete exclusion may be performed (see page 1257).

Ulcer of the Bowel.—In typhoid fever and in dysentery ulceration occurs. In erysipelas, septicemia, pemphigus, melena neonatorum, and uremia ulceration may occur. An ulcer may be due to tuberculosis or cancer. Most ulcers of the duodenum (see below) are due to the same causes as ulcer of the stomach. In rare cases ulcer of the duodenum results from a surface burn (Curling's ulcer, page 173). An ulcer of the jejunum sometimes develops after the performance of gastrojejunostomy for gastric ulcer (see page 1229). An ulcer may heal and, by causing thickening and constriction, produce chronic intestinal obstruction. It may perforate, causing collapse and subsequent peritonitis.

Ulcer of the duodenum may be due to tuberculosis. It may exist in septicemia, erysipelas, melena neonatorum, and uremia. It may be caused by burns. The last named and very rare condition is called *Curling's ulcer*, he having described it in 1841. Moynihan shows in his book on "Duodenal Ulcer" that James Long, of Liverpool, was really the first one to describe duodenal ulceration following burns. He did so in the "London Medical Gazette," 1840. A duodenal ulcer following a burn or scald is "a toxic ulcer, and, therefore, analogous to the ulcer which occurs in septicemia, uremia, typhoid fever, erysipelas, and pemphigus" (Moynihan, Ibid.). It occurs only when the burnt or scalded area has become septic, and septic emboli may be responsible for ulceration. Some believe that the irritant cause is in the bile. Ulcer from a burn is extremely rare to-day, rarer than formerly, if older reports are correct. This is probably due to the modern cleanly treatment of burns and scalds. When we use without qualification the term "ulcer of the duodenum" we mean an ulcer like the ordinary stomach ulcer and which may be regarded as a peptic ulcer of the duodenum.

Septic ulcers are acute. The peptic ulcer is nearly always chronic.

Peptic Ulcer of the Duodenum.—The condition was first described by Travers in 1817 ("Duodenal Ulcer," by Sir Berkley G. A. Moynihan). It occurs usually in that portion of the duodenum which is above the opening of the bile-duct; in other words, in the region acted on by the acid fluid from the stomach. In Perry and Shaw's list of 149 cases the first portion was involved in 123, the

second portion in 16, and the third and fourth portions in 2; in 8 the ulcers were scattered. Moynihan (Ibid.) says the first portion is involved in 95 per cent. of the cases. The most common seat of ulcer is on the anterior wall of the duodenum, ½ inch below the pylorus. The pylorus is definitely marked for the surgeon by the pyloric vein which runs upward from the greater curvature (Moynihan, Ibid.). The ulcer is often puckered like a scar. Any old ulcer is much indurated. In rare cases there is no induration. Sometimes an extensive area of the duodenum is indurated, sometimes a duodenal pouch or diverticulum is formed. In rare cases an ulcer completely encircles the bowel. Duodenal ulceration is much more common in males than in females in the proportion of 3 or 4 to 1. Out of 53 cases reported by John Deaver 47 were males (The Archives for Diagnosis," Jan., 1917). It may occur at any period of life, from early youth to extreme old age, but is most common between the twenty-fifth and forty-fifth years. The average age of Deaver's male cases was 41.5 years. The oldest was sixty-three, the youngest twenty-one. The average age of his 6 female patients was 36.8 years (Deaver, Ibid.). The condition can occur in infancy, producing hemorrhage and vomiting. Veeder reports 5 infantile cases ("Am. Jour. Med. Sciences," 1914, cxlviii). Duodenal ulcers are usually single, but may be multiple. It was long taught that gastric ulceration is vastly more common than duodenal ulceration. Some recent observers regard duodenal ulcer as likely to be met with one-seventh as often as gastric ulcer. In this connection Codman's statistics should cause us to revise our estimates. In 3000 autopsies held in the Massachusetts General Hospital an open duodenal ulcer was found in 1 per cent. of the cases. The duodenal ulcers were found twice as often as gastric ulcers (quoted by E. R. McGuire, "Buffalo Med. Jour.," June, 1912). A gastric ulcer may exist with a duodenal ulcer. Murphy sums up the supposed causes into hyperchlorhydria, local infection, embolism and thrombosis, and disturbances of the organs of elimination. An indurated chronic ulcer may exist, and this may heal and produce cicatricial stenosis. The scars of two ulcers may cause double constriction or hour-glass duodenum.

An ulcer may heal and break down many times. A duodenal carcinoma seldom arises from ulcer. What Moynihan calls the "tucked back" ulcer becomes adherent to the liver or posterior wall of the abdomen. An ulcer adherent to the pancreas may eat into that organ. An ulcer scar may clutch the common bile-duct in the duodenal wall or block the outlet of the ducts in the ampulla of Vater. Perforation is more common, but walling off is more frequent than in gastric ulceration (Wm. J. Mayo, "Med. News," April 16, 1904). In the vast majority of cases the patient gives a history of having suffered at intervals for many years from attacks of flatulent or acid and painful indigestion. The pain is near the umbilicus and radiates to the right. The attacks are far more common in fall and winter than in spring and summer. Usually tenderness and rigidity are demonstrable in the right epigastric region. A man suffers thus for days or weeks, and then gets apparently perfectly well, but after a variable time the attack returns. The attack comes on from two to six hours after a heavy meal. It seldom occurs after breakfast but comes after lunch and particularly after an evening dinner. If he eats his heavy meal at 7 P. M. his attack may usually be expected about 10 o'clock or later. These seizures of "indigestion" may be brought on by worry, overwork, wet feet or chilling of the body, or by eating some indigestible article of diet. They may be caused to disappear by rest, ease of mind, or change of climate. An alkali relieves pain. They have been called "hunger-pains" because food for a time distinctly relieves them. A patient learns this and is apt as soon as the annoyance begins to eat some crackers or drink a glass of milk. It was long believed that hunger pain was due to an open pylorus allowing acid material to run into the duodenum, and that food or an alkali caused the pylorus to close. Moynihan, Hertz, and others now reject this explanation because *x*-ray studies show that

food begins to leave the stomach at once and that pain begins when about half the food has left the stomach (Moynihan, "Duodenal Ulcer"). It must be that the last portion of food in the stomach is much more acid than the portions which pass out earlier. When the stomach is entirely empty there is no pain; when half empty there is pain.

Arbuthnot Lane would explain the relief of pain by food by invoking a reflex contraction of the duodenum caused by food and serving to empty that portion of the gut. The condition above described may go on for many years, periods of relief alternating with periods of pain, water brash, flatulence, etc. Usually, but by no means always, there is hyperacidity. In some cases acidity is normal; in some, actually subnormal. It is probable that during painful attacks there is hyperacidity. We have stated that the pain occurs from two to six hours after a meal. If it occur very late the ulcer is posterior; if it occur earlier than two hours stenosis has begun or the ulcer is adherent to the liver or belly wall (Moynihan, Ibid.)

Hemorrhage occurs in about 40 per cent. of the cases. The blood may be passed by bowel only or it may be passed by bowel and also vomited. In most cases it is passed by bowel and not vomited. When there is a severe hemorrhage the patient first has a peculiarly severe attack of indigestion, he then grows deathly pale, presents the symptoms of internal hemorrhage, and passes a quantity of blood which is first tarry black and later red, and perhaps he also vomits blood. Just as chronic gastric ulcer may be latent, no symptoms ever being observed, so may chronic duodenal ulcer be latent. The pain is located in the epigastric or right hypochondriac region and may last until the next meal. If the digestion of the evening meal is delayed the pain rouses the patient from sleep, but a glass of milk will quiet it. The pain is less severe than is usual in gastric ulcer and in many cases does not radiate to the back, although in others it does radiate to the right scapular region. There may be tenderness on deep pressure in the right hypochondriac region. Symptoms of indigestion are not nearly so marked as in ulcer of the stomach. Vomiting is far less common than in gastric ulcer and it does not relieve pain. Vomiting occurred in one-fourth of Deaver's cases (Ibid.). The hemorrhage from the bowels may be so profuse as to kill or almost kill the patient. It may be so frequently repeated as to make him profoundly anemic. Unlike the bleeding from gastric ulcer, bleeding from duodenal ulcer is often fatal. In some cases the man bleeds insidiously, perhaps even without knowing it, losing some blood daily, and finally becoming extremely anemic. Probably in every case of duodenal ulcer occult blood is at times present in the stools. In many cases there is no visible blood in the feces, but the guaiac and aloin tests show occult blood. Vomiting of quantities of blood is much rarer than in gastric ulcer. In very rare cases of duodenal ulcer the first symptom is perforation. I have operated on one such case. In other cases the first symptom is hemorrhage, or is due to stenosis or some other complication. Examination by *x*-rays after the taking of a meal containing bismuth or barium shows, if there be ulcer, greatly increased activity of the stomach. The viscus empties too rapidly. In some cases stenosis is demonstrated, in some a pseudodiverticulum. Moynihan[1] mentions the following complications: severe hemorrhage; perforation; periduodenitis; cancer, and cicatricial contraction involving the bile-duct. Cancer is a rare result of ulcer. Jefferson reported one case but could find but 30 cases in literature ("Brit. Jour. of Surgery," 1916, iv).

Acute perforation is more common than we once thought. Perforation is usually on the anterior wall. It is much less common on the posterior wall. It is extremely rare on the superior wall and practically never occurs on the inferior wall. Moynihan gathered 49 cases from literature and added 2 of his own. In the great majority of cases perforation of the duodenum can-

[1] "Lancet," Dec. 14, 1901.

not be differentiated from perforation of the stomach by a study of the symptoms. In some cases the symptoms resemble appendicitis. In most cases there is a sudden onset of violent abdominal pain, followed by vomiting, shock, rapid pulse, tenderness of the epigastric or right hypochondriac region, and board-like rigidity of the upper abdomen. Profound shock is rare. Often shock is trivial. Even if shock is severe the patient usually reacts after a few hours. Sheild's case got better in four hours and walked some distance to the hospital.[1] Lucy's case got better a short time after the onset, walked home, and attended to a horse, but then became rapidly worse. The improvement is apparent, not real, and is only temporary. The symptoms quickly become worse, and when they become worse, besides the pain, tenderness and rapid pulse, there will be occasional vomiting, rigidity of the abdomen, usually an elevated or normal temperature, and possibly diminution of the area of liver-dulness. Just as in stomach ulcer, there may be acute, subacute, or chronic perforation.

Treatment.—In duodenal ulcer the risks of serious hemorrhage and of perforation are much greater than in gastric ulcer, and operation should always be recommended if the diagnosis is made. We used to say operate only if the symptoms are not amended by rigid diet and medication; if severe hemorrhage occurs or if cicatricial contraction interferes with the passage of food through the bowel or bile into the duodenum. Moynihan refers to 4 cases of chronic ulcer operated upon, and all recovered. In some cases excision is practised; in others, excision with gastrojejunostomy; in still others, gastrojejunostomy alone.

If grave hemorrhage occurs and is repeated the surgeon should open the abdomen, ligate the bleeding vessels, bring the outer coats of the bowel together over the indurated area, and perform posterior gastrojejunostomy (Wm. J. Mayo, in "Surg., Gynec., and Obstet.," May, 1908). In such a bleeding ulcer the vessels entering it are usually varicose.

In perforation operation is performed, as in gastric ulcer, as soon as possible. In these cases, as in perforated gastric ulcer, I believe operation should be immediate and that we should not wait for a possible reaction from shock. Personally, I do not practise excision of the ulcer, as I believe that closure is just as permanently useful and is safer. The ulcer is inverted by two rows of silk sutures applied in a vertical line or as purse-string sutures. If the gap of the perforation be huge it may be impossible to close it by inversion. It may then be closed by the gall-bladder (as was done by Downes) or by an omental plug. Failing in this, a gauze tampon may be used or a duodenal fistula can be formed, a rubber catheter being inserted in the duodenum and wrapped about with a plug of omentum (Eliot, Corscaden, and Jamieson, in "Annals of Surgery," May, 1912). Then gastrojejunostomy should be done. Gastrojejunostomy is imperative if the suturing has narrowed the duodenum. It is valuable in any case because it removes irritants from the scar, allows of early administration of food, favors healing, and antagonizes recurrence. Some surgeons do not drain, but I feel it safer to drain. Sir Berkeley G. A. Moynihan[2] gathered 49 operations for perforated ulcer, with 8 recoveries. Mr. T. Crisp English reports 8 operations for perforation of duodenal ulcers, with 2 recoveries ("Lancet," Nov. 28, 1903). During 1912 in the Mayo clinic 6 cases of acute perforating ulcer were treated by suture and gastro-enterostomy. There was 1 death. In perforated duodenal ulcer the extravasated fluid is apt to flow into the right iliac region. If an erroneous diagnosis of appendicitis has been made, an opening in the right iliac region, by giving vent to this fluid, might for a time confirm the surgeon in error, but the character of the fluid should make evident the condition of affairs.

In subacute perforation we may separate adhesions, find and close the per-

[1] "Lancet," March 29, 1902.
[2] "Lancet," Dec. 14, 1901.

foration, and perform gastrojejunostomy, or follow Lund's advice ("Boston Med. and Surg. Jour.," 1905) and do gastrojejunostomy alone. Lund maintains that as the perforation is walled off it is not necessary to open it up in order that we may close it. The treatment for chronic perforation is that for an abscess about the duodenum. In every operation for duodenal ulcer Moynihan examines the appendix and often finds it diseased ("Lancet," Jan. 6, 1912).

Ulcer of the Jejunum After Gastro-enterostomy.—(See page 1229.)

Perforated Typhoid Ulcer.—Perforation occurs in 2 or possibly 3 cases out of 100. My colleague Prof. John H. Gibbon reported the experience of the Penn. Hospital from 1901–1915 inclusive ("Annals of Surgery," Oct. and Nov., 1915). There were 5891 cases of typhoid fever and 139 perforations. Twenty-seven were not and 112 were operated upon. About 70 per cent. of perforations occur in the second, third, or fourth week. Whenever a typhoid patient develops pain a surgeon should be called in consultation. Perforation in a typhoid ulcer is usually effected rapidly, a large opening is formed, and a considerable quantity of fecal matter is passed into the peritoneal cavity. In a few perforations very little fluid escapes. Severe pain and a nervous chill indicate that perforation is occurring or has occurred. Some maintain that the two above-named symptoms associated with marked leukocytosis indicate that perforation is about to occur, and they call this stage the *preperforative* stage. That distinct symptoms may in some cases point to impending perforation is, I believe, true and in 1 case I operated on this conviction and found two areas almost perforated. In most cases, however, I do not believe that there is a distinct preperforative stage, but the perforation exists when the symptoms are first noted. The conviction that perforation was occurring would be strengthened by a progressive increase in the leukocyte count. But as leukocytosis cannot occur for eight or ten hours, never wait for it. It is to be remembered however, that the leukocyte count is increased by sweating, cold bathing, vomiting, hemorrhage, severe diarrhea, or some positive complication. When perforation occurs, violent pain develops. As a rule, there are tenderness, rapid pulse, costal respiration, abdominal ridigity, vomiting, and shock. A sudden fall of temperature and increase of pulse rate may mean hemorrhage. Usually in perforation there is temporary reaction from shock, the subnormal temperature giving way to a normal or to an elevated temperature. The vomiting in some cases becomes stercoraceous. There is constipation and sometimes dulness on percussing the flanks. It should be the rule to make a digital examination of the rectum. The face is Hippocratic. The patient may die of the preliminary shock or may react and die subsequently of toxemia or lung complication. In a few hours after perforation distinct leukocytosis may be observed, but it may never take place at all. Even when leukocytosis arises, it may disappear as peritoneal infection spreads and systemic poisoning deepens. If the abdomen is distended diminution of liver dulness is not a reliable sign. Diminution of liver dulness with a flat abdomen is very significant. Micturition is usually painful and difficult. Le Conte points out that rupture of a mesenteric gland simulates intestinal perforation. A case of typhoid with lung complication or cholecystitis may be thought to have perforation. Whereas violent pain is the rule in perforation if the patient be stuporous, acute pain may not be manifested.

Treatment.—In 1884 Leyden suggested operation, and in the same year Milkulicz obtained the first operative success. In 1886 my colleague Dr. James C. Wilson, published a paper in which he advocated operation. Death is practically certain without operation. Operation should save at least one-fourth of the cases. It should be done at once, proper means being adopted to combat shock. In many cases a general anesthetic should not be given as it increases the danger of pulmonary complications. Gas and oxygen or a

local anesthetic should be employed. The incision should be made in the right iliac region and the colon should be first located and then the end of the ileum. By locating the colon we obtain a fixed point from which to begin our search for perforations, and by opening the abdomen in the right iliac region we come down at once on to the perforated gut in the vast majority of cases. When a perforation is found, it should, if possible, be inverted by two layers of Halsted sutures. It is not wise to excise the ulcer. If the bowel be very badly damaged, resection can be considered, but it is usually wiser to make a temporary artificial anus. In some cases the perforation can be used as the anus, a tube being inserted, or the bowel being stitched to the skin. Hayes ("Penn. Med. Jour.," 1908) advocates enterostomy in typhoid perforation and reports 38 cases of which 36 per cent. recovered. After finding a perforation and closing it, examine to see if there are others. It is not very unusual to have from 2 to 5 perforations. In 26 autopsies reported by Gibbon there were secondary perforations in 14 (Gibbon, Ibid.). Close every perforation, and if a point is found where the thinning of the bowel wall indicates that perforation is liable to occur, protect this point by inverting the area of ulceration by sutures. Many surgeons cleanse the peritoneum by flushing with hot salt solution, others do not irrigate. Leave the wound open, insert strands of iodoform gauze, and establish tubular suprapubic drainage. Elevate the patient in bed if not too weak, and employ continuous proctoclysis of salt solution. Early death is due to shock or exhaustion. Death occurring later results from peritonitis or lung complication. I have operated 10 times for typhoid perforation, with 3 recoveries; 3 cases died of shock. In 1 case the perforation was not found, but was discovered postmortem in the hepatic flexure of the colon, the gall-bladder being responsible for the ulcer of the bowel. One case improved greatly, lived for eight days, developed another perforation, and died of shock. The necropsy showed that the sutured perforation was soundly closed. One case, a young man, brought to me by Dr. Godfrey, was operated upon twenty-four hours after perforation. There was one perforation in the ileum and considerable fecal extravasation. The opening was large and the stitches would not hold. The 6 inches of bowel between the ulcer and the ileocecal valve presented several ulcers almost perforated. The patient was too weak for a resection. After cleansing the abdomen an artificial anus was made proximal to the perforation. The patient recovered and subsequently the anus was successfully abolished by resection. In another case, that of a young woman, on opening the abdomen violent appendicitis was found, the appendix being swathed in lymph and in a state of gangrene. The appendix was removed. Search showed a perforation in a loop of gut 2 feet from the ileocecal valve. There was considerable extravasation. The perforation was closed. The peritoneum was cleansed, drainage was inserted, and the patient recovered. Cultures from the appendix and from the peritoneal cavity showed the colon bacillus only. In a third case, that of a young woman, impending perforation was diagnosticated by Dr. Kalteyer because of pain, tenderness, some rigidity, and definite and increasing leukocytosis. Two ulcers almost but not quite perforated were found. They were covered over by the use of inversion sutures, the wound was closed without drainage, and recovery followed. Culture from the peritoneal cavity was negative. These 3 successful cases were operated upon in the Jefferson College Hospital. Harte and Ashhurst collected the cases operated upon up to January, 1903. There were 362 cases, with a mortality of 74.03 per cent. Dr. F. D. Patterson ("Am. Jour. Med. Sciences," May, 1909) collected 369 cases occurring since the paper of Harte and Ashhurst. Of these cases 242 died, a mortality of 65.58 per cent. The perforations were located as follows: stomach, 1; jejunum, 1; Meckel's diverticulum, 2; ileum, 279; cecum, 5; appendix, 15; colon, 12; not stated, 54. In Gibbon's 112 patients operated upon there were 27 recoveries, a mortality of 75.9 per cent. (Gibbon, Ibid.).

Primary Intestinal Tuberculosis.—Although intestinal tuberculosis is common in patients with chronic pulmonary tuberculosis, primary intestinal tuberculosis is a rare condition. The exact propriety of rigidly regarding such cases as *primary* is doubtful. Kocher's cases (reported before the Swiss Medical Congress in 1892) came from tuberculous stock, and suffered in infancy from enlarged glands, pleurisy, or bronchitis, and this surgeon says that, in all probability, there had for some time been somewhere in the body a latent tuberculous focus, and from this focus came the bacteria which attacked the intestine. Intestinal tuberculosis, in the victims of phthisis, begins with the formation of multiple ulcers, due to swallowing tuberculous sputum. Primary intestinal tuberculosis usually begins as one ulcer or several, or even many ulcers in the ileum or perhaps in the cecum. These ulcers when they heal tend to form strictures of the small bowel, seldom of the large. Primary tuberculosis is most common in the ileocecal region. It may exist as an ulcerative process with inflammation and abscess about the cecum or as enormous tumor-like thickening of the cecum. The first form is called by Hartmann *enteroperitoneal tuberculosis*. The second form is called *hyperplastic tuberculosis*. The cecum may be involved alone, but usually a portion of the ileum also suffers. The ulcers cause extensive sloughing. The appendix may be involved. All about the cecum a multitude of adhesions form containing masses of tuberculous matter, which may break into the intestine, through the skin of the abdomen, or in both directions. (See Hartmann, in "Revue de Chirurgie," Feb., 1907.) Tuberculous areas suppurate. In tuberculosis of the small intestine there are bloody diarrhea, colicky pain, emaciation, and weakness. There are very active peristalsis and gurgling. The abdomen may be tender. The bacilli may be found in the stools. As ulcers heal strictures develop and produce the usual symptoms. Peritonitis may arise or death may be due to pulmonary tuberculosis. In primary intestinal tuberculosis the urine is apt to show the diazo-reaction (Kocher).

In hyperplastic (conglomerate) tuberculosis the cecum and lower end of the ileum suffer as a rule. In some cases the colon participates in the process. Great fibromatosis with adiposis occurs simulating tumor and due to reaction of tissue *against infection*. Tuberculosis of the ileocecal region is most common between the ages of twenty and forty. There is seldom demonstrable phthisis.

The enteroperitoneal form of ileocecal tuberculosis simulates appendicitis. At first there may be diarrhea, the liquid stools containing blood. Pain in the right iliac fossa may be the first symptom. In any case pain becomes the permanent symptom. A lump can be palpated. After acute pain subsides the lump persists and increases. There may be attack after attack of pain. The symptoms of abscess arise. Spontaneous opening finally occurs, usually about Poupart's ligament. Several fistulæ may form. Each fistula discharges pus with fecal matter. An abscess may open into the intestine. When it does, pus appears in the stools. Bacilli may be found in the stools. In enteroperitoneal tuberculosis death occurs because of the development of pulmonary tuberculosis or, in a small number of cases, by peritonitis due to rupture of an abscess into the peritoneal cavity (Hartmann, Ibid.). The hyperplastic form develops slowly, the individual complaining of indigestion and annoying sensations in the right iliac fossa. During many months the patient feels at times better and at times worse. Then food begins to disagree radically. Several hours after a meal the patient suffers from colicky pain in the right iliac region and distention of the abdomen. Severe pain simulating appendicitis may occur intermittently. Constipation may be severe or may alternate with diarrhea. Gradually a tumor mass forms, evidences of obstruction become obvious, the patient becomes weak and emaciated. The lungs are involved very late, if at all. In some cases ulceration occurs. Conrath's study of 77 cases led him to believe that death occurs in from two and one-half to three years.

Treatment of Primary Intestinal Tuberculosis.—In the first stage the proper treatment is excision of ulcerated areas, possibly excision of the cecum. Later, if stricture is causing chronic obstruction, an operation may be performed to give relief. Laparotomy, careful separation of adhesions which are not fused with the gut, and the introduction of iodoform into the peritoneal cavity may prove of value. Hartmann ("Revue de Chirurgie," Feb., 1907) has collected 229 operations for ileocecal tuberculosis, viz., partial excisions of the cecum, resections (with end-to-end anastomosis, side-to-side anastomosis, or end-to-side implantation), resections in two séances, ileocolostomies, unilateral exclusions, bilateral exclusions, and other operations. There were 46 deaths in these 229 operations. He comments on the fact that there were 58 operations with 7 deaths since 1900, a mortality of 12 per cent.

Perforation in Intestinal Tuberculosis.—By this term we mean perforation into the peritoneal cavity, not into another segment of gut and not into a mass of adhesions. It is supposed to be a rare accident. Cruice estimates that it occurs in from 1 to 5 per cent. of phthisis cases ("Am. Jour. Med. Sciences," Nov., 1911). It may occur in either the primary or secondary tuberculosis of the gut. It is very rare in ileocecal tuberculosis, commoner in tuberculosis of the small bowel. It causes sudden and severe pain, shock, and usually nausea and vomiting. The abdomen becomes rigid. Distention soon occurs. Death may be due to shock or peritonitis. Now and then a perforation causes no characteristic symptoms at all (Cruice, Ibid.).

Tuberculosis of the Mesenteric Glands in Children.—This condition is very common. Corner ("Lancet," Feb. 17, 1912) makes a statement exactly in accord with my own experience when he says that "tuberculous mesenteric glands will be found in practically every child patient submitted to an abdominal operation." They are often recovered from unrecognized. They may produce the well-known symptoms of *tabes mesenterica*, viz., greatly enlarged abdomen, constipation or constipation alternating with diarrhea, loss of flesh, anorexia, anemia, and perhaps a palpable mass. There are abdominal pains about the umbilicus, coming on after taking food and particularly common at night.

In some cases vomiting occurs and pain is in the right iliac region and the case is mistaken for appendicitis. In such a case the pulse and temperature are normal or only slightly elevated and there is no leukocytosis. In mesenteric tuberculosis the appendix is apt to be dilated, constricted, or kinked. Mesenteric tuberculosis may undergo cure, the glands becoming fibrosed and calcified. It may lead to tuberculosis of the intestine, tuberculous peritonitis, or tuberculosis in some distant part.

I agree with Corner that the abdomen should be opened, the appendix removed, and the patient placed a long time on full antituberculous treatment.

Tumors of the Intestine.—**Innocent Tumors.**—Adenoma, lipoma, fibroma, myoma, fibromyoma, papilloma, angioma, and chylangioma may occur. Such tumors are rare. If attached by a pedicle or stem the growth is called a polypus. Adenoma is the commonest tumor. It may or may not be a polyp. It arises from an intestinal gland. There may be one, several, or many. Adenomata may produce no symptoms, may cause hemorrhage, may produce blocking, or may lead to intussusception.

Malignant Tumors.—*Sarcoma* is very rare, but does sometimes arise, particularly in young persons, and it enlarges very rapidly. It is most prone to attack the large intestine. Jopson and White[1] reported 1 case and collected 22 others. The mesenteric glands frequently enlarge. *Cancer* is not uncommon, attacking especially the middle aged. According to Rolleston, the average age in duodenal cancer is fifty-two years; in jejunal and iliac cancer, forty-seven; in cancer of the cecum, nearly forty-eight, and in cancer of the rest

[1] "Am. Jour. Med. Sciences," Dec., 1901.

of the large intestine, about forty-nine years. It is most common in the neighborhood of the ileocecal valve and in the sigmoid flexure. Ewald collected 1148 cases of cancer of the intestine. In 64 cases the cecum was involved; in 24 cases the ileum was involved. There is pain at the seat of growth. After a time constipation is noted, or constipation alternating with diarrhea. Finally, intestinal obstruction occurs. In some cases the symptoms appear suddenly, acute obstruction taking place or intussusception occurring. It is usually possible to palpate the tumor, which is hard and immovable. The patient wastes rapidly and is apt occasionally to pass blood at stool. The growth does not enlarge very rapidly and glands are not involved early. In some cases the supraclavicular glands enlarge. In more than one-half of the cases which die of intestinal cancer there is no lymphatic involvement.[1]

Treatment.—Early in the case exploratory laparotomy should be performed, followed, if possible, by excision with end-to-end or side-to-side approximation. This is done for either cancer or sarcoma. It may be possible to remove enlarged glands. In cancer of the cecum extirpate the cecum and implant the end of the ileum into the side of the colon (Wm. J. Mayo). If excision is impossible, the growth should be side-tracked by performing later anastomosis. In advanced cancer of the large bowel, if resection be impossible, make an artificial anus above the tumor. (See Cancer of Rectum, page 1326.)

Appendicitis.—The vermiform appendix is found in man, the higher anthropomorphous apes, the wombat and rodents. Chimpanzees in captivity are apt to die of appendicitis. Some mammals "closely allied to the anthropomorphous apes possess very large ceca; and in some of these the terminal segment of the cecum resembles the vermiform appendix in that it possesses a very large proportion of the peculiar kind of tissue known as adenoid or lymphatic" ("Evolution and Disease," by Sir J. Bland-Sutton). Some observers believe that it furnishes abundantly digestive ferments and an internal secretion which causes peristalsis. The appendix is usually regarded as a vestigial structure. Prof. Berry, Dr. Arthur Keith, and some others regard the appendix as a specialized region of the cecum. The fact that the appendix of a newborn child is as long absolutely as the appendix of a full-grown man is regarded by Bland-Sutton as proof "that the part was of great importance to the ancestors of the human species" (Ibid.). Appendicitis, which is an inflammation of the vermiform appendix of the cecum, is almost invariably the primary lesion of all of those various conditions known as typhlitis, perityphlitis, paratyphlitis, etc.—terms which seldom imply pathological entities, and are in most instances well relegated to obscurity. I say in most instances, not in all, because I believe there is such a condition as primary inflammation of the cecum, although it is extremely rare. This rare condition may cause perforation, perityphlitic abscess, or peritonitis when the appendix is sound. It is not to be distinguished clinically from appendicitis (McWilliams, in "Annals of Surgery," June, 1907). Involvement of the cecum as a result of appendicitis is common. Such a condition should be expected because the mucous membrane is continuous. It was recognized by some observers many years ago that such a disease as inflammation of the appendix existed, but the majority of the profession did not grasp the fact. In 1759 Mestevier, of France, reported a case of perforation of the appendix by a pin.[2] In 1812 a perforated appendix was shown to the Medico-Chirurgical Society of London[3] and in 1835 Southam reported an appendiceal abscess (Manley). In 1848 Hancock reported an appendiceal abscess ("Lancet," 1838, p. 380). It is interesting to note that this was a case of appendicitis in pregnancy. Ten days after a premature delivery an abscess was opened. About two weeks after operation two fecal

concretions came out of the wound. In 1827 Dr. L. Mélier described appendicitis, and named among its symptoms fixed pain in the right iliac fossa and colic. This brilliant and original young Frenchman was years ahead of his contemporaries. He reported cases of undoubted appendicitis verified by autopsy, described gangrene, perforation, associated peritonitis, and appendiceal concretions. His original article, Manley[1] tells us, is in the "Journal of Medicine, Surgery, and Pharmacy" for 1827, second series, 110. Howard Kelly quotes it from "Jour. gén. de méd.," 1827, vol. c, p. 317. Mélier said: "If it were possible to establish with certainty the diagnosis of this affection, we could see the possibility of curing the patient by operation. We shall perhaps some day arrive at this result."[2] In spite of Mélier's writings, the profession adhered for half a century to the view of Dupuytren, put forth in 1833, that abscesses in the iliac region take origin from the cecum and not from the appendix. Dr. Reginald Fitz, of Boston, in 1886 persuaded the world that the appendix was the real seat of most inflammations in the right iliac fossa, and introduced the term "appendicitis" ("Am. Jour. Med. Sciences," 1886, vol. xcii). This structure is particularly liable to infection because of the large amount of lymphoid tissue in its make-up, because it is in a dependent position, is always full of bacteria, has a poor blood-supply, and is readily blocked by kinking or by swelling of its mucous membrane Further, as a vestigial structure, it has a low resisting power. A functionless part, like a loafer in a city, is a dangerous element. Each is a menace. The loafer is apt to become a criminal; the appendix is apt to inflame and kill. The appendix is a long and narrow diverticulum (musculomembranous in structure), which comes from the posterior and internal part of the cecum, and which probably has no physiological function. The structure of the appendix is similar to the structure of the colon, except that the muscular structure is ill developed and trivial in amount. Lockwood[3] points out that there is an extensive lymph system in the appendix, and that the submucous and subperitoneal tissues communicate by numerous gaps in the muscles. This structure has a poor blood-supply, and in consequence gangrene occurs from rather trivial causes. It is supplied by a branch from the superior mesenteric artery. In women there is sometimes an additional supply by a vessel running in the appendiculo-ovarian ligament. The nerves are derived from the superior mesenteric plexus. The appendix averages about 4½ inches in length, but varies in size between the limits of ⅓ inch and a little over 9 inches. In 641 autopsies the longest appendix was 9⅓ inches and the shortest was ⅓ inch (Monks and Blake). Its diameter is, as a rule, about equal to that of a No. 9 English bougie; its canal is narrow and is partly closed by the valve of Gerlach (Talamon). The appendix enters the cecum at its posterior internal part, which is usually the seat of the most intense pain in inflammation, and corresponds to a point on the surface 2 inches from the anterior superior spine of the ilium, on a line drawn from the umbilicus to the iliac spine, which is known as *McBurney's point.* The free part of the appendix in one-third of all persons is in relation with the posterior surface of the cecum; in almost one-third of all persons it is fixed in the iliac fossa, so that if perforation occurs the contents will be voided into the retroperitoneal tissue (iliac abscess). In less than 2 per cent. of cases the appendix is extraperitoneal. In some cases it is external to the cecum; in some it passes downward, and in some inward. It is important to remember that the appendix may be met with in the most unexpected situations. When the ascending colon is displaced, the diverticulum may be upon the left side. It is not unusual to find its tip in the middle line, up toward or adherent to the gall-bladder, or in the pelvis. In about two-thirds of all cases the appendix is completely covered by peri-

toneum; in one-third of all cases it is in contact, in some part of its length, with cellular tissue (Talamon). Byron Robinson has called attention to the fact that the appendix in man is frequently in contact with the psoas muscle, and may be bruised by this muscle. The mesentery of the appendix (meso-appendix) is attached to one-half or two-thirds of the diverticulum but the tip is nearly always free. In 10,000 autopsies the appendix is said to have been absent five times. In most cases in which surgeons have been unable to find the appendix it was not absent, but was covered and hidden by peritoneum. Occasionally the appendix is found in a hernial sac.

Etiology and Pathology.—Appendicitis is very rare in infants. I operated unsuccessfully on a male two years of age for gangrenous appendicitis. Savage operated unsuccessfully on a baby sixty-one days old, and Weiss operated unsuccessfully on a child twenty months old.[1] J. P. Crozer Griffith[2] has collected 15 cases in children under two years of age. One of these patients was three months old. Nine of the 15 were operated upon, with 7 recoveries. In 4 of the cases the appendix was in the scrotum. In 2 cases a diagnosis of intussusception was made. In children nine or ten years old the disease is by no means infrequent (see page 1150). Appendicitis is common at any period beyond childhood, being more frequent in young and middle-aged people than in the aged. It is very rare in those over sixty years of age. A reason for this is that over half of all the appendix is obliterated or is being obliterated in people over sixty years of age.

Morris ("Annals of Surgery," Nov., 1917) believes that an appendix in a condition of fibroid degeneration is saved from infection by the destruction of structures very liable to infection and by the irritation productive of local hyperleukocytosis. It is for this reason that Morris refers to appendicitis obliterans or irritants as *protective appendicitis*. Appendicitis is about four times commoner in males than in females. It is more common in summer than in other seasons, and in warm countries than in cold or temperate climes. Appendicitis is a bacterial disease. It is produced in many cases by pus cocci, but most commonly by the action of the Bacterium coli commune of Escherich. The colon bacilli, which normally inhabit the appendix, are harmless when the appendix is healthy, but become active for harm when the diverticulum is bruised, obstructed, irritated by the presence of uric acid, congested because of chilling of the cutaneous surface of the body, or distended by the ingress of colonic fluid (C. Van Zwulenburg, in "Annals of Surgery," March, 1905). It seems probable that flatulent distention of the colon may be responsible for forcing fecal matter in quantity into the appendix and may lead to plugging of the opening (Rubin, in "Jour. Am. Med. Assoc.," vol, xliii, No. 1). It has been shown by Rosenau that certain toxins which enter the circulation have a selective action for the appendix. Such toxins may come from a distant focus of infection. When inflammation occurs, swelling of the mucous membrane may occlude the opening into the colon. If this occurs, the lumen of the appendix is dilated, filled up, and becomes distended by a thick mucopurulent fluid. Ulcers sometimes form which may only involve the mucous membrane, may pass deeply into the coats, or may even perforate. Dieulafoy[3] maintains forcefully that appendicitis is due *always* to the conversion of the appendix into a *closed* cavity, but cases are met with which disprove this assertion. Various conditions may bring about this transformation. Partial obstruction may be caused by calculi, which are composed of stercoral material and hordes of bacteria mixed with salts of lime and magnesia. These calculi are not formed in the colon, but are formed in the appendix. The theory that concretions form in the colon and are forced into the appendix by peristalsis has been very

[1] Manley, in "Med. Record," July 9, 1902.
[2] "University of Penna. Med. Bull.," Oct., 1902.
[3] "Progrès médicale," No. 11, 1896.

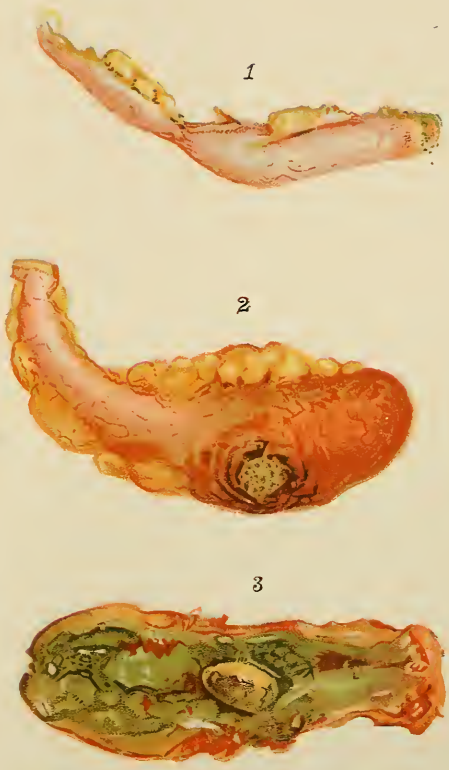
largely abandoned. Dieulafoy speaks of the condition as *appendicular lithiasis*, and says it has a tendency to run in family lines, and has a kinship to gout and rheumatism. Obstruction may be caused by local infection of a catarrhal area, by the formation of a fibrous stricture, or by several causes acting in unison. The presence of a concretion is always dangerous. It is frequently associated with ulceration, either as cause or effect. It is a mass of virulent bacteria. It may lead to perforation or gangrene. Talamon taught that the appendix resents the presence of the concretion, reflex contraction of the muscular coat taking place, with violent pain (*appendicular colic*). The muscular structure is so rudimentary that it does not seem probable that attempts at contraction, even should they arise, would produce violent pain and distant symptoms. Pozzi[1] believes that appendicular colic may be caused by torsion or bending of the appendix or malposition of the diverticulum, and holds that pain may arise when there is no lesion in the appendix and no inflammation of the peritoneum or pericecal structures. What is called appendicular colic is really inflammation of the appendix without involvement of the peritoneum. The term "appendicular colic" has led to much injudicious conservatism, and, as Lockwood shows, if an appendix is removed from an individual who suffers from attacks of appendicular colic, it will usually be found that the diverticulum is inflamed or the lumen contains a concretion. Foreign bodies such as pins, fish-bones, nails, buttons, date-stones, cherry-stones, and grape-seeds, may enter the appendix, but they do so far less often than is generally supposed, most alleged grape-seeds from the appendix being fecal concretions. Fitz found concretions in 15 cases out of 300. Ranvier collected the records of 459 postmortems, and found reported 179 fecal concretions and 16 foreign bodies. In Burgess's 500 cases fecal concretions were found in 21 per cent. ("Brit. Med. Jour.," Feb. 24, 1912). Appendicitis due to a foreign body, such as a grape-seed or a pin, is known as *foreign-body appendictis;* appendicitis in which a concretion is the assumed cause is known as *stercoral.* A foreign body may produce instant perforation. If impaction of a foreign body or concretion occurs, the orifice of the appendix is closed, the circulation is soon cut off, the secretions are retained, the coats become congested, the diverticulum enlarges enormously, microbes multiply with great rapidity, and the wall of the congested appendix inflames and may become gangrenous or ulcerated, and is finally perforated. Interference with the blood-supply of the appendix will predispose to appendicitis. This may be brought about by twists, bruises, adhesions, concretions, pressure, or bands; and the psoas muscle may play a part in the production of these conditions. In women appendicitis is occasionally secondary to tubo-ovarian disease. Appendicitis is rarer in women than in men, probably because in many females the appendix has a better blood-supply than in males, the additional supply coming through the folds of the appendiculo-ovarian ligament. In women disease of the uterus or adnexa frequently precedes or actually causes appendicitis. Catarrhal conditions of the intestine, habitual constipation, and indigestion with flatulence predispose to appendicitis. In fact, in a great many cases there has been a more or less prolonged history of diarrhea or constipation and flatulent indigestion before the development of acute appendicitis. An acute attack of appendicitis may arise after the eating of a large and indigestible meal, especially if such a meal was taken late at night. Bolting the food and eating large meals at irregular hours predispose to an attack. It seems probable that catarrhal appendicitis may result from extension of catarrh of the colon, and possible that, in rare cases, appendicitis may arise from external traumatism (*traumatic appendicitis*). In most cases, however, in which appendicitis seems to be produced by a blow, the injury at most simply "awakened a sleeping dog" and stirred into acute inflammation an appendix already diseased. It is well to

[1] "Progrès médicale," No. 19, 1896.

be skeptical as to external force causing appendicitis. Sprengel ("Deut. med. Woch.," Dec. 14, 1911) says that no case in literature, ascribed to abdominal trauma as causal, can be confirmed by scientific evidence. If before perforation the appendix adheres to the cellular tissue behind the cecum, cellulitis or abscess without peritonitis may result. When appendicitis goes on to perforation, there is always some peritonitis; but if the steps to perforation are gradual, and if the causative organism is the colon bacillus, the peritonitis may be local. Sometimes, by formation of adhesions, a barrier is made between the appendix and the peritoneal cavity before perforation occurs. When perforation takes place suddenly peritonitis is inevitable. When the causative organism is the streptococcus, general peritonitis is very apt to arise. Peritonitis may arise without perforation by contiguity of structure or by migration of bacteria through the congested walls of an obstructed appendix. In some cases perforation takes place into the peritoneal cavity, but pus is circumscribed by matting together of the intestines with plastic exudate. The appendix may become gangrenous very rapidly or after some time. A case of appendicitis in which gangrene and perforation come on very quickly is spoken of as *fulminating appendicitis*. In some cases, if the perforation is very small and the appendix is swathed in lymph, or if perforation does not occur, the inflammation may subside. Perforation rarely occurs from liquid pressure or from the pressure of a concretion; it is generally due to ulceration produced by the action of microorganisms. Appendicitis which subsides may at any time recur, and the life of such a patient is under constant menace. An enormous number of people have had appendicitis. Toft recorded 500 autopsies, and in 36 per cent. of them there were positive signs of past attacks. The disease is occasionally unsuspected during life. These facts prove that the disease may subside without the aid of surgery.

Forms of Appendicitis.—In what is known as *appendicular colic* the appendix is temporarily obstructed because of transitory inflammatory swelling of the mucous membrane of the outlet, and the stercoral contents are retained in the diverticulum. The peritoneal covering is not involved in the inflammation. This condition is called by Fergusson *constipation of the appendix*. If not relieved, it will eventuate in appendicitis with involvement of the peritoneal coat. It is an unfortunate term, sometimes used as an excuse for avoiding operation. In such cases a concretion is frequently or usually present.

Simple parietal or *catarrhal appendicitis* does not remain limited to the mucous membrane; hence the term *catarrhal* is not strictly correct. The vessels of the appendix are distended with blood, the lumen at the intestinal end becomes partially or completely obstructed, the epithelium desquamates from numerous glands, the mucosa ulcerates, and the lumen of the appendix becomes filled with a mixture of mucus, bacteria, and portions of organic matter. Bacteria enter the lymph-spaces of the wall of the appendix, and pass rapidly from the submucous to the subperitoneal tissues. In from twelve to thirty-six hours after the mucous coat begins to inflame the peritoneal coat will probably be involved. The inflammation may undergo resolution and the patient get well, or a wait for cure may result disastrously. The appendix may thicken, ulceration may take place, and peritonitis may arise. Suppuration or gangrene may occur, perforation may take place, or pyemia, with abscess of the liver, may arise. The acute condition may pass into chronic appendicitis or ulcerations of the mucosa may remain; the mucous crypts may be filled with bacteria; a concretion may exist; cicatricial contractions may occur. In any of these conditions the patient is in danger of a fresh attack at any time. In a catarrhal inflammation secondary to catarrh of the colon the case may be chronic from the beginning but most cases of chronic appendicitis follow acute attacks. If the lumen of the appendix is gradually and completely obliterated the condition is denominated *obliterative appendicitis*



Various forms of appendicitis (from drawings by Dr. M. H. Richardson): 1. Obstruction from stenosis of appendix. 2. Dilatation of distal end of appendix; perforation by a fecal concretion. 3. Gangrene of nearly the whole of the appendix; fecal concretion in lumen.

(Senn, in "Jour. Am. Med. Assoc.," 1894). It is present in more than half of all appendices in people over sixty years of age. Senn was of the opinion that the condition results from mild but prolonged relapsing infection. Eight years before Senn's paper Fitz claimed that obliteration of the appendix was the result of inflammation. One year before Senn's paper Ribbert asserted that obliteration was the result of non-pathological involution. Robt. T. Morris ("Annals of Surg.," Nov., 1917) believes appendicitis obliterans is "a normal involutional process belonging to a vestigial structure," nerve structures persisting in the midst of contracting hyperplastic connective tissue. It is an area of irritation occurring in those undergoing physical decline and is most common in neurasthenics. *Recurrent appendicitis*, it was once said, may be due to the inordinate size of the mouth of the appendix, making of this diverticulum a drag-net for foreign bodies; but we now know that it is more probably due to the smallness of the opening, so that it quickly closes from slight swelling and converts the appendix into a closed vase filled with septic material. *Suppurative appendicitis* is due to purulent infiltration of the walls. Pus in the lumen is not purulent appendicitis. Pus may form about the appendix, a condition known as *appendiceal* or *appendicular abscess*. *Gangrenous appendicitis* is a moist or septic gangrene, due to interference with the circulation and to tissue destruction by the action of micro-organisms. Perforation occurs and multiple perforations are common. The entire appendix may slough off. Interference with circulation may be caused by an obstruction, by a bend or twist or bruise of the appendix, or by the action of virulent organisms on an appendix whose tissue resistance is lowered by injury or disease. In gangrenous cases the vessels of the meso-appendix are usually obstructed by thrombi of the veins or arteries. In rare instances appendicitis is due to tuberculous ulceration, in other cases to typhoid ulceration, and genuine appendicitis may arise during typhoid fever.

By the term *syncongestive appendicitis* Morris means a congested appendix the congestion being synchronous with "obstruction to the blood and lymph circulation of the cecum and ascending colon. For example, it is a common complication of general enteroptosis" ("Annals of Surgery," Nov., 1917).

Fowler suggests the following classification of cases of appendicitis: Endo-appendicitis; parietal appendicitis; peri-appendicitis; para-appendicitis.

As a matter of fact genuine appendicitis, that is, actual inflammation of the appendix, is always one disease which varies in intensity and complication. It is useless to divide it into a great number of symptomatic groups.

Symptoms and Signs.—In what is known as *appendicular colic* the patient suffers from disorder of digestion and occasionally has a brief attack of abdominal pain associated with trivial and temporary tenderness in the right iliac fossa. The colicky pain is about the umbilicus and right iliac fossa; there is often nausea and usually constipation. This condition, if not soon relieved, is followed by the evidences of peritoneal inflammation. The symptoms of genuine acute appendicitis are as follows: In some cases the disease seems to begin suddenly, but in most of the cases there are noted for a few hours or even for a day or two distinct *premonitory symptoms*, among which are constipation or diarrhea, flatulence, nausea, anorexia, dyspepsia, coated tongue, weakness, general gastro-intestinal uneasiness, colicky pain about the umbilicus, and, perhaps soon, tenderness, a sense of weight, soreness, or uneasiness in the right iliac fossa. The acute symptoms suddenly appear after the premonitory symptoms have lasted a variable time, and the acute symptoms very frequently appear in the early hours of the morning. The first definite symptom is severe colicky pain. The tongue is coated and usually dry. Great thirst is often complained of. The face is expressive of pain or, later, in a fatal case, becomes Hippocratic. The posture assumed for greater ease is one of recumbency, with the right thigh and knee or both thighs and knees partly flexed. Respirations in acute appendicitis are shallow and thoracic.

The development of acute pain is usually the most prominent symptom. The pain is at first colicky and located about the umbilicus or through the abdomen in general, this distant, primary, or generalized pain, according to Treves, corresponding to the distribution of the superior mesenteric plexus. Mr. Burgess ("Brit. Med. Jour.," Feb. 24, 1912) states the present view when he says that the primary pain is referred to "the peripheral distribution of the spinal nerves arising from those segments of the spinal cord with which the appendix and small intestine are connected through their sympathetic nerve supply—eighth to eleventh dorsal." This primary pain may subside if the appendix succeeds in emptying its contents into the colon, but it may also subside if the appendix becomes gangrenous or ruptures (Murphy). Usually in from twelve to thirty-six hours the pain becomes localized in the right iliac fossa, and associated with tenderness and hyperesthesia of the skin—in other words, true inflammatory pain develops. It is due to peritoneal inflammation. "Thus, the closer the situation of the appendix to the parietal peritoneum, the earlier will the latter be irritated and the sooner will the pain be localized" (Burgess, Ibid.). The usual location of the pain in the right iliac fossa depends on the fact that the appendix is usually placed in that region. Occasionally, when the appendix crosses the belly, the pain is located on the left side, and occasionally, for like reasons, in the gall-bladder region, the right loin, or the pelvis. "If the appendix lies among coils of small intestine or in the pelvis there may at no time be local pain, the initial umbilical pain becoming steadily generalized" (Burgess, "Brit. Med. Jour.," Feb. 24, 1912). If the pain of appendicitis is violent the patient presents some evidences of shock. Nausea is the rule in appendicitis; vomiting usually occurs early—about three or four hours after the beginning of pain. In children vomiting is often early, violent, and persistent, but in adults, after the early hours of the attack, vomiting occurs, as a rule, occasionally or not at all, although nausea is complained of. Early vomiting is a reflex symptom due to distention of the appendix (Murphy). If vomiting persists, it points to peritonitis, to pus formation, or to intestinal obstruction unless it results from the administration of morphin. There is usually constipation in acute appendicitis, although diarrhea occasionally occurs. In appendicitis there is always some elevation of temperature, although it may be very slight and of brief duration. The fever is not ushered in by a chill, but the temperature mounts in the course of a few hours to 102° or 103° F. or even higher. The fever does not begin until several hours or a number of hours after the onset of pain. In a very mild case the temperature remains elevated for a day or two and then falls to normal. In severe cases it is apt to remain elevated for a longer period, but it is always to be borne in mind that in very grave appendicitis the surgeon may find very little elevation of temperature, no elevation, or actually a subnormal temperature. In gangrenous cases, and in cases in which a large perforation suddenly takes place, and when general peritonitis develops, there is usually, for a time at least, a subnormal temperature. A *sudden* drop of temperature indicates, as a rule, a calamity, particularly gangrene of the mucosa of the appendix, which prevents absorption (Murphy), or perforation of the appendix. Leukocytosis is usually present (see Diagnosis). The pulse in appendicitis is in most cases rapid. A very rapid pulse (well over 100) is significant usually of a severe case, and the auguries are especially ominous if the pulse is rapid but the temperature is normal or subnormal. Occasionally, however, a slow pulse exists, even in the worst cases.

Examination of the abdomen may discover, early in the case, general abdominal rigidity; but usually in the course of twenty-four hours or more the general rigidity passes away, the abdomen distends more or less, and rigidity of the lower half of the right rectus muscle becomes evident and persists. If general peritonitis begins early, general abdominal rigidity does not abate or pass away. If general peritonitis begins later, general abdominal rigidity, which was

present at first but which passed away, returns. Rigidity may not exist in the very beginning of appendicitis, in a case in which the appendix is retrocecal or pelvic, in some abscess cases, or in a case with relaxed belly walls.

A symptom almost invariably present in appendicitis is tenderness. In some cases the tenderness is diffuse; in most it is localized, or at least most acute, in the right iliac fossa. The point where tenderness is usually most acute is a spot about 2 inches internal to the anterior superior spine of the ilium, on a line drawn from that bony point to the umbilicus (*omphalospinous line*). This is known as *McBurney's point*, and overlies the usual point of origin of the appendix. In some cases, however, the greatest point of tenderness is nearer the gall-bladder; in others, in the loin; in others, toward the umbilicus, in the midline, or on the opposite side; in others, in the rectum. The seat of greatest tenderness depends on the situation of the appendix, and it is usually at McBurney's point, because this usually overlies the origin of the appendix. The lesson is that in appendicitis there is a point of tenderness or of greatest tenderness in a region which the appendix could occupy. If tenderness exists on the right side and then develops in the left side, severe spreading peritonitis usually exists (W. Meyer). When the appendix becomes gangrenous, local tenderness may for a time disappear, because the peritoneum of the involved region has become anesthetic; later, however, it returns, spreads, and may become general. In view of the fact that tenderness in the right iliac fossa is often demonstrable in tubal and ovarian disease, the sign in males "is of greater significance than in females" (A. H. Tubby, on "Appendicitis," in "Medical Monograph Series"). Pressure upon the left side will, in some cases, cause pain in the right iliac region. When rigidity abates or disappears the case may go on to cure, but sometimes a mass becomes evident in the right iliac fossa. The mass, of variable shape, is at first hard, and if of any considerable size, is dull on percussion. In some cases when no mass is palpable through the abdominal wall, rectal examination detects one. This mass may be agglutinated bowel and omentum or a collection of coagulated inflammatory exudate. It may gradually disappear or an abscess may form. The evidences of general peritonitis are: great distention because of intestinal paresis, general abdominal tenderness, rectal tenderness, very rapid pulse, hiccup, persistent vomiting which may become regurgitation, and, as Meyer points out, percussion dulness over the right iliac region or entire lower abdomen.

In some cases the symptoms, at first trivial, become grave. In some all the symptoms are violent from the beginning, the attack tends to linger, and is followed by persistent soreness of the appendix and harrassing digestive disturbances. Any case of appendicitis may become suddenly desperately grave because of perforation or gangrene, and in any case general peritonitis may develop. After sudden perforation or rapid gangrene the temperature falls, hiccup begins, abdominal distention, pain, and tenderness become marked and general, and the pulse becomes very rapid. In some cases these grave symptoms are present almost from the start (fulminating cases). A sudden perforation produces collapse and, if reaction takes place, general peritonitis arises. Peritonitis, be it remembered, may arise without either perforation or gangrene. If pus forms, it may be unlimited by adhesions. In such cases there is the rapid onset of fatal peritonitis and septicemia. Pus may be limited by adhesions and be practically extraperitoneal. In such a case a lump is felt in the right iliac region, but dusky discoloration and edema of skin very seldom exist. The surgeon does not wait for fluctuation before he makes a diagnosis. In an abscess case there are usually irregular fever and sweating, but rigors do not occur. Hawkins says we should always suspect pus if the symptoms continue after the sixth day, and particularly when the symptoms abate and suddenly increase between the seventh and tenth days. A limited collection of pus may be liberated into the peritoneal cavity by rupture of the

abscess wall. Such a rupture may be caused by pressure or muscular effort; rupture is followed at once by shock and later by diffused peritonitis. An abscess may rupture externally or into the vagina, intestinal tract, or bladder. It is desirable, if possible, to locate the situation of the appendix, and this is usually determined by locating the seat of swelling and of greatest tenderness. The surgeon should not lose sight of the fact that the appendix may be found in the most unexpected situations. In every case a rectal or vaginal examination should be made in order to detect swelling and tenderness, and thus determine if the inflammation took origin in or now involves the pelvic region. Pain at the end of micturition points to involvement of the vesical peritoneum.[1] In cases in which there is no *localized* swelling and no local tenderness—for instance, in gangrenous or perforative appendicitis with general peritonitis—"diagnostic localization" is impossible (Van Hook).

Terminations and Prognosis.—Acute appendicitis may terminate in death, in complete recovery, or in a condition of lowered vitality during the existence of which acute attacks are almost certain to recur. Sometimes after and sometimes without an antecedent acute attack the patient develops persistent soreness and tenderness in the right iliac region. Between the attacks of recurrent appendicitis there may be soreness, tenderness, and gastro-intestinal disturbance, or there may be no evident trouble whatever; yet, even in the latter case, there may be an ulcer or ulcers of the mucous lining. If a patient has once had appendicitis he will always be liable to suffer from another attack if the appendix has not been removed. The liability becomes almost a certainty if the intestinal end of the appendix is narrowed or if the lumen is obstructed at any point, if a concretion exists, or if there is an area of ulceration or of desquamating epithelium. After an attack the appendix may remain enlarged and tender; exercise or indiscretion in diet may cause it to become tender, or the patient may have occasional attacks of colicky pain. If any of the above conditions exist, another attack may be confidently anticipated if operation is not performed. In such cases the appendix can usually be palpated. The method of palpation in an interval proposed by Robert T. Morris[2] is very useful. It is applied as follows:

The surgeon stands to the right of the patient and uses three fingers of the right hand to feel with and three fingers of the left hand to press with. Morris insists that no muscular effort should be used by the hand which feels. The feeling fingers are pressed by the other fingers beneath the margin of the right rectus muscle on a level with the umbilicus, and are drawn toward the patient's right side, and the colon will be felt to roll under the fingers. The process is repeated several times until the end of the cecum is reached. The appendix is sought for by rolling the cecum from side to side with the finger-tips, and working toward the proximal end of the appendix.

Adhesions may form as a result of appendicitis, general peritonitis may arise, the appendix may slough or become perforated, or abscess may ensue upon local peritonitis. Lymphangitis of the appendix may accompany, and septic lymphangitis or phlebitis and secondary hepatic and lymphatic infections may follow, appendicitis. They are thought to be most common after mild attacks of appendicitis. The secondary *lymphatic* and *hepatic infections* are of the greatest importance. There may be abscess of the liver, subphrenic abscess, or retroperitoneal lymphangitis.

A subphrenic abscess may result from infection carried from the appendix by the lymphatics, from pus ascending along the posterior cellular spaces, or from direct invasion via the peritoneal cavity (John C. Munro, in "Annals of Surgery," Nov., 1905); such an abscess is usually on the right side, but may be upon the left.

[1] Van Hook, in "Jour. Am. Med. Assoc.," Feb. 20, 1897.
[2] "Medical Record," Sept. 17, 1898.

Lymphangitis is the rule in appendicitis, and when we open the abdomen there is usually evidence of it in the lymph-glands of the mesentery, and in children particularly these glands are apt to be enlarged. One lymph path from the appendix is through the ileocecal glands, another is posterior to the cecum and retroperitoneal, and the latter reaches the liver and diaphragm (Munro). In lymphatic infection an abscess may form anywhere in the course of the lymphatics. Abscess of the liver usually results from portal invasion, but may result from lymphatic infection.

Sometimes jaundice arises. Jaundice is due to toxins which enter the portal vein and reach the liver. It is ushered in by a chill and the chill is apt to be repeated daily, every other day or every third day. Such a patient may die in two or three days or may live a week or two. In these cases the liver is small, the liver-cells are degenerating and there is acute nephritis. The red blood-cells are destroyed in immense numbers and these dead cells add to the jaundice. A similar jaundice may happen after anesthesia by chloroform or ether (Lenzmann, in Zentralb. für Chir., Feb. 14, 1914) and in fatty degeneration of the liver cells as a complication of pregnancy.

Among other possible consequences of appendicitis may be mentioned pyemia, empyema, inflammation of the parotid gland, and thrombosis of the right iliac vein. A positive prognosis of any case of appendicitis is an absolute impossibility. The future of every case is clouded with uncertainty, and the most that can be attained in the field of prediction is a scientific guess of more or less probability. All surgeons have seen apparently hopeless cases recover, and have observed cases with the most trivial symptoms grow progressively worse or suddenly develop a fatal complication. Further, after one attack other attacks are very apt to arise. The medical man who estimates that 80 or 90 per cent. of cases get well without operation has probably dealt with many catarrhal cases, and he certainly is optimistic as to freedom from future attacks, because, as stated before, recovery from an attack does not of necessity mean freedom from the disease. In appendicitis there may be delusive evidences of improvement; for instance, the abatement of pain and the lessening of fever, being regarded by the patient himself as indubitable signs of improvement, may, in reality, be indicative of gangrene. In spite of the previously mentioned difficulties and obscurities we can in the majority of cases decide with a reasonable probability of accuracy whether or not the patient is becoming worse. In a delusive improvement some signs and symptoms improve, but all do not; and in endeavoring to form a prognosis, *all* the signs and symptoms must be noted and weighed: pain, tenderness, rigidity, distention, nausea and vomiting, delirium, intestinal obstruction, shock, the temperature, the rapidity of the pulse, the blood examination, etc. If *all* these elements, not only some of them, point to improvement, we may be reasonably confident that improvement is really taking place. If only some of them point to improvement we will in many cases be altogether uncertain as to the significance of the change.

The **diagnosis** is not invariably so easy, as many light-hearted operators seem to believe. It is frequently far from easy and is sometimes altogether impossible without exploratory operation. Sonnenburg maintains that we can diagnosticate the pathological condition of the inflamed appendix. Personally, I am unable to do this with any certainty, although I always try, and am often right and just as often wrong.

In attempting to make a diagnosis, besides the ordinary examination of the abdomen a rectal or vaginal examination should be made, associated in many cases with bimanual palpation. If an appendix is enlarged and an individual has a thin abdomen which is not rigid, it may be possible to palpate the appendix. Sometimes it can be felt after the administration of ether when it could not be detected before. In an acute case forcible or prolonged palpation is always unjustifiable, as it may force an ulcer to perforate,

or may rupture an abscess, and the information gained is not of sufficient importance to justify the risk. In a chronic case information of great value may be obtained and there is no real risk in the maneuver. I am persuaded John B. Murphy is correct in attaching the greatest possible importance to the order in which symptoms appear in acute appendicitis. Pain *precedes* nausea and vomiting, elevated temperature, and abdominal tenderness. If fever precedes pain the condition is not appendicitis. If vomiting precedes pain the condition is probably not appendicitis.

The disease may be confused with a number of different conditions. It sometimes is confused with typhoid fever; in fact, early typhoid fever associated with marked abdominal pain gives a picture very similar to that furnished by appendicitis.

In typhoid fever the temperature is usually distinctly higher than that commonly encountered in appendicitis. Maurice H. Richardson[1] tells us that in every case in which typhoid is suspected, operation is not justifiable on the hypothesis of existing appendicitis, unless there are local pain and localized tenderness in the appendix region, associated with definite muscular resistance or distinct rigidity; and that operation should be postponed in a case in which the constitutional signs are severe and the local signs are difficult to detect; but when there are pain, tenderness, and rigidity with or without distention, operation must be performed, even when one recognizes the possibility of the existence of typhoid fever. Richardson lays down the following rule: Soft abdomen plus high temperature suggests typhoid, even if there are pain and tenderness. In appendicitis there is usually leukocytosis; in typhoid, leukocytosis is absent, except when perforation is imminent or has occurred, or when some other complication exists. I have seen the operation performed twice for supposed appendicitis when the condition in each case was found to be early typhoid fever.

Acute intestinal obstruction is sometimes confused with acute appendicitis, and the mistake is particularly likely to occur if the obstruction is due to intussusception. In acute obstruction, as in appendicitis, the pain is first appreciated about the umbilicus; but in acute obstruction it remains in that region, does not pass to and localize itself in the right iliac fossa, and is not associated with tenderness of the right iliac fossa. In obstruction the vomiting is persistent; in appendicitis, except in the beginning, it is usually trivial and often absent, although in children it may be violent and persistent. In acute obstruction shock is much more pronounced than in appendicitis, and early and great distention of the abdomen is noted. The temperature in obstruction is seldom elevated and is usually subnormal; while in appendicitis, at least in the majority of cases, the temperature is distinctly elevated. Further, in acute intestinal obstruction the constipation is absolute, not even gas passing. In children, intussusception is capable of particularly confusing the diagnosis, because, after the first day, it is by no means unusual to have distinct fever in this condition, and occasionally a tumor-like mass is found in the right iliac fossa; but in intussusception the tumor does not remain fixed, but alters its position; it is movable; and the patient usually suffers from tenesmus and the passage of bloody mucus. One should bear in mind that in acute appendicitis associated with septic peritonitis acute obstruction may exist; and that the diagnosis of obstruction may be made without recognizing the appendicitis.

In those rare cases of typhlitis occasionally encountered the symptoms are much milder than in appendicitis: the temperature is not much elevated, the pulse-rate is only slightly accelerated, the leukocytosis is not marked, there is seldom rigidity, there may be tenderness, but seldom pain. Pain when present is colicky rather than continuous. There may be a doughy mass or a

[1] "Boston Med. and Surg. Jour.," Jan. 9, 1902.

mass feeling "like an air-cushion" in the right iliac fossa (Raymond Russ, in "Surg., Gyn., and Obstet.," Oct., 1912). Chronic typhlitis causes muscular atony and intestinal stasis (Russ, Ibid.).

Lesions of the kidney are sometimes mistaken for appendicitis, but in renal colic the pain runs into the groin and testicle of that side, and occasionally passes down the front of the thigh or into the rectum; and if any tenderness exists, it is found in the loin or in the groin, rather than in the right iliac fossa. Besides, there are other symptoms of kidney trouble. The urine may contain blood or pus, and there may be a history of difficult or of frequent urination, though one should bear in mind that in appendicitis with inflammation of the vesical peritoneum there may also be a record of urinary difficulties. An *x*-ray picture may exhibit a calculus in the ureter or kidney, and a movable kidney is distinctly palpable. In ordinary renal colic there is vomiting in the beginning, just as in the beginning of appendicitis. In movable kidney and renal colic the vomiting is often more violent and prolonged than is common in appendicitis. Movable kidney and appendicitis may exist coincidentally. Very confusing cases are those in which *hematuria accompanies appendicitis*. I have seen it twice and in neither case was there any apparent connection between the appendix and the kidney, ureter, or bladder. The hematuria must have been due to acute nephritis which is known to occur in some cases of appendicitis, the nephritis resulting from the toxins of a bacterial disease. This form of nephritis Dieulafoy calls "nephrite toxique appendiculaire." As pointed out by M. G. Seelig ("Annals of Surgery," Sept., 1908), hematuria may also be due to direct involvement of the kidney, ureter, or bladder. When the tip of an inflamed appendix is adherent in the region of the right ureter there may be symptoms inseparable from those of renal colic.

Gall-bladder difficulties, too, may be confounded with appendicitis. I have operated upon 2 cases of cholecystitis under the supposition that they were cases of appendicitis; and upon several cases of appendicitis in the belief that the condition in each case was cholecystitis. In an inflammation of the gall-bladder, with a distended gall-bladder hanging low down, and with muscular rigidity, the distinction between appendicitis and cholecystitis is always difficult and sometimes impossible. So it is when the cecum has not descended and the appendix is in the gall-bladder region. So it is when the tip of the appendix is adherent to the gall-bladder. In ordinary gall-stone colic the condition is generally sudden in onset; it is characterized by pain in the epigastric region, passing toward the shoulder-blade and the shoulder, the pain being most acute and becoming more or less localized in the region of the gall-bladder; and there is always tenderness over the gall-bladder region. In gall-bladder colic the vomiting is usually violent and often almost continuous.

The perforation of a gastric or of a duodenal ulcer may be diagnosticated as appendicitis. In perforation of a gastric ulcer there is usually a history of previous difficulty with the stomach, though this is not always the case. The onset of acute perforation is sudden, with greater shock than is characteristic of the onset of appendicitis. The pain is violent, the rigidity intense, and the pain, rigidity, and tenderness are in the epigastric region.

Among other conditions that may be confused with appendicitis may be mentioned malignant disease of the cecum, tuberculosis of the cecum, acute tuberculous peritonitis, twisting of the pedicle of an ovarian tumor, tubal disease, extra-uterine pregnancy, membranous colitis, perinephric abscess, tuberculous abscess of the loin or of the groin, and abscess from hip-joint disease. I have operated on three cases in which sciatica was caused by appendicitis. In each case the appendix was adherent posteriorly. All were promptly cured. One had been bedridden for many months before the operation.

Pneumonia of the right base and pleurisy may cause abdominal pain and be mistaken for appendicitis. The pain may be due to inflammation of the diaphragmatic pleura or may be reflected along the lower six intercostal nerves

which supply the lower part of the pleura and the abdominal wall. Irritation of the eleventh thoracic nerve causes pain in the iliac region. There may even be superficial tenderness in the abdomen, but deep pressure is well tolerated (Donald W. Hood, "Brit. Med. Jour.," Dec. 30, 1905). There may be abdominal rigidity. The abdominal pain seldom persists more than a few hours. It is intensified by deep respiration and is accompanied by high fever. As Hood says, whenever a patient suffers from vomiting, abdominal pain, and high fever, examine the chest. Sir Thomas Oliver has described what he calls "the abdominal type of pneumonia." It is characterized by the sudden onset of severe abdominal pain. Vomiting often occurs. There is then a chill, usually a rise of temperature, and in some cases collapse. The pain is accompanied by tenderness, and both these phenomena may be in the right iliac region. Early there are no physical signs of pneumonia. In a few hours the patient reacts from collapse, the abdominal pain and tenderness subside, the temperature rises, and signs of pneumonia become evident. In young children pneumonia is particularly apt to cause abdominal pain and rigidity. Beyond a doubt, more than one abdomen has been opened for supposed appendicitis when the real condition was pneumonia.

In chronic appendicitis there is no rigidity. The diagnosis of chronic appendicitis is usually lightly and sometimes wrongly made. The conditions which lead to confusion are many; among them may be mentioned Lane's kink, enteroptosis, movable kidney, adhesions, Jackson's membrane, twisted cecum, gall-bladder disease, pelvic disease, etc. F. Gregory Connell speaks of cases which he calls *pseudo-appendicitis* ("Jour. Am. Med. Assoc.," July 29, 1916). They occur particularly in young, thin adults and in females. Attack after attack of pain may occur. The pain is aggravated by exercise and relieved by recumbency. During the attack there is muscle spasm, there may or may not be tenderness, the intestine is inflated with gas, the temperature is normal or subnormal, there is no leukocytosis, seldom vomiting, and the patient is seldom driven to bed. Connell (Ibid.) believes the condition to be due to "a lack of balance between the vagus and sympathetic divisions of the autonomic nervous system." Removal of the appendix does not cure such a case. Robt. T. Morris ("Annals of Surgery," Nov., 1917) points out a fact of great importance in regard to chronic appendicitis. In all forms of chronic appendicitis there is tenderness about an inch and a half to the right of the navel. This tenderness is due to hypersensitiveness of the right lumbar sympathetic ganglion. It is a striking fact, the difference in the location of the tenderness in acute and in chronic appendicitis. In the latter condition the tenderness is not over the appendix. In chronic appendicitis, in addition to tenderness of the ganglion we note gaseous distention of the ascending colon. These two symptoms pointed out by Morris are undoubtedly realities and I have been able to confirm their genuineness many times. The explanation of them will be found in the study of appendicitis obliterans. Robt. T. Morris ("Annals of Surgery," Nov., 1917) discusses the diagnosis of *appendicitis obliterans*, which he designates *appendicitis irritans*. He points out that it occurs most frequently in neurasthenics with relaxation of peritoneal supports and who show other stigmata of physical decline ("narrow costal angles, crowded teeth, gunstock scapulæ, or a defective helix of the ear"). An advanced degree of atrophy of the appendix does not occur in the very young but more or less of the atrophy exists in one-third of all appendices in people over twenty years of age. The chief symptoms are those of chronic appendicitis. Morris (Ibid.) sums them up as follows:

1. Hyperesthesia of the right lumbar sympathetic ganglion. This ganglion is an inch and a half to the right of the navel and "a trifle caudad" and is near the spinal column. There is no direct nerve route from the appendix to the ganglion and the hyperesthesia is probably due to an efferent impulse from the spinal cord to the ganglion. The impulse having originated in the appendix,

passes first to the cord center and then to both the ganglion and the skin, the skin becoming hyperesthetic, and pressure over the ganglion causing pain.

2. Distention of the flaccid colon with gas. This is due to overstimulation of the innervation of the ascending colon by irritation from the appendix. As Morris puts it "the muscularis of this part of the colon becomes more or less exhausted from persistent nagging." Morris says in his graphic style: "the percussion note of the right side of the abdomen in these cases is suggestive of the percussion note of a cider barrel in January. The percussion note of the left side of the abdomen in these cases is suggestive of the percussion note of a cider barrel in October."

3. Transitory pains in the appendix region which are not sufficiently severe to send the patient to bed.

The *Bastedo sign* in chronic appendicitis was suggested by Bastedo in 1911 ("Am. Jour. Med. Sciences," 1911, cxliii) and is of service. A tube is passed as high as possible into the rectum and air is forced in by the bulb of an atomizer. Distention causes pain and tenderness over the appendix (see Rosenbloom, in "Surgery, Gynecology and Obstetrics," Oct., 1916). Contraction of the psoas parvus muscle may be mistaken for chronic appendicitis and may result from appendicitis. It causes pain in the inguinal region and leg and flexion of the thigh which may persist under ether (Cremer, in "Lancet," 1914, xxxiv; Macdonald, in "Surgery, Gynecology and Obstetrics," 1914, xix; White, "Annals of Surgery," 1913, lviii).

In reaching a diagnosis in doubtful cases of appendicitis I believe that the blood-count is often of service. It is, of course, not to be maintained that the diagnosis of appendicitis may be made by counting the blood; but the blood-count may furnish evidence that, when added to the other signs and symptoms, may be of great importance. In nearly every case of acute appendicitis the hemoglobin is diminished by at least 30 per cent. In a catarrhal appendicitis or in an interstitial appendicitis the leukocytosis is trivial; but in cases of abscess or of gangrene of the appendix the leukocytes, as a rule, rise from 15,000 to 20,000. It is to be remembered, however, that when the patient is profoundly septic the systemic condition is so depressed that leukocytosis is impossible; hence leukocytosis may be absent in trivial catarrhal cases or in grave cases with overwhelming general sepsis. This latter condition, however, is extremely rare. The blood-count will not help one in making the differentiation between appendicitis and an inflammatory disorder of the pelvis or abdomen, but will aid one in making a diagnosis from typhoid fever, intra-abdominal or pelvic neuralgia, and movable kidney (see J. C. DaCosta, Jr., study of 118 cases, "Am. Jour. Med. Sciences," Nov., 1901).

Appendiceal Dyspepsia.—Indigestion may, for a longer or shorter time, precede an attack of acute appendicitis. A like condition may follow an attack.

In chronic recurrent appendicitis dyspepsia may so dominate the clinical picture as to lead the physician to regard the case as one of gastric disease. Such a patient has prolonged attacks of epigastric pain aggravated by food. The pain radiates downward toward the appendix and is not so severe as the pain of duodenal ulcer. There may or may not be tenderness in the appendix region but in most cases there is tenderness to the right of the navel and the ascending colon is distended with gas (page 1148). The condition may be due to hypersecretion of the gastric juice resulting reflexly from appendix inflammation. Fenwick regards chronic hypersecretion as a direct cause of this form of dyspepsia. The epigastric pain may be due to pyloric spasm or gastritis (Eusterman, "Jour. Missouri State Med. Assoc.," May, 1913). At times, however, during some of the attacks appendiceal tenderness is demonstrable and perhaps there is pain in the right iliac fossa. The epigastric or abdominal uneasiness may be constant. Food may immediately cause pain. Nausea and flatu-

lence are common. "As a rule there is not the regularity of onset of pain after food—the periodicity of attack—which characterizes gastric ulcer" (Eusterman, Ibid.). Food does not relieve pain except in the less common cases in which there is hyperacidity.

Appendicitis in Children.—The disease is much more common than was once thought (see page 1138). Russel S. Fowler ("Am. Jour. Diseases of Children," August, 1912) collected 183 cases occurring in children under twelve years of age and brought to the German Hospital of Brooklyn. During the same period (1900–1912) the total number of cases was 1115, the proportion of children being 16.41 per cent. The youngest patient in this series was two years and nine months old. Morf of the Cook County Hospital in Chicago reports 822 cases of appendicitis and 150 of them were under fifteen years of age ("Jour. Am. Med. Assoc.," March 24, 1917). There is usually a history of antecedent attacks of gastro-intestinal disorder. The onset is apt to be sudden, but may be insidious, the symptoms as a general thing are violent, and the progress of the disease is rapid. Vomiting is usually more violent and prolonged than in adults. There is a great likelihood of pus formation and general peritonitis and gangrene are more common than in adults. Marked leukocytosis usually exists. Occasionally in young children pneumonia begins with so much pain and rigidity in the lower abdomen that the signs seem to point to appendicitis, and an attack of appendicitis may begin coincidently with or soon after a pulmonary inflammation. I have seen 4 cases in children in which pneumonia was ushered in by abdominal pain and rigidity. The surgeon should be awake to the possibility of typhoid fever, indigestion, fecal impaction, intussusception, and tuberculous peritonitis. In children the appendix occupies a lower position than in adults, the point of abdominal tenderness is usually lower than in adults, the inflammation usually reaches the right side of the pelvis, a painful point can generally be discovered by a finger in the rectum, hence a digital rectal examination must always be made. This usual involvement of the pelvis is responsible for the frequent and painful micturition which is very common (Karewski). Sometimes when the bladder symptoms are very prominent they dominate the clinical picture and the bladder is thought to be the real seat of disease. An attack of peritonitis in a child is more apt to result in general peritonitis than is the same disease in an adult (Selter). I agree with Springer ("Prag. med. Woch.," 1909, xxxiv, Nos. 7 and 8) that operation in children should invariably be prompt and that purgatives should not be given. In Fowler's series of cases ("Am. Jour. Dis. of Children," Aug., 1912) the operative mortality was 3 per cent. Clopton's mortality was 4 per cent. ("Pediatrics," 1915, xxvii).

Appendicitis in Pregnant Women.—Appendicitis is a very dangerous, but, fortunately, a very rare complication of pregnancy. In 731 women operated on for appendicitis in the Mount Sinai Hospital, of New York, from 1898 to 1907, only 7 were pregnant (Cooke, in "New York Med. Jour.," May 1, 1909). Lobenstine states that in 30,000 cases under the care of the New York Lying-in Hospital there were but 5 cases of acute appendicitis (Cooke, Ibid.). Most of the patients who develop appendicitis during pregnancy have had previous attacks.

The condition may arise at any stage of pregnancy. It is usually violent, rapid in progress, and accompanied by vomiting. Early in pregnancy the pain and tenderness are significant and are located regionally, as when pregnancy is absent. Cooke points out that later in pregnancy the pains may be so spasmodic as to cause them to be attributed to beginning labor, and they are often located in the region of the liver or even on the left side of the belly (Ibid.). Two hundred and fifty cases have been reported and over 100 have been operated on (Renvall).

Appendicitis in the pregnant is far more dangerous than in the non-pregnant.

In from 20 to 40 per cent. of cases abortion occurs, and usually the child dies from infection. In some cases of successful operation pregnancy continues to term. In only 10 per cent. of Morf's 22 operations did abortion occur ("Jour. Am. Med. Assoc.," March 24, 1917). The diagnosis is often very difficult because of the enlarged uterus.

Appendicitis Following Childbirth.—Hilton collected reports of 29 cases and added 1 of his own ("Surg., Gynec., and Obstet.," Oct., 1907). Hilton demonstrates that childbirth and the puerperium may be causal of appendicitis. The signs and symptoms are apt to be masked or are thought to be due to the puerperal state. The prognosis is grave. In cases developing within ten days of labor 45.5 per cent. died (Hilton, Ibid.).

Acute Appendicitis in Typhoid Fever.—An ordinary acute appendicitis may arise during or soon after typhoid fever. In some of these cases a chronic appendicitis has been driven into violence by the fever. I have operated on two ordinary cases of gangrenous appendicitis and one of acute suppurative appendicitis occurring during typhoid fever. During the fever a typhoid ulcer may form in the appendix and this ulcer may perforate or the appendicitis may be secondary to typhoid infection of the lymph-follicles. Undoubted cases due to the typhoid bacillus have been reported (Homer Gage, in "Annals of Surgery," August, 1915). In such cases the typhoid bacilli are lodged in the lining of the appendix. Pus cocci may cause appendicitis in a victim of typhoid. The appearance of leukocytosis during typhoid fever should lead us to investigate for some inflammatory complication especially appendicitis and perforation. Pain and diarrhea usually exist. Rigidity may be absent.

Fig. 700.—Tuberculous appendix with perforation and abscess.

Tuberculous Appendicitis (Fig. 700).—Acute symptoms may develop resembling acute appendicitis. There is usually a history pointing to intestinal stenosis, the stenosis existing at the ileocecal valve.[1] There is always great thickening, and an abscess of large size is apt to form. The cecum usually, but not always, is involved in the tuberculous process. Chronic cases, with palpable enlargement, are sometimes mistaken for cancer of the cecum.

Appendicitis in the Victims of Pulmonary Tuberculosis.—Many cases present the well-known symptoms of appendicitis but they may be very mild. Appendiceal dyspepsia (page 1149) may exist. Dieulafoy described a form of appendicitis in the tuberculous which is characterized by pain and diarrhea. Most cases show no tuberculous lesions of the appendix. One-fourth of the cases show such lesions. Lesions are found when the pulmonary tuberculosis is advanced rather than when it is incipient (Kinghorn, in "Jour. Am. Med. Assoc.," 1916, lxvii). Kinghorn (Ibid.) operated upon 28 patients and 3 of them died.

[1] Andrews, "Annals of Surgery," Dec., 1901.

Malignant Disease of the Appendix (Fig. 701).—This is a very rare condition (less than ½ of 1 per cent. of appendices removed for supposed inflammation). It is impossible of recognition clinically, but is sometimes discovered postmortem or during operation for supposed acute or chronic appendicitis or pelvic disease. Inflammation does not cause the malignant disease, but the malignant disease is apt to block the appendix and so cause inflammation. The condition may be carcinoma, sarcoma, or endothelioma, and usually there are distinct inflammatory changes. It is more common in women than in men. Rolleston and Jones collected 42 cases. McWilliams reported 3 cases and collected 45 not in Rolleston's table. This makes 90 reported cases ("Am. Jour. Med. Sciences," June, 1908). Since writing his article McWilliams has found 15 more cases reported. No case is counted in which the colon is diseased. The combined statistics show the average age of the patients to be only twenty-nine years. Two patients were only eight. In most cases the appendix alone is diseased; in some the colon or glands of the mesentery are involved. In three-fourths of the cases the growth is distal to the middle of the appendix. Glands are involved late. Out of 90 cases in McWilliams' table only 8 had enlarged glands, and in 4 of these it was proved that the glands were not cancerous. In about 5 per cent. of cases concretions were found. The chance for permanent cure after removal of an appendix the seat of malignant disease is very good if the disease is limited to the appendix, and is particularly good if the growth is spheroidal-celled carcinoma (Rolleston and Jones). Metastasis is rarely noted. The growth is seldom larger than an almond.

Fig. 701.—Carcinoma of bowel and belly wall after appendix operation. Appendix removed by English Army Surgeon in Burmah. Portion of bowel removed at Heidelberg.

Treatment.—If the diagnosis were always certain from the beginning, and if the case were seen at the very start by a surgeon, immediate operation in every case would be eminently proper. If this plan could be followed, the mortality from appendicitis would be extremely small. At this early stage the peritoneum is free from infection, and the appendix can be rapidly and easily removed without risk of infecting the peritoneum. Whenever I see a case early, that is, during the first thirty-six hours of the attack, I practically always advise operation. Unfortunately, this plan cannot be habitually followed. As a rule, when the physician first sees the case the appendicular peritoneum is inflamed, and the surgeon usually sees the case at even a later period than the physician. At this time the barriers of leukocytes are being heaped up to limit the spread of infection, and delicate encompassing adhesions are usually being formed. Even in these later cases I often, in fact, usually, advise operation. Operation at this stage may be imperatively necessary because of the rapid spread and dangerous nature of the process; but when operation is not done, in some cases at least, a temporary limitation will be secured and the case will go on to an interval. Operation in the acute period is always dangerous; operation in an interval is safe. In some instances, when the case is not seen early, it is wiser

to avoid operating at the time, and it is proper to wait for an interval. The period in which the surgeon usually sees the case for the first time was said by Maurice Richardson to be "too late for an early operation and too early for a late operation." Those who say "operate as soon as the diagnosis is made," operate, as a rule, in this dangerous period, and in this period I do not believe that every case should be promptly cut. Many cases, it is true, must be operated on as soon as seen, irrespective of the duration of the disease. We must operate promptly if the pulse is small, tense, and well above 100; if there is persistent vomiting; if there is delirium; if intestinal obstruction exists; if a chill has occurred; if the pain and rigidity are very marked; if a mass can be felt in the right iliac fossa or by rectal examination; if there is marked abdominal distention; if there are evidences of pus formation; if the patient is growing worse; if there is or has been shock; or if the pain suddenly passes away without the use of opiates.

In an ordinary mild case, not seen early, in which none of the above-named conditions or symptoms exist, it is best to defer operation. Those who advocate operating upon every case consider such delay reprehensible and dangerous, point out that even in apparently mild cases gangrene or perforation may quickly occur, and cite striking cases to emphasize their belief. There is much force in this view, and it must not be hastily rejected. The choice, however, is not between a dangerous delay and a safe operation, but rather between a dangerous delay and a dangerous operation. It is a question of two dangers, and each side chooses the danger which seems to it the least. Richardson's elaborate study of 750 cases, showing a mortality of 18 per cent. in operations for acute appendicitis, determined us in the practice of the more conservative plan. General peritonitis is the most common complication and more than half the deaths are due to it. It may arise in abscess cases from spontaneous rupture, from rupture due to rough handling, from digging out an appendix from an abscess-wall or from removing drainage too early.

The mortality of abscess cases is not half that of gangrenous cases. Coffey collected 13,445 reports of operations for acute appendicitis. The mortality was 7.4 per cent. ("New York Med. Jour.," August, 1906).

In an ordinary mild case of appendicitis in which operation is refused, it is a common custom to purge by means of Epsom or Rochelle salt. This practice was begun because of the belief that inflammation of the appendix is associated with fecal impaction in the head of the colon. This belief has been exploded, but the treatment is still used by some who regard it as beneficial. If the condition of the stomach prevents the administration of salines, high enemata are often given. My own belief is that if operation is refused, or if the surgeon determines to wait for an interval, he should not give a purgative, but follow the plan of treatment suggested by Ochsner to control peristalsis and favor limitation of infection. The patient is kept perfectly quiet, is placed in the Fowler position, no cathartics are given, no food or drink is administered by the mouth, and thirst is allayed by enemata of salt solution. Nutritive enemata may be given. It is also my custom to place a hot-water bag instead of an ice-bag over the appendix region.

To permit peristalsis favors diffusion of the infection; to prevent peristalsis is to favor the formation of encompassing and defensive adhesions. A purgative is very dangerous. It may cause rupture of the appendix. By causing peristalsis it diffuses the infection.

Many surgeons use the ice-bag, but I do not believe in it in these cases. We have already shown (see page 107) that cold as a remedy for inflammation is useful only in the brief stage of hyperemia, and when a surgeon sees a case of appendicitis there is certainly more or less stasis. Cold adds to stasis and does harm, and I am persuaded that the routine use of the ice-bag is responsible

for some cases of gangrene. Again, cold actually antagonizes the migration of leukocytes and the formation of adhesions. For a number of years I have believed and taught that the ice-bag weakened resistance in appendicitis. These views seem to find confirmation in the article of Dr. A. M. Fauntleroy, U. S. N. ("The Ice-bag and Appendicitis," "Med. Record," August 3, 1912). The study of a number of cases led him to the conclusion that the ice-bag is often responsible for "a noticeable lack of effort on the part of Nature to wall off from the rest of the abdominal cavity the appendix." Further: "It was also noted in the ice-bag cases that there was a surprisingly low white count when one took into consideration the condition." These reports are most significant. They are in strict accord with my own results. It is my belief that the use of the ice-bag antagonizes the limitation of the infection and favors dissemination of toxins and bacteria. I believe that its employment is a grave mistake.

Heat is a remedy which favors limitation of the process. It relieves stasis, draws leukocytes to the part and stimulates their activity, favors the formation of an encompassing barrier of phagocytic cells, and aids the cellular proliferation which leads to the formation of adhesions. Hence I prefer the hot-water bag.

The ice-bag, when applied before the diagnosis has been made, that is, in the earliest hours of the attack, when it might be thought to be most serviceable, allays pain and lessens rigidity in some cases almost like a full dose of opium, and hence masks the symptoms as does that drug.

Opium should never be given until the diagnosis has been made. In the first place, it is not needed, for if the pain is so violent as absolutely to demand opium, operation should be performed. In the second place, opium masks the symptoms, makes the patient feel comfortable, and gives the physician an unfortunate and ill-founded sense of security. The pain about the umbilicus, if severe, can be distinctly and safely relieved by the administration of 30 min. of spirits of chloroform every half-hour until three doses have been taken. Opium should not be given if the surgeon, having decided not to operate at once, is awaiting an interval, because it may prevent or delay the recognition of some disastrous change. If a patient refuses operation, it can be given.

When we are inclined to wait for an interval, the case should be seen again within six hours. We are accustomed to follow McBurney's rule, which is as follows: If on seeing the patient again, six hours after the first visit, the patient is worse, operate at once. If he is no worse there is no pressing danger.

If in twelve hours after the beginning of the attack the symptoms are not intensified, they will soon begin to abate; if the symptoms have become worse during this time, operate. If in twenty-four hours after the beginning of the attack the severity of the symptoms lessens, it is usually possible to wait for an interval; but if during the second twenty-four hours there has been no abatement in the severity of the symptoms and there is doubt as to the condition, operate at once.[1] When the attack has subsided, and about three weeks or more have passed, the appendix can be removed with remarkable safety. After a patient has had two or more attacks of appendicitis all surgeons agree that the appendix should be removed.

If pus is present some surgeons delay operation in the hope that firm adhesions will form around the pus, and that the necessary operation will simply be the opening of an abscess. I do not believe it is safe to delay operation in a pus case. The pus may become limited, but it may instead pass up toward the liver or down into the pelvis. Delay is fraught with peril.

If only one attack has occurred, there may never be another, and the question arises, "Should the appendix be removed after one attack?" We do not know that a man has really recovered after purely medical treatment. Many cases reported as cured by medical means have subsequently required operation.

[1] For McBurney's views, see "New York Polyclinic," Jan. 15, 1897.

As Lockwood[1] puts it, "To say that a man with appendicitis has been cured by medical means is in many cases equivalent to saying that a man with a stone in his bladder has recovered from calculus after the cure of a cystitis by rest in bed."

Even after a first attack, if the appendix remain tender or become tender after exercise, or if attacks of colicky pain occur, or if there be tenderness to the right of the navel and gaseous distention of the ascending colon, operate.

In some cases even a single attack of appendicitis is followed by persistent dyspepsia and ill health, and in such cases operation should be performed. In the majority of cases, even after one well-marked attack, operation is necessary. It is always necessary after two attacks. (See Operation for Appendicitis.)

Appendicitis cases which are far advanced in general peritonitis when seen by the surgeon some operators decline to touch. If we make a custom of operating on such cases we will lose very many, but will save some few, and these few would have died if we had not operated. To operate spoils statistics, but occasionally saves lives. The operation should consist of a simple incision to relieve tension and afford exit to infected fluids—rapid removal of the appendix if it is easily accessible, otherwise leaving it alone—and drainage of the pelvis. After such an operation the patient is placed in Fowler's position and a continuous stream of salt solution at low pressure is caused to trickle into the rectum. (See Murphy's Treatment for Peritonitis, page 1162.)

Appendicitis in a child is treated exactly as in an adult. Appendicitis in the pregnant woman is treated as in the non-pregnant. Early operation is particularly indicated, and it is not proper to induce premature labor in a patient far advanced in pregnancy unless there is general peritonitis. Then it is proper to empty the uterus—primarily, to obtain drainage and to give the patient a chance for life, and secondarily, to obtain a living child.

When operating upon a woman for appendicitis, bear in mind that ovarian, tubal, or uterine disease may have preceded, actually caused, or resulted from the appendicitis; examine the adnexa and remove them if necessary.

An operation for tuberculous appendicitis is rather apt to be followed by a fecal fistula. An ordinary laparotomy is sometimes followed by cure, but the rule of an operator should be, when possible, to remove the appendix and resect the diseased bowel. Andrews[2] mentions as expedients suited to special cases of tuberculous disease: total exclusion; partial exclusion; lateral anastomosis, and the formation of an artificial anus. If, in any operation for appendicitis, the psoas parvus muscle is found to be contracted, the peritoneum should be stripped up and the tendon should be bared and divided.

Intestinal Diverticula.—Congenital diverticula sometimes exist in the duodenum. Pressure diverticula may arise in the small intestine; they are, as a rule, small and multiple. The descending colon and the pelvic colon are the most common seats of diverticula. They occur at any portion of the circumference of the tube, are usually multiple, and vary much in size. Occasionally a diverticulum becomes enormous. A diverticulum contains fecal matter and, perhaps, fecal concretions. When free from acute inflammation and when unobstructed a diverticulum may cause fecal stasis or may cause nosymptoms whatever. A diverticulum may inflame, suppurate, cause pericolonic suppuration, perforate, or become the focus of a great fibrous area (fibromatosis), which is usually mistaken for cancer. The *x*-rays are invaluable in diagnosis.

Acute diverticulitis occurs in "adults, mostly in males in midlife and given to obesity" (Joseph Ransohoff, in "Annals of Surgery," August, 1913). There may be catarrhal inflammation. An abscess may form about the diverticulum. Perforation may occur, followed by abscess or general peritonitis, or the diver-

[1] "Brit. Med. Jour.," Jan. 27, 1900.
[2] "Annals of Surgery." Dec., 1901.

ticulum may become gangrenous. When perforation occurs it is apt to take place into the mesocolon or through an epiploic appendix. Diverticulitis may cause in the intestinal wall the formation of scar tissue which can be mistaken easily for a malignant growth. As most diverticula are in the lower colon the symptoms are usually left sided and strongly resemble appendicitis. Occasionally the condition is found in the cecum or ascending colon. Suppuration about the sigmoid does not of necessity arise from acute diverticulitis. Acquired diverticula do not arise in children, and yet Ransohoff (Ibid.) reported cases of acute perforating sigmoiditis in children.

Chronic Diverticulitis.—This occurs particularly in the sigmoid, produces pain, hemorrhoids, constipation and great thickening and is commonly mistaken for carcinoma.

Meckel's Diverticulum.—(See page 1122.)

Treatment of Acute Diverticulitis and of Perforating Sigmoiditis.—As for appendicitis.

Fibromatosis of the Colon.—This condition produces symptoms strongly resembling those caused by carcinoma, and many cases have been operated upon under this conviction, the truth having been discovered by microscopical examination of the specimen. It is an inflammatory condition most often met with in the pelvic colon. A large, hard mass forms and constriction occurs. The mucous membrane is thrown into deep folds and ulceration occurs between these folds.

The fibromatosis is a reaction to infection. The infecting agent gains entrance through a desquamating area, a wound of the mucous membrane, an ulcer, or an inflamed diverticulum. Even when cancer exists there may be extensive fibromatosis about it, the area of real malignancy being much less than the induration suggests.

Fibromatosis may arise at any age, but is most common during and beyond middle age. There is continuous abdominal uneasiness now and then rising to pain. The general health deteriorates. The victim suffers from habitual constipation, but occasional attacks of diarrhea occur. Blood and mucus are at times found in the stools. If the constricting mass is within reach of the finger, it will be found that the induration is beneath thick and soft mucous membrane. If it can be seen by the sigmoidoscope, the folds of mucous membrane will be obvious. Abdominal palpation often detects the mass, which is sausage shaped. (See Miles, in "A System of Surgery," edited by C. C. Choyce.)

Treatment.—Resection and anastomosis if possible. If real obstruction exists, or if the mass seems irremovable, do colostomy. After colostomy the mass usually shrinks greatly and may actually disappear.

Congenital Idiopathic Dilatation of the Colon (Hirschsprung's Disease; True Megacolon).—This condition is of prenatal origin. The large intestine is chiefly involved. The rectum and small bowel seldom suffer, "and in more than one-third of all the cases the sigmoid flexure is alone involved" (Finney, in "Surg., Gynec., and Obstet.," June, 1908). There is no definite mechanical obstruction demonstrable at autopsy or operation. It is in this that Hirschsprung's disease (true megacolon) differs from pseudomegacolon (Finney, Ibid.). The diameter may reach 6 or 8 inches, and the colon may seem elongated and be in loops. Dilatation and hypertrophy produce marked changes in the wall of the gut. The condition may be obvious in early life or it may not become so until adult years, being aggravated and developed, but not caused by habitual atony of the bowel. The supposed cause is an anatomical anomaly (perhaps elongation) leading to looping of the colon, a muscular aplasia leading to dilatation and valve formation. Various causes have been suggested.

The victim of this condition is obstinately constipated and has a distended abdomen, usually from early infancy, although, as previously stated, the con-

dition may not manifest itself until childhood, youth, or even adult life. It is most difficult to get the bowels to move at all. Gay reported a case in which there was no bowel movement for three months. Periods of several weeks without a movement are by no means uncommon. Now and then an attack of diarrhea may cause the emptying out of great quantities of feces. The abdomen is enormously distended and the patient is emaciated.

The abdominal veins are distended and the rectus muscles may be separated. In Finney's cases (as in some other reported cases) the cords of distended gut could be seen or felt to be more prominent on one side than on the other. There is no abdominal tenderness and pain is absent unless there is diarrhea. Borborygmus is often very loud. Vomiting is rare. The urine shows a marked increase of indican.

The disease does not directly cause death, but the ill-nourished condition lessens the chance for recovery from any attack of illness.

In 358 cases collected by Schneiderhöhn (Internat. Abstract, Oct., 1915, from "Zeits. f. Kinderh.," 1915, xii) the mortality was 43 per cent. Surgical treatment shows a less mortality than medical treatment. Schneiderhöhn (Ibid.) collected 143 cases treated surgically with a mortality of 36 per cent. and with 46 per cent. of cures.

Treatment.—Very early cases ought to be treated medically. Medical treatment consists of the ordinary plans for combating constipation. Surgery is more dangerous in young children than in older subjects. Some surgeons have removed almost the entire large intestine; others have performed entero-anastomosis; others, colopexy; others have established a permanent artificial anus; others have made an artificial anus preliminary to entero-anastomosis. Finney believes that the operation of choice is resection of the affected gut followed by entero-anastomosis.

Splanchnoptosis (Visceroptosis).—Coffey ("Surg., Gynec., and Obstet.," Oct., 1912) points out that in man special provisions have been made to keep the viscera from riding down because of the upright posture. He names four forms of support: (1) Peritoneal fusions before birth to the parietal peritoneum; (2) a shelf above each psoas muscle; (3) tone of the abdominal wall; (4) packing of subperitoneal fat which regulates intra-abdominal pressure. Visceroptosis is generally said to be due to relaxation of the abdominal walls and decrease of intra-abdominal tension, which lead to gradual stretching of suspensory ligaments and finally to movement of the viscera downward. The prolapse may involve all the abdominal viscera, one viscus, or several viscera. The heart, too, may droop. Fossier collected a number of cases of movable heart ("New Orleans Med. and Surg. Jour.," Nov., 1910). According to Coffey (Ibid.), when the intestine descends, kinks occur at the junctions of fixed and movable parts, and general ptosis is an attempt on the part of Nature to prevent intestinal kinks. Prolapse of the stomach is known as gastroptosis (see page 1109); prolapse of the liver, as hepatoptosis (see page 1177); prolapse of the spleen, as splenoptosis (see page 1204); prolapse of the kidney, as nephroptosis (see page 1419); and prolapse of the intestines, as enteroptosis or *Glénard's disease* (see below).

The causative relaxation of the abdominal walls is most common in women, but is by no means confined to that sex. It may be produced by ascites, pregnancy, muscular effort, febrile maladies, or wasting disease. In some cases no cause can be assigned. Such a relaxed abdomen may or may not be thin. The fascial strands and muscular fibers are stretched, and usually attenuated and separated, the belly bulges downward and forward, and a viscus or the viscera follow because of lack of support.

Enteroptosis, or Glénard's Disease.—This disease is a prolapse of the intestine. It may be but a part of ptosis or prolapse of all the abdominal viscera; it may exist alone; it may be associated with movable kidney,

prolapse of the stomach, of the liver, or of the spleen. The recti are apt to be separated. Symptoms usually begin at puberty but may arise in childhood. It is much more common in females than in males.

In Glénard's disease the intestines occupy the lower portion of the abdomen, and the belly below the costal margins is flat, is dull on percussion, and the pulsations of the aorta are very evident. The right portion of the transverse colon begins to descend first, and other portions of the intestine follow. The splenic and hepatic flexures are elongated, and sometimes there is venous engorgement of dependent parts of the mesentery (Lambotte, in "Presse Med. Belge," Nov. 24, 1901). The victims of this disease are irritable, dyspeptic, anemic, constipated, hysterical, and neurasthenic. Mucous colitis is common. They suffer from severe migraine, loss of flesh, weakness, pain in the back, the coccyx and in various parts of the body, attacks of pseudo-angina, vasomotor disturbances, variable temperature which tends to become subnormal and, whereas there is seldom tenderness, pressure may induce cramps (Lerch, in "New York Med. Jour.," Dec. 19, 1914). Most of the victims of enteroptosis are emaciated but there is a type of case in which the stature is short, the patient is fat with a pendulous belly and has an enlarged thymus (Lerch, Ibid.). Normally the tenth rib is firmly attached by fibrous tissue to the ninth costal cartilage. In enteroptosis the tip of the tenth rib is freely movable and obviously separated from the ninth costal cartilage (*Stiller's sign*). The *x*-rays used after a bismuth or barium meal are of the greatest help in diagnosis. The ptosis may arise without apparent cause, but may follow the wearing of ill-fitting corsets, falls, blows, lifting heavy weights, or prolonged vomiting. Lerch thinks an abnormal form of the spine is responsible ("New York Med. Jour.," Dec. 19, 1914). In one type there is no lumbar curve, in another type there is an extreme lumbar curve. The dyspepsia is due to dragging on the duodenum, the tube becoming flattened out (A. K. Stone). The flattening of the duodenum may be followed by kinking of the pylorus, and in such a case the stomach dilates, otherwise it does not dilate. Where a movable portion of the gut has a junction with a fixed portion a kink may form and chronic intestinal stasis may ensue.

Treatment of Visceroptosis.—In many cases medical treatment is of benefit. The following is the usual plan: Employ lavage, abdominal massage, and electricity. Fresh air and tonics are of benefit. Laxatives and sedatives are required. Mineral oil is the most useful laxative. Insist on regular exercise, and treat the anemia and dyspepsia. Abdominal support is of great importance. It sustains the viscera in place and saves them from congestion. Support is obtained as in movable kidney by a well-fitting, straight-front corset. This corset takes a bearing as low as the great trochanters. It laces in front and is applied while the patient is recumbent, pillows beneath the buttocks making the pelvis higher than the head. It is to be laced tighter below than above. Pads are harmful. We strive to support the organs by intra-abdominal pressure. Lerch (Ibid.) says the patient should go to bed for an hour or two after the midday meal and should sleep on the face without a pillow. Surgery is resorted to if intestinal stasis exists and cannot be relieved by medical and dietary treatment. The surgical methods applicable to special organs are discussed under those headings. When the intestines are ptosed and there is stasis there are two commonly employed surgical plans, and each has its advocates: (1) The suture of the prolapsed intestine to some adjacent structure or shortening its supporting ligaments. (2) Plastic operation to lessen the area of the abdominal wall and thus increase intra-abdominal tension. Depage makes the abdominal wall less in both directions. Webster, in cases of separation of the recti, resects and sutures the fascia of the muscles. I believe that Depage's method of shortening the diameters of the abdominal wall cannot permanently succeed, because the viscera, hanging to relaxed ligaments, will eventually stretch the wall; it will be

stretched easily because of damage done to its nerve-supply by operation, and hernia will be apt to occur; and if it should, the patient will be worse off than before operation. Of course, whatever operation is done, diastasis of the rectus muscles must be corrected by approximation and suture. For ptosis of the small intestine the mesentery may be shortened, as suggested and performed by Davis, of Omaha, in 1897.

In prolapse of the transverse colon good results are said to have been obtained by attaching the splenic and hepatic flexures to the abdominal wall (*Lambotte's operation*). The surgical treatment of ptosis of the stomach is considered on page 1110; of the liver, on page 1178; of the spleen, on page 1204; of the kidney, on page 1422.

The Peritoneum

Acute Peritonitis.—Peritonitis, or inflammation of the peritoneum, is a common and usually a very dangerous disease.

Aseptic irritation by a traumatism or a chemical irritant produces *aseptic peritonitis*, a condition which is strictly limited; which may produce local pain and tenderness; which may cause aseptic fever from the absorption of fibrin-ferment and the products of tissue change; which leads to the formation of temporary or permanent adhesions, and which is, in reality, a process of repair.

"Peritonitis," as the term is used by the surgeon, is always due to bacteria. Bacteria may reach the peritoneal cavity by means of an abdominal wound or the entrance of foreign bodies; by extravasations from the stomach, bowel, vermiform appendix, gall-bladder, urinary bladder, kidney, Fallopian tube or uterus, or by the passage of micro-organisms through the damaged walls of any of these viscera or structures; by way of an open Fallopian tube; from the breaking of an abscess into the peritoneal cavity; from rupture of an infected mesenteric gland; from perforation of a diverticulitis of the bowel; from areas of necrosis due to volvulus, strangulation, or intussusception of the intestine; twisting of the pedicle of an ovarian tumor, a floating kidney, or a floating spleen; blocking of a mesenteric vessel by a thrombus or an embolism; gangrene of the pancreas or spleen, and fat-necrosis.[1] In some cases the peritoneum may contain a point of least resistance, and bacteria contained in the blood reach this point and produce infection. Infection may be brought to the peritoneum by the lymphatics during child-birth. It was once taught that cold could produce peritonitis, but it seems probable that it can only act by producing an area of least resistance. The capacity of the rheumatic poison to produce peritonitis is doubtful.

The peritoneum, as Byron Robinson pointed out and Fowler confirmed, is, in reality, a great lymph-sac, and peritonitis is lymphangitis. "When the peritoneum is infected the lymphatics furnish an exudate which clots in the lymph-channels, blocks them, and limits or prevents absorption. This blocking of the lymph-channels serves to preserve the life of the subject, on the one hand, while a failure in this respect, either because of the enormous and overwhelmingly rapid increase of septic material and the large size and number of channels necessary to destroy and obstruct, on the other hand, permits the destruction of the organism."[2] Absorption takes place most actively from the region of the diaphragm, hence peritonitis in this region is peculiarly fatal. Absorption takes place very rapidly from the intestinal region, although not quite so quickly as from the diaphragmatic area. Absorption takes place slowly from the pelvic region, hence peritonitis of this region is much less dangerous than is the disease in the intestinal region, and vastly less dangerous than is the disease in the diaphragmatic region (Fowler).

When severe bacterial infection of the peritoneum occurs, exudation of blood-liquor takes place, leukocytes migrate from the blood-vessels be-

[1] See Park's "Surgery by American Authors."

[2] George R. Fowler, "Diffuse Septic Peritonitis," in "Medical Record," April 14, 1900.

neath the endothelial layer, particularly into the peritoneal cavity, and the causative bacteria rapidly spread about the cavity. The fibrinous exudate, in many infections, coagulates in masses on the free surface of the peritoneum, and thus serves a useful purpose by blocking the lymph-channels and hindering the absorption of toxins and bacteria. The fibrinous exudate may break down in a widespread suppuration or may be organized into an adhesion. In very virulent streptococcic infections a patient may die and there may be scarcely any coagulated exudation or may be none at all. Exudation and migration take place also in the subserous tissues and into the muscular coat of the bowel, and the segment of bowel which is attacked becomes paralyzed and distended with gas, the gas within causes it to rise up, and, as peristalsis is absent, obstruction occurs (James P. Warbasse, in "Am. Jour. Med. Sciences," July, 1905). Absorption of poison in peritonitis takes place in part from the peritoneal cavity and in part from the subserous tissues. Warbasse believes that the inflamed peritoneum is scarcely an absorbing surface, but in cases in which coagulated exudate has not formed or has been destroyed, it seems probable that it is an active absorbing surface, and absorption may occur from some regions, but not from others.

Various bacteria may be responsible for peritonitis, especially staphylococci, streptococci, pneumococci, and colon bacilli. The infections which spread most rapidly and widely are due to streptococci. In streptococcus infection the protective exudate does not coagulate, barriers of leukocytes are not heaped up, encompassing adhesions do not form, there is rapid absorption of toxins, and overwhelming systemic poisoning. Colon bacilli cause a very grave form of peritonitis, but less rapid and diffuse than that caused by streptococci—in fact, the process is often encompassed for a time by coagulated lymph, leukocytes, and adhesions. The omentum particularly is thickened, and is apt to apply itself about the area of infection. Staphylococci and pneumococci produce peritonitis which is more apt to be limited than that produced by colon bacilli. In most cases of peritonitis a mixed infection exists; for instance, colon bacilli and staphylococci or colon bacilli and streptococci. Gas-forming bacilli cause a form of peritonitis in which gas gathers in the abdominal cavity (*pneumoperitonitis*). It may arise after a stab wound or a gunshot wound. In some apparently severe cases of acute peritonitis cultures have remained sterile.

Forms of Peritonitis.—An accurate bacteriological classification is not as yet possible.

Peritonitis can be named, according to regions, *pelvic*, *subdiaphragmatic*, etc.; it can be divided pathologically into *diffuse septic*, *putrid*, *hemorrhagic*, *suppurative*, *serous*, and *fibrinoplastic* (Senn); it can be classified, etiologically, into *traumatic*, *puerperal*, *perforative*, *metastatic*, *scarlatinal*, etc.; and it can be divided, clinically, into *circumscribed suppurative*, *diffuse suppurative*, and *diffuse septic*.

Circumscribed Suppurative Peritonitis.—In this condition, which is frequently met with in appendicitis, the area of infection is circumscribed by coagulated exudate, leukocytes, and adhesions, and an abscess forms. After a time distinct localization becomes evident.

The *symptoms* of circumscribed peritonitis are pain, at first general and then local, tenderness in a particular region, muscular rigidity, distention, vomiting, rapid and often wiry pulse, constipation, fever, great weakness, and dorsal decubitus with the thighs flexed. After a time a distinct mass can usually be detected by palpation, and there may be dulness on percussion, local rigidity, irregular temperature, sweats, and possibly edema of the belly wall. An abscess, though limited for a time, is always liable to break through its walls and produce general peritonitis. Such an accident may be produced by muscular effort on the part of the patient or by injudicious palpation on

the part of the surgeon; or by rough handling of the patient while transporting him from place to place; its occurrence is announced by shock, and the symptoms of general peritonitis quickly arise.

Diffuse or general septic peritonitis is apt to destroy life even before the peritoneum presents any marked change. Death ensues from the absorption of toxic alkaloids. Septic peritonitis may arise during the puerperium, through lymphatic infection; it may be due to infection from without by an operation or an accident; to perforation of an ulcer; to gangrene of a portion of the intestine; to rupture of an abscess into the peritoneal cavity; to rupture of a mesenteric gland; to perforation of a diverticulitis of the bowel; or to migration of micro-organisms through a damaged wall of the bowel. Peritonitis due to perforation is called *perforative peritonitis*. Perforation is made manifest by pain, a chill, shock, or perhaps collapse. Gas may pass into the peritoneal cavity, and if it does so, the area of liver dulness may be lessened or abolished. Symptoms and signs of hemorrhage may arise. Diffuse septic peritonitis is announced by a very rapid pulse, which is at first wiry and later gaseous; a temperature which may at times be febrile, but which is apt to be subnormal or which soon becomes so; general abdominal pain and tenderness, dry tongue, delirium, persistent vomiting, constipation, and collapse. Rigidity exists, and also intestinal obstruction due to paralysis of the gut. Usually, but not invariably, there is distention. In puerperal peritonitis or septic peritonitis from operation there is often no severe pain. In perforative peritonitis there is acute pain. Victims of general septic peritonitis if unoperated upon usually die within five or six days.

Diffuse or general suppurative peritonitis differs clinically from diffuse septic peritonitis in the fact that it is less apt to be fatal and widespread. In fact, adhesions may form about an area representing a considerable portion of the peritoneal cavity. The causes of both are identical. In septic peritonitis death occurs from absorption of toxins before obvious pathological changes occur in the peritoneum; in suppurative peritonitis the microbes are fewer, are less virulent, or vital resistance is more decided, and suppuration follows marked changes in the peritoneum. In suppurative peritonitis the pyogenic bacteria are always present, and there exists in the peritoneum a wound or damaged area to constitute a point of least resistance.

Symptoms.—Chilliness or a rigor is common, followed by fever, the temperature rising to 102° or 104° F.; pain is intense, and is accentuated by motion and pressure; the attitude of the patient is assumed to relieve pain (he lies upon his back, with the shoulders raised and the thighs drawn up); there are vomiting, obstinate constipation, and rigidity of the abdominal walls, followed by distention when the intestine becomes paretic from septic poisoning. The pulse is rapid; is at first wiry, but may become gaseous. The constipation may be due either to tympanitic distention or to the shock and toxemia inhibiting intestinal peristalsis. Obstruction arises. Vomiting is frequent. In perforation gas often passes into the peritoneal cavity, and it may obscure the liver dulness; in tympanites without perforation the liver is apt to be pushed up and its dulness remains, but on a higher level. Pus unconfined by adhesions will gravitate to the most dependent part of the peritoneal cavity. In some cases of suppurative peritonitis there is no tympanitic distention or rigidity; in some cases there is no elevation of temperature, in fact, the temperature may be actually subnormal.

Treatment of Peritonitis.—After an abdominal operation the patient may have pain, slight rigidity, constipation, nausea, flatulence, etc., and the surgeon is in doubt if peritonitis is beginning or about to begin. Our custom is in such cases to give a saline cathartic, which will empty the peritoneal cavity of fluid, will favor the elimination of microbes, and will combat inflammation. The old-time remedy was opium, but Tait denounced it as inefficient, and showed that it masked the symptoms and often created a false sense of security

in the very midst of imminent dangers. The usual method of administering salines is to give 1 dram of Rochelle salt and 1 dram of Epsom salt every hour until a free movement occurs. Administer an enema of turpentine at the time the first dose of the saline is given. Atropin, eserin, and pituitrin may be useful (see page 1127). This treatment will often abolish pain and distention and will perhaps prevent peritonitis after an abdominal operation. If, however, genuine peritonitis is known to exist no purgative should be given. It is a deadly dangerous thing to give one, as it diffuses infection. Operation is required. Prompt operation is the only hope in genuine postoperative peritonitis and any delay means certain death. When diffuse septic or suppurative peritonitis exists from any cause and the surgeon sees the case early (within thirty-six hours) the abdomen should be opened. In a perforative case operate even if the case is first seen later than thirty-six hours. If a nonperforative case is seen later it may be wise to use Ochsner's treatment and wait for localization (Stanton, in "New York Med. Jour.," Aug. 27, 1910). If a perforation exists, it should be closed. A perforated or inflamed appendix should be removed. Until recently it was surgical custom to break up adhesions, eviscerate, wash the belly with gallons of very warm salt solution, wipe out the space between the liver and diaphragm, wipe out the pelvis, wipe off the intestines, and remove masses of adherent coagulated exudate. We thus produced dreadful shock, tried to cleanse the peritoneal cavity when it is impossible thoroughly to cleanse it, carefully removed the exudate which was doing good by plugging the lymph-spaces, and yet we did not reach the infection inside of the lymphatics, which is, after all, the greatest source of danger. Then we drained through two or more incisions and put the patient recumbent in bed, and thus permitted infected material to flow up to the diaphragm, where it was quickly absorbed. The mortality from this procedure was dreadful. John B. Murphy has taught us wisdom and has combined some of the conservative views of Ochsner with the use of the semi-erect position of Fowler, and with the continuous rectal irrigations that several advocated. Murphy's plan is founded upon the following principles:

Fig. 702.—Murphy treatment for suppurative peritonitis.

First, that the initial lesion of the peritonitis should be removed as quickly as possible and with the slightest possible amount of handling. For instance, we should remove a gangrenous appendix; we should close a perforation in the bowel, etc. Flushing of the peritoneal cavity with gallons of salt solution is inadvisable. It cannot thoroughly cleanse the peritoneum; it may diffuse the infection to regions that it had not previously reached, and it may tear up adhesions. Inflammatory exudate should not be removed from the intraperitoneal structures. It is Nature's method of sealing the lymph-spaces,

and if we remove it we open thousands of channels, previously sealed, for the dissemination of the infection. A drainage-tube should be introduced through the operation wound, and suprapubic incision should also be made and a drainage-tube be carried through this to the depths of the pelvis. When the operation is completed the patient should be placed in the semi-erect position, which is commonly called *Fowler's position*. This is done in order that the intraperitoneal fluids may gravitate away from the diaphragm, where absorption is extremely rapid, and into the pelvis, where absorption is much slower.

When the patient has been placed in the bed quantities of warm salt solution are passed slowly into the rectum. The mucous membrane of the large intestine absorbs fluid with great rapidity when that portion of the gut is in its normal condition of moderate distention. Overdistention leads to spasm, which expels the fluid. Hence the fluid must be given at low pressure and administration should be continuous. The simplest sort of apparatus is shown in Fig. 703. It consists of a fountain syringe, a large rubber tube, and a rectal tip of hard rubber. The nozzle that is used is angled, has one opening on the end and several on the side, and this nozzle is passed so that the angle fits the sphincter (see Fig. 705). The tube is strapped to the thighs by adhesive plaster. The hose that comes from the nozzle is attached to a reservoir, the base of which is hung from 4 to 6 inches above the level of the patient's buttocks; and the fluid, therefore, enters the rectum only about as fast as the rectum will absorb it. The reservoir is kept warm by bags of hot water hung about it. The fluid is allowed to enter continuously, unless it should run out from the side of the tube; if this happens, the flow may be cut off for a short time and then allowed to begin again. Gas from the bowel passes into the openings of the tube, and every now and then bubbles up through the reservoir. By this continuous, low pressure instillation (*proctoclysis*) an enormous quantity of fluid is absorbed by the rectum. In some cases a number of quarts are taken up in twenty-four hours. The absorption of this fluid greatly increases the amount of urine eliminated, removes toxins, and stimulates the heart. The reservoir must not be high. Increase of pressure will cause expulsion of fluid and defeat the possibility of continuous administration. The plan so often followed of keeping the reservoir high and limiting the flow by a clip on the tube is a mistake. Murphy says: "It should never have a headway of more than 15 inches hydrostatic pressure, and it gives the best and most uniform results at 4 to 7 inches" ("Jour. Am. Med. Assoc.," April 17, 1909). A straight tube is sometimes responsible for expulsion of the fluid, because it touches the posterior rectal wall of a patient in Fowler's position. Fig. 704 shows a more elaborate apparatus than that just described.

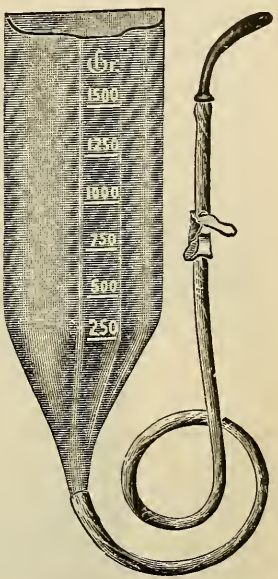


FIG. 703.—Proctoclysis apparatus consisting of fountain syringe, large rubber tube, and hard-rubber or glass tip (Murphy).

After the water has been entering the rectum for some time a profuse discharge of sour-smelling material comes from the drainage-tube. This discharge may be profuse for one day, two days, or longer, when its sour smell disappears and it greatly lessens in quantity. The outflow of this fluid from the wound means that saline fluid from the rectum has entered the lymph-spaces and run into the peritoneal cavity. Murphy thinks the lymph-current has been reversed. Whether this be true or not the peritoneum certainly

seems to become a secreting instead of an absorbing surface, and the lymphatics are washed out. During the time that this treatment is pursued the patient has no food or water given him by the mouth. Stomach feeding is rigidly forbidden in order to prevent peristaltic movements. Small amounts of morphin may be given to prevent peristalsis. If the patient is in a weak condition, stimulants or food can be given by the rectum, the solution in the reservoir being allowed to reach a low level, and then the material that it is desired to give being poured into the receptacle. Besides the above method of treatment antistreptococcic serum is usually given.

I am convinced that this method of treatment is of the greatest value, and that the principles upon which it rests are entirely sound, and I have had a number of striking successes from its employment.

If a case of diffuse peritonitis has lasted for three or four days and any sign points to localization, do not operate at once. Wash out the stomach, place the patient in Fowler's position, give salt solution by the rectum, and with-

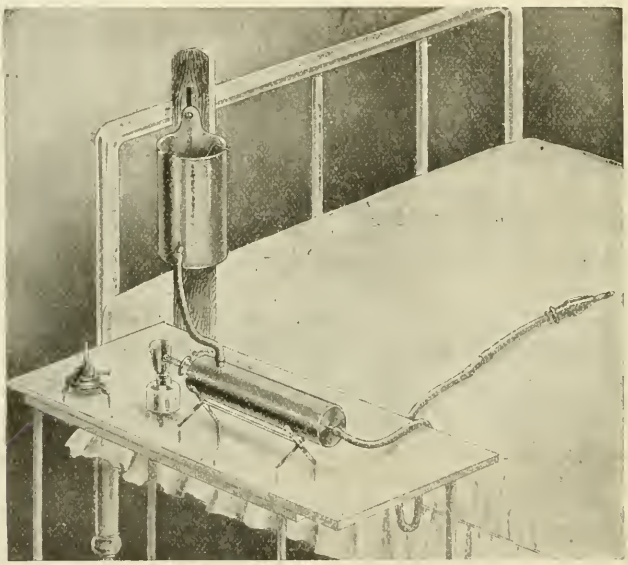

Fig. 704.—Alcohol or gas heater in operation, showing it properly connected. A short glass tube connects catheter to rubber tubing (Murphy).

hold purgatives and food. The inflammation may subside or may localize into a circumscribed suppuration. When in a patient with peritonitis the skin is blue, cold, and moist, the pulse very rapid and weak, the abdomen immensely distended, and the temperature subnormal death is almost certain, and the only chance is the conservative plan set forth above. We wait in hope that the infection may localize in an abscess. (See Buchanan, in "Med. Record," Jan. 28, 1911, and Stanton, in "New York Med. Jour.," Aug. 27, 1910.)

A *circumscribed suppuration* is treated as follows: Open the abscess. It will be possible, if the abscess is adherent to the abdominal wall, to open the abscess directly without opening the peritoneal cavity. If this be not possible, after opening the abdominal cavity pack gauze pads in a manner about the abscess so as to prevent the diffusion of pus when the abscess is evacuated. After opening the abscess the primary lesion is sought for and, if possible, removed. The surgeon should not, in most cases, tear away the abscess walls in an attempt to find the primary lesion, but should rather let it go undiscovered. Pack iodoform gauze against the intestines to reinforce the barrier

of lymph and insert a tube. It is frequently advisable to leave the wound wide open and drain by means of gauze.

Every patient with peritonitis requires stimulants.

Tuberculous Peritonitis.—Tuberculosis of the peritoneum is not very common. In 1170 autopsies in the Boston City Hospital tubercle existed in some region in 197, and in 14 of these the peritoneum was involved.[1] Primary local peritoneal tuberculosis is occasionally, though rarely, seen by the surgeon. In a great majority of cases of peritoneal tuberculosis other distant structures are involved. In about half of the cases the lungs are involved. In 28 cases reported by Bottomly[2] not one was primary. In every one of these cases the diagnosis was confirmed by the microscope, by the tuberculin test, or by autopsy. In most supposed cases of primary peritoneal tuberculosis another focus of disease exists, but is not demonstrable by clinical methods or has been overlooked. The disease sometimes exists as a part of general tuberculosis. Tuberculous peritonitis may be only a part of acute miliary tuberculosis. Bacteria may be swallowed with tuberculous food or a tuberculous patient may swallow tuberculous sputum and intestinal tuberculosis may result, the peritoneum being involved later. Peritoneal infection may follow a tuberculous lesion of the intestine, the bacteria may enter by way of the Fallopian tube, the initial lesion may be tuberculous appendicitis or tuberculosis of the mesenteric glands. The germ may lodge from the blood or lymph. The lymphatic form most commonly attacks the cecum. Tuberculous peritonitis is four times as common among women as among men, and most frequently attacks those between twenty and forty years of age, but I have seen it in a child of two and in a colored man of sixty. In all probability it is more common in childhood and infancy than we suspected formerly. Probably the diagnosis is not unusually missed in such subjects and the patient dies, or the disease makes great advances before it is recognized. In very early life tuberculous peritonitis may be confounded with rickets, pseudoleukemia and other conditions (H. R. Sheffield, in "Amer. Med.," 1916, xi). There are two groups of cases —the common chronic form and the rarer acute condition. The acute form begins suddenly, and such cases, as pointed out by Lejars, resemble acute appendicitis. In either the acute or chronic condition it is frequently the case that pulmonary phthisis exists. Cirrhosis of the liver is sometimes found with tuberculous peritonitis. There are three forms of chronic tuberculous peritonitis: the *ascitic*, the *fibrinoplastic*, and the *caseous*,[3] although, as a matter of fact, these so-called forms are only stages of the same disease. Tuberculous infection may exist for some time without causing symptoms, acute symptoms may suddenly arise, or intestinal obstruction may take place. Symptoms sometimes develop quickly after pregnancy. In other cases the symptoms appear gradually and progressively grow more positive.

FIG. 705.—Tube with orifices filled with chalk in order to show openings better.

Symptoms of the Chronic Form.—Usually the disease begins insidiously.

[1] Bottomly, in "Amer. Med.," Feb. 15, 1902.

[3] Parker Syms, in "Medical Record," April 2, 1898.

The digestion is found to be disturbed, there is nausea, the bowels are out of order, the abdomen is distended and tender, there is occasional colicky pain, and the patient is weak, loses flesh rapidly, and becomes very anemic. Frequently pain is the symptom which leads the patient to seek advice. The pain may be present from the very beginning, it may arise after malaise and gastro-intestinal disorder have existed for some time. but sooner or later it will develop.

In many cases there is ascites, but the amount of fluid is rarely very great. In some cases the fluid is serous, in some seropurulent, in some purulent, and in some bloody. Chylous fluid occasionally exists because of fatty degeneration of tuberculous masses. Ascites may be either unconfined or sacculated by adhesions. In some cases, and especially in early youth, there is little or no ascites, and the condition is characterized by the production of a quantity of adhesions which bind coils of intestine to each other, to the omentum, to the stomach, liver, and other viscera. In this condition, which develops very slowly, small cavities are formed between adhesions and the spaces contain fluid and bacteria. This is the most chronic form of the disease. In any case of tuberculous peritonitis the mesenteric glands may enlarge. There is usually moderate fever, but there may be episodes of high fever and protracted periods of subnormal temperature, or the temperature may be slightly elevated in the evening and subnormal in the morning. When the temperature becomes markedly elevated, pain, tenderness, and distention notably increase. In some cases there is a continued fever resembling typhoid. Tumor-like formations may be detected. These formations may consist of indurated omentum, encysted exudate, or enlarged mesenteric glands. If diarrhea exists for a long period there is probably tuberculous ulceration of the gut.

In every suspected case a bimanual examination should be made under ether, in order to discover if there are any matted masses of intestine (Thomson). In young children the tuberculin reaction is of high diagnostic value but it is of far less use in older persons.

In many cases a careful examination will detect tuberculous disease of other regions of the body, particularly of the lungs. If tuberculous disease of the lungs or pleura is detected, if tuberculous glands exist or have been present, if a nodule not due to gonorrheal inflammation is palpable in an epididymis, or if there are indurations in the prostate, the probability of the presence of tuberculous peritonitis is much enhanced. In many cases there is dilatation of the superficial abdominal veins. In some cases tuberculous peritonitis undergoes spontaneous cure. In the majority of instances death ensues from the tuberculous peritonitis directly or from associated or secondary disease in other organs.

If an intraperitoneal tuberculous area caseates, a large cold abscess may form, and such an abscess may break into the intestine or may be opened externally, and may be responsible for the formation of a fecal fistula.

In a case of tuberculous peritonitis intestinal obstruction may occur, the gut getting caught by bands or adhesions, or becoming a rigid tube because of the formation of tubercles.

Symptoms of the Acute Form.—This is sometimes mistaken for appendicitis. It comes on rather suddenly, but a carefully elicited history will usually show the previous existence of malaise, gastro-intestinal disturbance, loss of flesh, and anemia. The symptoms are not so strictly localized to the right iliac fossa as in appendicitis. There are abdominal distention, a certain amount of rigidity, nausea and vomiting, colicky pain which may be very severe, general abdominal tenderness, fever, and exhaustion. It may be possible to palpate masses like tumors, or to feel nodules in the prostate or epididymis, or to detect tuberculosis in some other part. In young children the tuberculin reaction is of decided value.

Treatment.—In some cases there is a tendency to spontaneous cure, and in them medical treatment is of great service. The patient should be placed under antituberculous conditions, nutritious food and tonics should be administered (see page 255), the abdomen should be counterirritated and massaged, and purgatives should be given frequently. Guaiacol applied daily to the abdomen is thought by some to be of service, but I doubt it. A mixture is made of 1 part of guaiacol and 5 parts of olive oil; 1 dram of this mixture is rubbed into the abdomen, and the part is covered with a piece of flannel held in place by means of a binder. If medical treatment is not soon productive of benefit, the advisability of operating must be considered. It is a curious fact, but one confirmed by ample evidence, that after simple abdominal section, without the introduction of germicides and without drainage, at least 30 per cent. of the cases recover from the disease in from six months to one year. Some surgeons doubt the curative effect of operation. For instance, the late Professor Fenger was strongly of the opinion that many patients recover after operation, but not as a result of operation. In his opinion they recover because they are strong, free from fever, and well nourished, and because the disease tends to spontaneous cure. He further believed that some die from operation because the traumatism lessens the already lowered tissue resistance. The majority of surgeons, however, believe that operation in many cases tends to cure. Ochsner, in a paper before the American Surgical Association in 1902, apparently proved that simple incision and evacuation of fluid tends to cure. It is uncertain how an operation tends to cure. It has been thought that the ascitic fluid is a culture-medium for bacilli, and when it is withdrawn the bacilli die, but opposed to this view is the fact that aspiration is rarely curative. It has been suggested that the operation brings numerous phagocytes to the peritoneum; that it stimulates vital resistance; that it leads to the exudation of antitoxic serum. The entrance of air seems to play a definite and important part in effecting a cure.

The ascitic cases are most frequently benefited by operation. If there be encysted fluid operation often cures.

In cases in which there are numerous adhesions operation is not so likely to produce a cure. Great care should be exercised in separating adhesions, because the bowel is apt to be torn and a fecal fistula may result. It may be necessary to separate adhesions or short-circuit a portion of gut to relieve obstruction. Drainage should not be used unless a cold abscess exists. Not only is drainage of no service, but it is dangerous; death is more apt to ensue in a drained case and a fecal fistula will arise in nearly one-fourth of the drained cases. If operation is performed for cold abscess, tube-drainage must be used for some days. In a woman with tuberculous peritonitis the abdomen should be opened in the midline, and if the Fallopian tubes are tuberculous they should be removed. In a man the incision should be made over the appendix, and if this is tuberculous it should be removed. In either sex it may be necessary to resect tuberculous intestine or perform anastomosis because of stricture. (In confirmation of these views see W. J. Mayo, in "Jour. Am. Med. Assoc.," April 15, 1905.) The Mayos have performed 26 radical tubal operations on cases of tuberculous peritonitis and 25 recovered. Of these, 7 had previously been operated on from one to four times by simple laparotomy ("Jour. Am. Med. Assoc.," April 15, 1905). In a very advanced case, in a case with notably high temperature, or in a case with marked and advancing tuberculosis in another region, an operation should not be performed except to relieve obstruction or drain an abscess. If a patient does not die within a few months after an operation, he will probably recover, and in most cases operation secures at least temporary improvement (Bottomly, "Amer. Med.," Feb. 15, 1902). The mortality from operation is 1 or 2 per cent. (Fenger).

Pneumococcus Peritonitis.—This condition is an unusual one. It is most apt to arise during the progress or after the termination of pneumonia or some other pneumococcic lesion, but is sometimes primary—is far commoner in females than in males and in children than in adults. Out of 74 reported cases, 57 were children under five years of age (Dr. Max von Brunn, in "Beiträge zur klinischen Chirurgie," Bd. xxxix, Heft i). In primary cases the bacteria may enter by way of the blood-stream or, perhaps, in some cases through the bowel wall or Fallopian tube. In secondary cases infection may arise from an adjacent pneumococcic area (pleura) or be carried by the blood from a distant point (*pneumococcic septicemia*). The condition may appear in a sufferer from otitis media. The symptoms in children are sudden in onset. The first symptoms are general abdominal pain, usually a continuous pain with colicky exacerbations, tenderness, rigidity, vomiting, elevated temperature, distention, and diarrhea. In a few days the symptoms abate and some of them disappear, although pain, tenderness, and rigidity are apt to localize at some point, particularly about the umbilicus, and may remain for a number of weeks. In such a chronic case physical signs of a fluid collection are usually demonstrable. In the chronic stage, as Brunn points out, there is seldom severe tenderness and there may be no fever at all, and a septic temperature is very rarely observed. Pus may form, and if it does, it contains pneumococci. Adhesions practically always form. These adhesions glue the intestines together and often encompass pus. Rapid emaciation and progressive weakness are always noted. In adults the symptoms are irregular and less characteristic than in children (Brunn). The prognosis is excellent.

Treatment.—Incision and drainage.

A **subphrenic abscess** is a collection of pus beneath the diaphragm. It is a rare condition. The pus may occupy a part of the lesser peritoneal cavity; it may be extraperitoneal (when it is of **renal origin**); in some cases it is contained in the area between the diaphragm, cardiac end of the stomach, and liver or spleen. It is impossible to classify accurately these abscesses by anatomical position. George A. Ross ("Jour. Am. Med. Assoc.," August 12, 1911) classifies them as right, left, anterior, and posterior. Most are on the right side, but even an abscess due to appendicitis may be on the left side. It is an unusual thing for such an abscess to break into the general cavity of the peritoneum, but it may break into the pleural sac (Maydl).

Causes.—Perforation of a gastric ulcer, perforation of the gall-bladder or gall-ducts, ulceration of the duodenum, disease of the liver, spleen, pancreas, intestine, appendix, or kidney, hydatid disease, internal injury, metastasis, external injury, caries of rib, disease of the pleura, general peritonitis, or portal infection may be responsible for a subphrenic abscess. We have abandoned the notion that the infecting source must be in the upper abdomen. Appendicitis is the most common cause. Charles A. Elsberg[1] has collected 73 cases of subphrenic abscess after appendicitis. He points out that the condition may arise from direct extension or by way of the lymph-channels, and may be either intraperitoneal or extraperitoneal, although in the majority of cases it is intraperitoneal. In rare cases extension is by way of the portal vein. Ross claims that in most cases due to appendicitis the infection extends by cellular tissue directly upward from the lower peritoneal fossæ. In some cases infection ascends between the colon and the parietal peritoneum (the *parietocolic sinus* of our French colleagues). In all but 7 of Elsberg's cases there was suppuration about the appendix. The pus was thick and foul in all the cases. In 15 per cent. of them gas was also present, and in 25 per cent. of these cases the diaphragm was perforated. In 3391 consecutive cases of appendicitis operated on in the German Hospital of Philadelphia there were 30 cases of subphrenic abscess (Ross, "Jour. Am. Med. Assoc.," Aug. 12, 1911). Subphrenic abscess

[1] "Annals of Sugery," Dec., 1901.

may develop soon after an appendicitis, it may develop extraordinarily late. Ashhurst's case arose four years after appendicitis ("Trans. Phila. Acad. of Surg.," 1910), 1 of Ross's cases, one year after (Loc. cit.). If ascending retroperitoneal infection exists during appendicitis, removal of the appendix does not arrest it (Lance, in "Gaz. d. Hôp.," 1909, lxxxvii). In 2 cases on which I operated the abscess developed after cholecystitis; in 2 others, after suppurative appendicitis.

The **symptoms** usually come on suddenly, but may do so gradually. There may or may not be abdominal symptoms. A patient with subphrenic abscess usually complains of pain in the lower part of the chest on the right side. Usually there is high temperature and often delirium, but, as Jopson ("Annals of Surgery," July, 1910) says, the temperature may be only moderately elevated and the pulse may be nearly normal. The area of liver dulness is, in many cases, distinctly enlarged, and there is tenderness in the lower part of the right chest when pressure is made through one or through several intercostal spaces. Frequently friction sounds may be heard about the region of the dome of the liver. Breath sounds and vocal fremitus are lessened. The signs are usually best heard posterior, but may be lateral or anterior. There is cough and also bulging of the chest wall. Jaundice is absent in uncomplicated cases. There may be hiccough. Sometimes the symptoms are obscure or indefinite, and not accompanied by particular pain. If the abscess happens to contain not only fluid but also a considerable amount of gas—and about one-half of such abscesses do contain gas—not only will there be no increase in the area of liver dulness, but the normal area of dulness may be diminished or obliterated. The presence of gas may be due to some connection with an organ which contains gas or to gas-forming bacteria. It is very common for a pleural effusion to be associated with a subphrenic abscess. A pleural effusion will be preceded by or accompanied by symptoms pointing to the lung or pleura; and it is to be remembered that the area of percussion-dulness found in the pleural effusion shifts its position whenever the position of the patient is changed, which is not true of the area of dulness found in subphrenic abscess. When the abscess breaks through the diaphragm the patient collapses, cough and other thoracic symptoms develop; and if the abscess breaks into a bronchus the patient will expectorate pus. In subphrenic abscess the diaphragm of the diseased side is paralyzed—a condition rarely met with in liver abscess. There are general symptoms of suppuration and a swelling in the subdiaphragmatic region following some recognized causative condition. The history of chills with recurrent fever and sweats is rather indicative of abscess of the liver; but in abscess of the liver there is usually pain in the shoulder-blade of the right side, and this is rarely encountered in subphrenic abscess. The *x*-rays show that the diaphragm is elevated on the side of the lesion. The proof of the diagnosis is not, however, obtained until an exploratory incision has been made and the purulent matter has been found. Empyema and subphrenic abscess resemble each other. In empyema the upper limit of the fluid is concave; in subphrenic abscess it is convex. In empyema the flow of pus through an aspirating-needle will be most marked during expiration; in abscess, during inspiration. The same is true of the rush of gas. In empyema the needle does not oscillate; in abscess it does.[1] If an abscess contains gas, percussion elicits a tympanitic note over a part of the cavity, and there is an alteration in the area of tympany with an alteration in the position of the patient. An abscess of the liver almost never contains gas and decidedly changes the outlines of the organ.[2] Empyema may follow subphrenic abscess.

Treatment.—Incision and drainage. The incision is made in the lumbar

[1] Wharton and Curtis, "Practice of Surgery."

[2] In a case of abscess of the liver secondary to appendicitis operated upon in the Jefferson Hospital the abscess did contain gas produced by gas-forming bacteria.

region if the abscess points there. In some cases it is made through the abdominal wall (epigastric region, iliac region, hypochondrium). In other cases the chest wall is incised, the ninth or tenth rib is resected, and the abscess is opened below the pleura or the pleura is opened, the parietal and diaphragmatic layers are sutured together, if possible, and the diaphragm is incised. If appendicitis has been the cause, be sure the appendicitis is well; and if it has not been, open the appendix region and drain freely (Elsberg). If it be necessary to open the pleural sac, first try to stitch the parietal to the diaphragmatic layer of the pleura, or, if this be impossible, protect the cavity with iodoform gauze to prevent infection.

The Liver, Gall-bladder, and Bile-ducts

Rupture and Wounds of the Liver.—Rupture of the liver is due to very great force, and is usually accompanied by injury of other viscera. It may be produced by a blow, by a fall, or by the end of a broken rib. The superior surface or margin most often suffers. It is a very fatal accident. Out of 543 reported cases over one-half died of hemorrhage within twenty-four hours of the accident.[1] At least 80 per cent. will die if not operated upon. Wilms[2] collected 19 cases, and only 3 recovered after operation. Eisendrath[3] has collected 37 cases of suture of the liver for rupture and 22 of them recovered (59.5 per cent.). The first operation was performed by Willette in 1888. Out of Kraussine's 13 stab-wounds of the liver 7 died (Murphy, in "Practical Medicine Series," 1910, vol. ii). An attempt should certainly be made to save the patient by opening the abdomen and arresting hemorrhage, and in a suspected case an exploratory operation should be performed. A wound of the liver causes violent hemorrhage, which is usually rapidly fatal. Such a wound is apt to divide bile-ducts and allow bile to escape into the peritoneal cavity, and perhaps externally. Bile, if sterile, will do little harm to the peritoneum, but if it contains bacteria it will produce diffuse peritonitis. Even sterile bile is corrosive and may cause fibroplastic peritonitis. The symptoms of a rupture or wound of the liver are those of severe intra-abdominal hemorrhage, with collapse, accompanied by hepatic tenderness and respiratory embarrassment. Soon after the injury the abdomen is soft and flat, but it quickly becomes rigid and ultimately distended. The diagnosis becomes more probable when it is known that violence was applied to the hepatic region. Usually there is abdominal pain and often pain in the back. Sugar may appear in the urine. In a few cases after several days jaundice and skin itching have been noted. The area of liver dulness is usully increased. Patients do not always die from a serious traumatism of the liver. Some recover because operation has saved them. Some few recover without operation. This last fact is proved by reports of autopsies in which scars were found in the liver parenchyma (Nussbaum). The fatality which usually ensues after a liver injury may be due to hemorrhage or peritonitis. If a surgeon is called to a patient suffering from wound of the liver, he must open the abdomen to arrest hemorrhage. If a penetrating wound is suspected, it may be desirable to enlarge the wound in the abdominal wall layer by layer, in order to determine if the liver be wounded. If the left lobe of the liver be wounded, or if it be uncertain which lobe is wounded, the incision should be median. If the right lobe be wounded, a curved incision is made along the line of the costal cartilages. In some cases these two incisions are joined.[4] The convex surface of the liver can be reached by Lannelongue's plan. Lannelongue resects the eighth, ninth, tenth, and eleventh costal cartilages and draws the ends of the ribs well out. It can also

[3] "Jour. Am. Med. Assoc.," Nov. 1, 1902.
[4] See Schlatter, "Beiträge zur klinischen Chirurgie," Bd. xv, Heft ii, 1896.

be reached by Langenbuch's plan, that is, by cutting the coronary ligament and the right lateral ligament. This allows the liver to be pulled well up into the wound in the belly wall. The site of the wound can be discovered if the hepatic vessels are grasped between the thumb and a finger (the finger in the foramen of Winslow and the thumb in front, on the gastrohepatic omentum). This completely arrests hemorrhage, and the blood that has gathered may be sponged out and the wound sought for in a clear field. (See Pringle, of Glasgow, in "Annals of Surgery," Oct., 1908.) When the wound in the liver is discovered and well exposed, deep sutures of catgut should be inserted in the liver and the capsule should be stitched with fine silk (Schlatter). If sutures fail to arrest hemorrhage, the organ should be sutured to the belly wall and the wound in the liver packed with iodoform gauze. It is useless to try packing without first attaching the liver to the abdominal wall, because pressure will simply push the liver away and will not arrest the bleeding. The cautery is a very useful means of arresting bleeding. It should be avoided if possible in a large wound, because, even if it arrests primary hemorrhage, secondary hemorrhage may occur. After arresting hemorrhage, wash out the abdomen with hot saline fluid, insert drainage, and close the abdominal wound. In a case of the author's in the Philadelphia Hospital the liver was wounded by the sharp ends of fractured ribs. The abdomen was opened, a wound was found, and bleeding was arrested by suturing the liver to the belly wall and packing the wound. The patient died, and necropsy showed another wound on the posterior portion of the organ. The possibility of such an occurrence should not be lost sight of.

Tumors and Cysts of the Liver.—The liver may be the seat of primary carcinoma, sarcoma, endothelioma, angioma, lymphangioma, adenoma, fibroma, myxoma, or lipoma. Many tumors called adenomata are really adenocarcinomata. Secondary malignant growths are far more common than primary neoplasms—in fact, 96 per cent. of liver tumors are secondary. Primary cancer of the liver is found once in every 2000 autopsies (Eggel). The commonest variety is nodular, but the diffuse form, known as *cancerous cirrhosis*, may occur. The nodular form is most often encountered in the right lobe, and it has been found in persons under the age of twenty. Metastases occur early. "There is always more or less co-existing cirrhosis of the liver" (Leonard Freeman, in "Trans. Am. Surg. Assoc.," 1904). It takes origin from the hepatic cells. The frequency of cancer of the liver secondary to cancer of the stomach has already been alluded to. The commonest primary tumor of the liver is cavernous hemangioma. It is especially apt to take origin in the atrophying liver of an elderly individual. Primary sarcoma may arise at any age and may even be congenital. The growth is rapid and emaciation is soon noted. The liver enlarges, often greatly. Jaundice and ascites are rather rare. The patient soon becomes very weak. There is always pain. As Knott ("Surg., Gynec., and Obstet.," Sept., 1908) points out, the condition may simulate abscess, and if it arises in a middle-aged or elderly person can scarcely be differentiated from carcinoma.

Knott ("Surg., Gynec., and Obstet.," Sept., 1908) has collected 59 cases of primary sarcoma from literature, and adds 14 reported by personal communications and 1 of his own, 74 in all.

He shows that 28 cases have been operated upon. In 9 the operation was exploratory and no attempt was made to remove the growth. In 19 the growth was extirpated, with 10 recoveries and 9 deaths. One of these patients was well after nineteen months, 1 after two years, 1 after seven months. Operation is indicated for a circumscribed growth.

Among the cysts occurring in the liver are blood cysts, congenital cysts, bile cysts, and hydatid cysts. Terrier and Auvray in 1901 collected 52 operations for hepatic tumors.

Angiomata have been removed successfully by hepatotomy, a cautery-knife at a red heat being used to cut through the normal liver tissue around the base of the tumor, the large vessels having been tied with catgut. Enucleation is not feasible because of excessive hemorrhage. If a tumor be pedunculated, the base may be encircled by an elastic ligature held in place by a steel needle, and five or six days later the tumor may be cut across by the cautery.[1] I assisted Prof. W. W. Keen in such an operation.

Carcinoma of the liver has been extirpated, but it is seldom that a growth is recognized early enough and is found to be sufficiently limited to justify such a procedure. Operation is proper only when there is a limited nodule of primary cancer. In 1901 Terrier and Auvray collected 9 operations for primary cancer. In most cases there has been rapid recurrence or secondary growth, but Schrader's case was well at the end of seven years and Leonard Freeman's at the end of sixteen months. (For operative methods, see Leonard Freeman, in "Trans. Am. Surg. Assoc.," 1904.) Hunbald has collected 96 cases of resection of the liver, with a mortality rate of 26 per cent. Probably the best method of arresting hemorrhage is the use of suture ligatures of doubled catgut passed by round, blunt needles, as advised by Mikulicz.

Hydatid cysts of the liver may be of small size and productive of no signs or symptoms; or may be of large size and productive of the signs of tumor. In the epigastrium the mass may be prominent and fluctuate. In cyst of the right lobe the dulness is found in the axillary line and the growth encroaches on the pleura. In a large cyst fluctuation and hydatid fremitus may exist. Hydatid fremitus is a vibration imparted to the palpating fingers of one hand when the fingers of the other hand knock upon the cyst. There may be no discomfort produced by even a large cyst, but, as a rule, the patient suffers from a dragging sensation in the epigastrium and pressure symptoms. Suppuration in the cyst produces the symptoms of abscess of the liver and septicemia. Rupture of the cyst produces shock and even death. Rupture may take place into the pleural sac, the lung, or the peritoneal cavity. If the shock is recovered from, inflammation arises, the area of which depends upon the structures damaged. The escape of even a small quantity of hydatid fluid into the peritoneal cavity produces urticaria (*hydatid toxemia*). Aspiration for diagnostic purposes is not advisable.

Treatment.—Exploratory incision may be necessary to confirm the diagnosis, and the operation is completed at this time. After exposing the cyst it is packed around with gauze and a trocar is introduced. If there be a considerable thickness of liver tissue over the cyst, incise the liver by the cautery knife. When the fluid is evacuated the sac is incised and is drawn partly through the wound in the abdominal wall, and is attached to the wound margins (*marsupialization*). The endocyst can then be removed by the hand or by irrigation. A large drainage-tube is introduced.

Syphilis of the liver is a very able actor and often impersonates with surprising accuracy various other diseases. It may be congenital or acquired. The congenital condition may cause cirrhosis, miliary gummata, spots of fibrosis, and occasionally large gummata. Sometimes the liver manifestations of congenital or hereditary syphilis may be postponed for years (ten, fifteen, or more) and then appear as ordinary tertiary lesions. Acquired syphilis may cause hepatic disease in the secondary and in the tertiary stage.

In secondary syphilis there may be temporary jaundice due, Rolleston thinks, to catarrh of the smaller bile-ducts within the liver. It is possible, according to Rolleston, for temporary pericellular cirrhosis to exist in the secondary stage.

The tertiary lesions are the most common and important. Among these lesions are gummata and scars. They are most common ten years or more

[1] Russell S. Fowler, on "Tumors of the Liver," "Brooklyn Med. Jour.," Dec., 1900.

after the primary sore. Tertiary syphilis may appear as irregular patches of inflammation in Glisson's capsule (a condition apt to eventuate in hepatic sclerosis)—as a large solitary gumma (only one-eighth of cases of gumma present a solitary lesion)—or as multiple and usually small gummata. Gummata are most usual upon the anterior surface of the right lobe. A gumma adjacent to the common duct or the hepatic duct causes jaundice. A large gumma is often mistaken for cancer of the liver, and it is a curious fact that in many cases of hepatic gummata we are unable to obtain any history of syphilis. Syphilis may be mistaken for ordinary cirrhosis, but in the latter disease the general nutrition is more impaired than in the former, and vomiting of blood, dilated cutaneous veins, ascites, and indigestion are far more apt to be present (Archibald MacLaren, in "Annals of Surgery," August, 1908). The victims of gumma are apt sooner or later to develop jaundice, colicky pain, moderate fever, and palpable enlargement of the liver. The spleen may enlarge. The fever may be continuous or may occur episodically. In some cases it continues for weeks. It may be intermittent, preceded by a chill and followed by a sweat. Such a fever may be due to Spirochæta cholangitis. It may be due to absorption of toxic material from a breaking-down gumma. The Wassermann reaction is a valuable aid to diagnosis. A gumma sometimes undergoes secondary infection and an abscess forms. A gumma may rupture into the pleural or peritoneal cavity or some viscus.

Treatment.—Mercury and iodid will cure most cases. If these drugs fail, it is proper to remove the tumor, if solitary, by resecting the involved area of the liver. MacLaren (Ibid.) collected 9 cases of resection for solitary gumma and added 1 of his own. There were 2 deaths in this series. MacLaren's 10 cases added to Keen's 12 ("Annals of Surgery," Sept., 1899) and Cumston's 15 (quoted by Rolleston in his work on "Diseases of the Liver") make 37 cases.

If an area is opened for exploration and a solitary gumma is discovered, the abdomen should be closed and specific treatment be tried before resorting to resection, that is, if specific treatment has not been tried before.

Abscess of the Liver.—An abscess of the liver may be produced by bacteria, especially staphylococci and streptococci. These organisms reach the liver by the general circulation or, what is more frequent, are taken up from the intestinal tract and reach the liver by the portal circulation, or pass to the liver by the lymphatics. Appendicitis with lymphatic infection may result in hepatic abscess. A subphrenic abscess may break into the liver and thus induce a liver abscess. Liver abscess may directly result from peritoneal infection. The fact that abscess of the liver is, in hot countries, frequently preceded by amebic dysentery led to the presumption that the Amœba coli produces the abscess, and in a large majority of cases of tropical abscess amebæ exist in the pus or at least on the abscess walls. Habitual intemperance and constant overeating predispose to abscess of the liver. The disease may follow traumatism, dysentery, diarrhea, cholangitis, suppuration of a hydatid cyst, gall-stones, typhoid fever, appendicitis, and a chill to the surface of the body.[1] Abscess of the liver may be metastatic, and such abscesses are multiple. It may be caused by foreign bodies and parasites. A tropical abscess is an abscess of the liver in an inhabitant of a hot country.

There are three forms of abscess of the liver: traumatic, pyemic, and tropical.

Traumatic abscess may result from a wound of the liver or may follow a contusion without a break of the skin. In the latter case bacteria from the blood are arrested in the injured liver tissue. Such an abscess is usually solitary. Streptococci, staphylococci, or colon bacilli may be found. Traumatic abscesses are more common in children than in adults, are situated superficially, and the symptoms are usually acute. Recovery is

[1] G. B. Johnston, "Annals of Surgery," October, 1897.

usually rapid and permanent after incision unless the causal injury brings danger or fatality.

Pyemic Abscess.—Multiple abscesses exist, but they may fuse into one. It is frequently due to suppurative inflammation of radicles of the portal vein, infected emboli forming and reaching the liver; it may follow ulceration of the intestine, hemorrhoids, or appendicitis.

Occasionally abscess may arise from the extension of an infective process, such as pylephlebitis. It may arise from cholecystitis or cholelithiasis with obstruction. In these latter cases both the Bacillus typhosus and the pneumobacillus of Friedländer have been found as the direct bacterial agent. Colon bacilli are a common cause. Abscess of the liver following appendicitis may be due to portal infection (*portal pyemia*) or to lymphatic infection. It is usually multiple, but in a case of mine in the Jefferson Hospital it was solitary, several cavities having probably joined to form one. Echinococcus cyst of the liver may suppurate and form abscess. I operated unsuccessfully on 1 such case which was brought to me by Dr. Hultsizer. The round-worm, the liver fluke, and the Balantidium coli sometimes cause abscess, and, finally, it has been observed in measles, epidemic influenza, and perforating ulcer of the stomach.[1]

Tropical abscess of the liver is rare in temperate climates, but is extremely common in the tropics. Its usual antecedent in either climate is dysentery. The reason for the great frequency of the disease in tropical regions is that the chief causative agent, the Amœba coli, is found widely distributed in hot countries; and that passive congestion of the liver is a common condition among the white inhabitants of tropical regions. It has been pointed out that tropical abscess is particularly common among white persons who abuse alcohol, the condition of passive congestion of the liver making that organ a nutritious soil for a fruitful infection. Predisposing factors are protracted malaria and chilling of the surface of the body.

Major Charles F. Kieffer, U. S. A.,[2] in a lecture on tropical abscess of the liver, stated that in his own experience he found, in a series of 33 abscess cases in soldiers, that dysentery was present in every case; and that in a second series of 25 cases in natives and civilians he elicited a history of dysentery in 22 cases. Some observers—notably McLeod—state that dysentery is the antecedent factor in 97.5 per cent. of cases. Kieffer points out that in all the figures allowance must be made for a number of latent dysenteries, as well as for cases in which no effort has been made to elicit a history of dysentery one or two years previously. It is also to be remembered that a case of amebic infection of the colon may have been so mild in the beginning as to have caused but a transient diarrhea, which the patient may have forgotten. Amebæ occasionally exist in the colon without producing any dysenteric evidences. From 20 to 25 per cent. of severe amebic dysenteries lead to the formation of abscess of the liver, and at least 85 per cent. of all tropical abscesses are due to infection with the Amœba coli. Occasionally, an abscess begins very soon after the dysentery; but, as a rule, it does not form for some time afterward—weeks, months, a year, or even two years.

When an abscess of this sort forms in the liver that organ becomes enlarged and congested, and an area or areas of necrosis exist in it. But one abscess may be present; there may be an abscess with satellite abscesses about it; several abscesses may coalesce, making a very large cavity; or genuine multiple abscesses may exist. In about 70 per cent. of cases, however, the tropical abscess is solitary.

The right lobe of the liver is the region most frequently involved. The

[1] Major Charles F. Kieffer, U. S. A., in "Phila. Med. Jour.," Feb. 21, 1903.
[2] Ibid.

abscess is found in the right lobe in at least 90 per cent. of cases, and it is more often toward the convexity of the liver than toward the base.

An abscess of the liver of this type contains characteristic and peculiar material; it is different from the pus found in other abscesses, and, in fact, is not pus, but is necrotic liver substance. Liver abscesses due to pyogenic organisms contain true pus; a tropical abscess, free from pyogenic infection, does not. Ordinary pus contains hordes of leukocytes, but the fluid of a tropical abscess contains very few. Riesman is of the opinion that the reason there are so few leukocytes is that the abscess contains a substance that, by chemotaxis, repels leukocytes. The matter is of a reddish-brown color, is thick, and frequently contains some blood. Occasionally it is offensive in odor. Microscopic examination shows it to contain portions of necrotic liver tissue, some liver-cells that are not destroyed, elastic tissue, blood, some few leukocytes, and amebæ. On bacterial examination it may be found that the fluid is infected, containing staphylococci, streptococci, or pyogenic bacteria. In about 20 per cent. of the cases the matter contains neither bacteria nor the Amœba coli. In over 60 per cent. of the cases the matter of a recently opened abscess is free from bacteria. In cases in which the fluid is sterile it is possible that bacteria were originally present, but have died. The reason for the death of microorganisms in this matter is in great doubt, because, as Riesman points out, bile cannot kill them as organisms may be grown in this fluid. In the large majority of cases amebæ are readily demonstrable in the matter; but in some few cases it is necessary to rub a piece of gauze on an abscess wall in order to obtain amebæ, and in others they can be demonstrated only after the abscess has been discharging for some days. The causative rôle of the amebæ has been doubted by some observers, but most surgeons who have had experience in the tropics believe it to be a fact.

The *symptoms* may be very definite and positive; they are frequently misleading and obscure; and in some cases nothing whatever directs the surgeon's attention to the liver until the patient passes a huge quantity of puriform fluid at stool or coughs up an enormous amount of the characteristic material. If rupture takes place, death usually ensues. As a rule, the symptoms of a tropical abscess are positive and marked.

Kieffer sums up the chief symptoms under four heads: *fever, sepsis, enlargement of the liver,* and *pain.* In about three-fourths of the patients fever and sweats are definitely present; in about one-fourth they are absent or are very trivial. The type of fever met with is what has been previously spoken of as hectic. Usually there is an evening rise, preceded by a chilly sensation or by a chill; and as the temperature begins to fall, toward morning, there is a profuse sweat. It is seldom that there is any violent chill, though there are frequently slight ones. The sweats are extremely exhausting. They may occur either during the night or in the daytime, according to the time in which the patient sleeps. Kieffer says that they should not be called night-sweats, but rather *sleeping sweats.* In very chronic cases there may be no pyrexia. As a rule, the temperature resembles that of malaria, but it is not controlled by quinin and the blood is free from malarial parasites. Sometimes the temperature suggests typhoid, with the exception that from time to time there are episodes of subnormal temperature. The patient loses flesh and strength, the appetite fails completely, and the skin becomes pasty or dirty yellow.

The entire liver is usually enlarged, and the enlargement may be detected by percussion, and in some cases a hard, smooth area can be palpated. Sometimes the liver reaches as high as the third rib anteriorly, or to the spine of the scapula behind, and it may extend downward to the anterior superior spine of the ilium. It is rarely, however, that the enlargement takes place in a downward direction; it is usually upward. In many cases the right side

of the chest appears to be rather full, and sometimes there is actual obliteration of several intercostal spaces. If an abscess becomes adherent to the surface, there may be skin edema and dusky discoloration. In rare instances, if a very large abscess comes near the surface, fluctuation may be obtained. By auscultation it is frequently possible to obtain friction sounds in the region of the diaphragm and the superior surface of the liver.

The liver becomes tender. This tenderness may be developed particularly by pressure upon the lower edge of the organ, and sometimes by pressure through the intercostal spaces. There is not always, but, as a rule, there is pain. The pain may be dull and heavy, but as the abscess nears the surface of the organ the pain becomes sharp and lancinating. The pain is persistent and is not strictly localized, but radiates to the back, the right shoulder-blade, and the point of the shoulder. Pain is increased by pressure, coughing, sudden or violent movement, and is sometimes felt in the esophagus when food is swallowed. When the upper surface of the liver is involved the patient breathes as if he had pleurisy; and pleurisy frequently does develop, with marked effusion.

Paralysis of the diaphragm rarely occurs in abscess of the liver, and the respiration is not much affected unless the diaphragm of that side and the pleura become involved, though the patient frequently has a dry cough. A severe cough suggests that the abscess is on the convex surface of the organ. Such a cough is aggravated by recumbency. Kieffer points out that the patient lies on his right side, and almost on the right front aspect, the shoulder being drawn down and the right knee drawn up to relieve the tension of the abdominal muscles. In about one-fourth of the cases of tropical abscess of the liver jaundice occurs. It is most apt to occur when the abscess is on the inferior surface. Jaundice does not occur unless the common or hepatic ducts are compressed or cholangitis exists. The leukocyte count is of no particular help in the diagnosis, as there may or may not be leukocytosis. The urine is usually scanty. Diarrhea is a common accompaniment, but constipation may exist, and nausea and vomiting are by no means unusual.

Diagnosis.—With an antecedent history of dysentery the diagnosis is easy. Without such a history, it is always difficult and may be impossible. In the tropics exploratory aspiration is freely used, but exploratory incision, if necessary, with subsequent exploratory aspiration of the liver after the organ is exposed, would seem to be safer and more certain.

Symptoms of Traumatic Abscess.—Similar to those of tropical abscess.

Symptoms of Pyemic Abscess.—The liver is enlarged and tender, there is slight jaundice, and the general symptoms of pyemia are present.

Treatment of Tropical Abscess.—If in doubt as to the diagnosis, make an exploratory incision, exposing enough liver surface to permit of exploration by finger and needle. If pus is not found, pack the wound with gauze to keep it open, and when adhesions form explore again. The operation for abscess is incision and drainage. The *abdominal route* is used when the liver bulges front or when it extends well below the costal margin (McGill, in "Surg., Gynec., and Obstet., Nov. 1911). If the abscess is adherent to the parietal peritoneum and is not covered by liver substance open it at once. If it is not adherent, or is covered by a considerable layer of liver substance, make a ring of gauze about the periphery of the abscess cavity. The abscess may be opened at once within the ring, the gauze being a coffer-dam to protect the peritoneal cavity. It is safer to catch the gauze to the parietal peritoneum with two or three fine catgut sutures and wait for forty-eight hours before opening. This is an easier plan and just as safe as attempting to stitch the liver to the visceral peritoneum or to the parietal peritoneum. The operation consists in evacuating the pus by a trocar and cannula, incising the abscess, stitching its edges to the edges of the abdominal wound, irrigating, and inserting a drainage-tube. If the abscess be covered by a layer of liver tissue, after locating it by an aspirating cannula,

open into it by means of a cautery knife and arrest hemorrhage by packing. When the parietal and visceral layers of peritoneum are adherent, packing will arrest bleeding; if they are not adherent, packing will only push away the movable liver (John O'Connor). The *transpleural route* gives the best access to the right lobe, which is far and away the commonest region for liver abscess. The operation devised by McGill (Ibid.) may be at first exploratory; it avoids pneumothorax and empyema. It is performed as follows:

The ninth and tenth ribs are exposed by a curvilinear incision; the flap (which does not include the fascia of the muscles) is raised; 4 inches of the tenth rib are resected; the gutter left by the removal of the bone is closed by catgut suture. This gutter can be pushed against the diaphragm by two fingers of an assistant, and while the pressure is being made an incision is carried along near to the upper border of the eleventh rib. The incision goes directly into the peritoneal cavity through the layers of chest wall and through the diaphragm, but, as the parietal pleura is being pressed directly against the diaphragmatic pleura, pneumothorax does not occur. The edges of the chest wall and diaphragm are clamped together and sutured, the pleural cavity being thus closed. The liver is exposed and may be needled for exploration, or an abscess can be drained at once or after causing adhesions by gauze, as previously described.

Rogers and Wilson ("Brit. Med. Jour.," June 16, 1906) advocate aspiration and examination of the pus. If amebæ only are present, they inject a solution of quinin, a material quickly fatal to amebæ. The dose is 30 gr. of bihydrochlorate of quinin in a sterile solution. If the abscess holds less than 10 oz. of matter the quinin is given in 2 oz. of fluid; if it holds more, in 4 oz. of fluid. The authors report 2 cases cured by this method.

Treatment of Traumatic Abscess.—Same as for tropical abscess.

Treatment of Pyemic Abscess.—Surgery is usually futile, because multiple abscesses exist, but an operation should be performed in the hope that it may do good. In a case in the Jefferson Hospital in which abscess of the liver followed appendicitis the patient recovered after operation.

Hepatoptosis (Floating or Movable Liver).—Hepatoptosis may be congenital, but is usually acquired. In a congenital case certain ligamentous supports of the liver are absent. In the following discussion the acquired form is the variety referred to. This condition is rare. Ninety-eight cases have been reported.[1] It is a form of splanchnoptosis and is due to relaxation of the abdominal wall and stretching of the supports of the liver. It may occur alone, but it is more often a part of a general abdominal relaxation or of Glénard's disease, and often a kidney is movable, or uterine displacement or hernia may exist. The liver may descend into the lower abdomen, may be upside down (Demarquay), may rotate on its transverse axis (Griffiths), the anterior surface may become posterior, or the organ may lie with the superior surface in the right flank and the inferior surface looking to the left,[2] may be movable, or may be anchored by adhesions. It is most common in women. The liver is supported by ligaments and also by the inferior vena cava (which vessel is firmly adherent to the central tendon of the diaphragm—Faure), by the abdominal wall, and by the intestines (Glénard). The cause of the condition is in dispute. It can result from relaxation of the belly wall, relaxation of the ligaments, enteroptosis, great enlargement of the gall-bladder, increase in weight of the liver, atrophy of the connective tissue between the liver and diaphragm, pregnancy, the growth of a liver tumor and tight lacing. Either a strain, cough, or the dragging of an adherent tumor may be the exciting cause.

Signs and Symptoms.—An abdominal mass may appear suddenly after a blow or a strain, and if it does appear suddenly there are always pain in the

[1] J. H. Carstens, "Jour. Am. Med. Assoc.," May 17, 1902.
[2] Terrier and Auvray, "Rev. de Chir.," Aug. and Sept., 1897.

hepatic region, nausea, and weakness. When the condition comes on gradually there may be no symptoms for a long time, but, as a rule, there is some pain in the loin which becomes worse after exercise or effort. In rare cases jaundice appears, and occasionally there is ascites. The abdominal walls are relaxed and the signs of splanchnoptosis are manifest. When the patient stands, a transverse furrow of skin covers the lower part of the umbilicus (*Glénard's sign*). In most cases the shape, the movability, and the absence of the liver from its proper position are diagnostic. Even when the organ is dislocated and attached in its new situation, it is missed from its proper abode, and palpation outlines the characteristic shape. When the patient lies down the liver usually returns to place, and in most cases it can be restored by manipulation. In some cases, however, it will not return to place and cannot be restored by manipulation. A floating liver causes a recognizable enlargement in the right loin, and the mass usually moves on respiration.

Treatment.—In many cases the patient can be kept comfortable by wearing an abdominal support, and can be distinctly improved by the application of massage and electricity to the abdominal wall, the administration of tonics, and a course of forced feeding. If these means fail and the patient suffers, an operation should be performed. The operation of *hepatopexy* was devised by Marchant. He opens the abdomen and tries to restore the liver to its proper position. This can usually be accomplished. In some cases it can be done after adhesions have been separated. In other cases it can be only partially accomplished. After the liver has been restored, he sutures it by means of catgut or silk to the abdominal wall or costal cartilages, the stitches passing through the hepatic parenchyma and being carried through the liver by means of a round and blunt needle. The sutures attaching the liver to the belly wall are tied beneath the skin. Marchant scarified the dome of the liver in order to favor adhesions. Ramsay rubs the upper surface of the liver with gauze to promote adhesion and transfixes the round ligament with a suture which is carried around the cartilage of the seventh rib. In a severe case Depage advises us to associate hepatopexy with an excisionof a portion of the abdominal wall to amend relaxation (*laparectomy*). If, in operating on a floating liver, it is found impossible to get the liver back into its norml position, fix it with sutures as near its proper abode as is possible. Terrier and Auvray report 11 cases of hepatopexy. One case died and 8 completely recovered.

Floating Hepatic Lobe (Partial Hepatoptosis).—This condition is not uncommon in cases of chronic disease of the gall-bladder and is not often met in cholelithiasis. It is believed that it can be caused by tight lacing. A tongue-like projection forms upon the right lobe of the liver (*linguiform lobe, lacing lobe*). It can be palpated below the costal margin and the dulness of the mass on percussion is continuous with liver dulness. A linguiform lobe can usually be moved laterally and forward and backward; it is always tender and is sometimes the seat of pain.

Treatment.—When this condition is associated with gall-bladder trouble, it may disappear, or at least cease to cause pain, when the gall-bladder is drained by cholecystostomy. Langenbuch has successfully removed a linguiform lobe.

Cholecystitis (Inflammation of the Gall-bladder).—Inflammation of the gall-bladder is produced by infection. Healthy bile is sterile; and when bacteria are found in the bile, the condition is one of disease. Microorganisms may find entrance into the gall-bladder by way of the blood, the bile becoming infected secondarily to the infection of the gall-bladder; or they may enter by way of the ducts, from the intestine. The conditions that follow infection depend upon the characteristic tendency and the virulence of the infecting germs. A trivial infection produces mucous catarrh; a more

active infection causes suppuration, and possibly ulceration; a very violent infection leads to gangrene.

In most cases of cholecystitis an inflammatory swelling blocks the cystic duct, and obstructs it so that the bile stagnates in the gall-bladder. In many cases this condition lasts but a short time; and when the obstruction is relieved, bile flows down the duct. Occasionally, as a secondary consequence, cholangitis, or infection of the hepatic duct, follows.[1] Occasionally, also, the obstruction of the duct is not relieved, and a quantity of clear, thin mucus gathers in the gall-bladder and overdistends it—the condition known as *hydrops*. The gall-bladder may likewise become distended with pus, constituting an *empyema* of the gall-bladder; and any overdistended gall-bladder may rupture. A gall-bladder may distend to a most enormous size. Terrier reported a case of distended gall-bladder in which the viscus contained 42 pints of fluid. F. W. Collinson ("Brit. Med. Jour.," May 29, 1909) reports the case of a woman thirty-one years of age who was tapped twice before operation and at each tapping 25 pints of fluid were withdrawn. At the operation 22 pints were obtained. Collinson's case arose from blocking of the common duct as a result of traumatism, followed by kinking of the cystic duct and subsequent opening of the common duct. In cases of very chronic inflammation of the gall-bladder this structure becomes fibrous and contracts, until it may become no larger than the thumb, in which condition it may contain a very small amount of thickened bile. In some inflammatory conditions due to infection the bile mixes with thickened mucus, and micro-organisms form the nucleus upon which bile salts are deposited to form gall-stones. As the same author points out, cholelithiasis may result from cholecystitis, and may cause chronic cholecystitis, because the stones existing in a gall-bladder are sources of irritation.

Bacteriology of Cholecystitis.—It has been proved by abundant observation that the fact that bile contains micro-organisms is no evidence that the gall-bladder is inflamed; but that when the gall-bladder is inflamed micro-organisms are demonstrable in the bile. We know that the bile is infected during the course of typhoid fever, and that it is frequently so in pneumonia. The colon bacillus is not unusually demonstrable in cholecystitis; and pus cocci, either in pure culture or mixed with other germs, constitute the most common cause of the inflammation. It is probable that bacteria entering the gall-bladder and not being particularly virulent produce no immediate harm when the flow of bile is unobstructed, though even then they may become the nuclei of gall-stones; but if the bacteria are very virulent they may actually lead to obstruction. Stagnation of the bile favors infection, and infection may be the cause of stagnation. Each influence reacts upon the other and aggravates the other, and it seems more than possible that infection of the gall-bladder is to be regarded as serious only when there is obstruction to the outflow of bile. The same variety of germ may, under some circumstances, cause catarrhal, and under others suppurative, inflammation; that is, when bacteria are virulent and tissue resistance is slight, suppurative cholecystitis results; but when the bacteria are not virulent and the tissue resistance is powerful, the gall-bladder is not infected at all, or only catarrhal inflammation is produced. I operated upon a case of acute suppurative inflammation of the gall-bladder three weeks after the termination of an attack of typhoid fever. The culture taken from the gall-bladder showed an unidentified bacillus, which was not the colon bacillus or the paracolon bacillus, and which was not identifiable as the typhoid bacillus or the paratyphoid bacillus. It strongly resembled the typhoid bacillus, but possessed no agglutinative power (the author, in "New York Med. Jour.," April 8, 1905).

A patient in the medical ward of the Jefferson Hospital was supposed to be developing a typhoid relapse, but no fresh spots appeared, and there were pain, tenderness, and rigidity in the region of the gall-bladder. I oper-

[1] Joseph McFarland, "Proceedings of the Phila. County Med. Soc.," Sept., 1902.

ated and found the gall-bladder full, dark colored, and surrounded by numerous recent adhesions. It could be emptied slowly by pressure. There was no pus. It was drained and the symptoms promptly passed away and the man recovered. The culture was reported sterile. I cannot understand this finding, as inflammation undoubtedly existed. It may have been peritonitis rather than cholecystitis, but from what cause is unknown. No culture was taken from the peritoneal cavity. The finding of sterile bile at the end of an attack of undoubted typhoid is of interest.

Catarrhal Inflammation of the Gall-bladder and Bile-ducts.—This condition is known as catarrhal jaundice, acute or chronic, and is usually treated by the physician; but, as A. W. Mayo Robson points out, chronic catarrhal jaundice sometimes resembles the jaundice of organic disease, and is occasionally associated with gall-stones, malignant disease, or hydatid cyst. The same authority asserts his belief that chronic catarrhal jaundice usually results from interstitial pancreatitis and duct obstruction. This condition usually comes on without pain. If there be pain it means some complication. Robson ("Surg., Gynec., and Obstet.," Jan., 1908) names among such complications catarrhal cholecystitis, cholangitis, gall-stone, and duodenal ulcer. The jaundice is striking. It is often accompanied by itch. There is loss of flesh and anemia, and the liver is enlarged and smooth. Robson tells us that if the gall-bladder is not shrunken from stone, and if there is great duct obstruction, the bladder will be distended. Chills and fever mean infective cholangitis. In a case of chronic catarrhal jaundice in which medical treatment fails, surgical treatment must be considered (cholecystostomy or cholecystenterostomy).

Catarrhal Cholecystitis.—This is a catarrhal inflammation of the gall-bladder usually without jaundice. The gall-bladder becomes thick and its mucous membrane is frequently plicated. Very thick mucus is secreted, which gathers in masses, and the descent of these plugs causes pain that is sometimes indistinguishable from that produced by the passage of a gall-stone. Such a plug may temporarily block the cystic duct. In catarrhal cholecystitis the gall-bladder is frequently distended, but rarely admits of palpation; and there are no adhesions to surrounding structures, unless gall-stones have been present (Robson). Catarrhal cholecystitis may lead to the formation of gall-stones; may result from the presence of gall-stones; or may be found in cases in which gall-stones have been present, but have passed. In 1 case upon which I operated the gall-bladder was enlarged, thick, and without adhesions; the mucous membrane was convoluted; and the viscus was filled with thick, tenacious mucus, and the mucous membrane of the gall-bladder contained many minute concretions. In this case stone formation was probably beginning to follow upon catarrhal cholecystitis. In another case a woman had presented violent symptoms of gall-stone colic, and stones had been recovered from the feces; but on opening the gall-bladder no stones were found—only a condition of catarrhal cholecystitis. Jaundice is rare in catarrhal cholecystitis unless gall-stones are present; it is, however, occasionally noted. Even if jaundice does occur, it is slight and lasts but a short time. The painful attacks that occur during catarrhal cholecystitis are similar to gall-stone attacks; but the pain is less violent and of briefer duration, and jaundice is not apt to follow the passage of a plug of mucus and is apt to follow the passage of a gall-stone. Further, as Robson has shown, in catarrhal cholecystitis with gall-stones there may be tenderness, but there is rarely tenderness in uncomplicated catarrhal cholecystitis.

Treatment.—The majority of the cases recover under medical treatment. If a case fails to recover under medical treatment, one cannot be sure whether there are gall-stones or not; but an operation is indicated in either case. Cholecystostomy should be performed and the gall-bladder should be drained for a week or two. This treatment will almost always produce cure.

Croupous Inflammation of the Gall-bladder and the Bile-ducts.—This is an extremely rare condition, due to the formation in the bile-passages of a thick membrane which causes obstruction to the flow of bile and spasmodic contraction of the gall-bladder. The symptoms are identical with those of gall-stones. Robson points out that a study of the evacuations may discover membranous intestinal casts; and that, as membranous enteritis is usually associated with croupous inflammation of the gall-bladder and bile-ducts, a diagnosis may thus be reached. The same author says that one may, in some cases, even find a cast of the gall-bladder in the evacuations.

Treatment.—If medical treatment fails, cholecystostomy should be performed and drainage should be employed for a considerable time.

Suppurative Inflammation of the Gall-bladder and Bile-ducts.—Adopting the classification of Mr. Robson, we divide these suppurative inflammations into simple suppurative cholecystitis, suppurative and infective cholangitis, phlegmonous cholecystitis and gangrene of the gall-bladder, ulceration of the gall-bladder and bile-ducts, pericystic abscess with adhesions, and certain consequences of these conditions, such as stricture of the gall-bladder and bile-ducts, perforation of the gall-bladder and bile-ducts, and fistula of the gall-bladder and bile-ducts. Suppurative inflammations of the gall-bladder and the bile-passages are due to infection by virulent organisms or to infection when the tissue resistance is at a low ebb.

One fact must strike the physician in regard to these cases; that is, that there is a strong similarity between the possible changes of acute cholecystitis and the possible changes of acute appendicitis. In the gall-bladder, as in the appendix, there may be a catarrhal inflammation, which may not advance beyond this stage, or which may advance into a more dangerous form; in each structure blocking and stagnation favor infection and aggravate existing infection; in each there may be suppuration, ulceration, gangrene, and perforation; in each there may be grave complications and disastrous and fatal consequences; and in each prompt surgical operation is usually life-saving.[1]

Simple Suppurative Cholecystitis.—This condition is also spoken of as *suppurative catarrh* of the gall-bladder or *simple empyema* of the gall-bladder. It is a rare condition unless gall-stones exist or unless some infectious disease—especially typhoid fever—has antedated the condition. I operated for this condition upon a boy eleven years of age three weeks after the termination of an attack of typhoid fever. It is not only typhoid fever that may be causative, but also other continued fevers. No matter, however, what organism is primarily responsible—be it colon bacillus, typhoid bacillus, or what not—a mixed infection with pyogenic cocci usually takes place. Pyogenic cocci alone may be causative. In simple suppurative catarrh of the gall-bladder, when the duct becomes blocked, the condition known as simple empyema exists; and when hydrops of the gall-bladder undergoes suppuration simple empyema is produced.

In an ordinary case of suppurative catarrh following gall-stones one usually obtains the history of a number of attacks of biliary colic, the pain finally having become localized and persistent instead of radiating and intermittent, and a definite swelling being palpable in the gall-bladder region. This swelling is tender on pressure. There are usually constitutional symptoms, sometimes trivial, often severe. The trivial symptoms are a somewhat rapid pulse, sweating at night, and some elevation of temperature. The more severe symptoms are chills, a remittent fever, and profuse sweats. The development of severe symptoms indicates that a dangerous change is taking place—usually ulceration of the gall-bladder, occasionally phlegmonous cholecystitis. Distinct jaundice is rare in simple empyema, though the patient usually shows loss of flesh, has a very poor appetite, and suffers considerably from thirst.

[1] The author, "Proceedings of Phila. County Med. Soc.," Sept., 1902.

To distinguish an enlarged gall-bladder from any other intra-abdominal mass is sometimes difficult. Very large gall-bladders, such as have been placed on record by Collinson, Terrier, Lawson Tait, Gersuny, and others, may be mistaken for ovarian cysts. Alban Doran discusses such cases in the "Brit. Med. Jour.," June 17, 1905. An enlarged gall-bladder moves on respiration unless the mass becomes adherent to the abdominal wall, when it will cease to do so. An enlarged gall-bladder is sometimes mistaken for a movable kidney, and the diagnosis between these conditions is discussed in the section on Movable Kidney (see page 1422).

Treatment.—The gall-bladder should be opened and drained by the operation of cholecystostomy. After it has been exposed, it is packed about with gauze pads, a considerable portion of the contents is removed through an aspirator, the gall-bladder is opened and irrigated with salt solution, and a search is made for any cause of obstruction in the cystic duct. This cause should be removed, and any gall-stones that are present should, of course, be

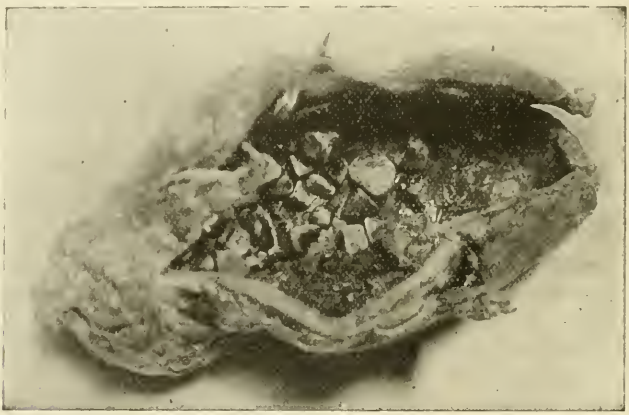

FIG. 706.—Gall-bladder filled with calculi. Removed by cholecystectomy.

taken away. The walls of the gall-bladder will frequently be found diseased and softened, so that it is impossible to apply stitches. In some cases, if the gall-bladder is badly diseased, it should be removed, but in others incision with drainage is sufficient.

Recurrent Simple Empyema of the Gall-bladder.—In this condition a person develops, at intervals, pain, fever, tenderness, and enlargement of the gall-bladder. Then the symptoms clear up and he is well for a time, but they again become manifest; and at last they may become persistent or violent because of the development of some complication. In these cases it is impossible, after a number of attacks, to palpate any enlargement of the gall-bladder; and when an operation is performed the gall-bladder is found shrunken, thickened, and deeply placed, containing some purulent matter, and strongly fixed to the surrounding structures by adhesions.

Treatment.—Cholecystectomy is usually the proper operation.

Acute Phlegmonous Cholecystitis.—Some call this condition *acute empyema*. It is extremely dangerous, and is apt to cause gangrene of the gall-bladder. It is due to infection by extremely virulent organisms. It may, even without perforation, produce rapid peritonitis and death. As a rule, in advanced cases perforation takes place. It is generally associated with the presence of calculi, but sometimes none are found; and the condition sometimes develops during typhoid fever or septicemia.

This disease begins with sudden and violent pain in the gall-bladder region. This pain usually radiates toward the right shoulder-blade, and soon becomes

general throughout the abdomen. There are tenderness in and great rigidity over the gall-bladder region, thoracic respiration, exhausting vomiting, septic fever, and in some cases jaundice. If an operation is not performed promptly general peritonitis quickly takes the patient's life. In one case upon which I operated there were intense jaundice, tenderness, violent pain, abdominal rigidity and distention, chills, and septic fever; and when the abdomen was opened it was found that a portion of the gall-bladder was gangrenous and that a calculus projected through the gangrenous opening.

It is this form of cholecystitis that is especially likely to be mistaken for appendicitis. In making a diagnosis the situation of the primary pain is of importance, and likewise the situation of the tenderness; but a displaced gall-bladder or an abnormally situated appendix may lead to error. Acute phlegmonous cholecystitis is usually accompanied by absolute constipation, and the sudden onset and the abdominal distention may lead to the disease being mistaken for intestinal obstruction. It may also be confused with perforating ulcer of the stomach or of the duodenum.

Treatment.—In any case of doubt an exploratory incision should be made. If phlegmonous cholecystitis is found to exist, the gall-bladder should, whenever possible, be extirpated; but if the desperate condition of the patient forbids this operation, the bladder should be incised, surrounded with iodoform gauze, and a drainage-tube should be carried well up toward the cystic duct.

Pericystic abscess may follow infection of the gall-bladder. It is especially common in the condition known as recurrent simple empyema. When a pericystic abscess exists there are great localized abdominal tenderness and rigidity and the temperature is usually indicative of suppuration. The causative micro-organisms may have passed through a diseased gall-bladder wall, rupture not existing; or the abscess may follow ulceration or perforation of the gall-bladder wall.

Treatment.—Operation should invariably be performed, though it is frequently difficult. After a pericystic abscess has been drained it will be found necessary in some cases to extirpate the gall-bladder, whereas in others incision of the gall-bladder and drainage will prove sufficient.

Infective Cholangitis.—Cholangitis is usually inaugurated by infected bile, but when it arises during a general infection the bacteria may be brought by the blood. It may arise in a case of hepatic cirrhosis. Naunyn ("Deutsche medizinische Wochenschrift," Berlin, Nov. 2, 1911) says that most germs can cause cholangitis; that mixed infection may occur, and that during an acute general infection cholangitis is seldom recognized. The usual cause of infective cholangitis is gall-stones lodged in the common duct. Some maintain that duct-stones are causal, particularly in those cases in which a gall-stone acts as a ball-valve. A. W. Mayo Robson, though he believes that infective cholangitis does occur when the gall-stones are freely movable in the common duct, sets it forth as his experience that it is much more common in such cases to find gall-stones impacted in the common duct.

In such cases the patient gives a history of attacks of gall-stone colic without jaundice for several years, and then of attacks followed by temporary jaundice (see page 1188). Finally comes an attack that is followed by a chill and fever; and jaundice, varying in intensity, ensues upon this, and now, though it may fade, it seldom completely disappears between the attacks of pain. Robson points out that the interval between the attacks may be short or long, and that the rigors may be repeated daily or at uncertain intervals; that the gall-bladder is usually, but not always, contracted; and that after the condition has persisted for some time the liver becomes distinctly enlarged. There are tenderness over the gall-bladder or in the epigastric region, loss of flesh, and persistent jaundice which may vary in hue.

Infective cholangitis, even after it has lasted for a considerable length of

time, may be recovered from; but it may pass on into an acute condition in which poisoning takes place from the biliary elements, suppurative cholangitis may arise, an empyema of the gall-bladder may develop, and there may be an abscess of the liver or some other dangerous or fatal complication. The ague-like attacks of infective cholangitis have been called by Charcot *intermittent hepatic fever* (see page 1189).

Treatment.—After an incision has been made the common duct is opened, the cause removed, and the duct drained; but, as Mr. Robson points out, the complication should be anticipated. When one finds that carefully applied medical treatment has failed to free the patient from gall-stones, they should be removed surgically.

Suppurative cholangitis is usually a development of the ordinary infective cholangitis, which has just been discussed. Among the other causes that Robson sums up are acute infectious diseases, particularly typhoid fever and influenza, cancer of the bile-ducts, and hydatid disease.

In this condition the liver enlarges notably and becomes tender. In some cases there is an empyema of the gall-bladder, but this is rare; in fact, the gall-bladder is usually very much shrunken. When, in a chronic case, there are enlargement of the liver, blocking of the common duct, and enlargement of the gall-bladder the inference is in favor of cancerous obstruction of the common duct. If the obstruction is due to cancer there will usually be little pain; but when it is due to gall-stones there will be violent attacks of pain, accompanied by rigors and fever, with deepening of the jaundice. In this disease there is always jaundice, usually unfading; but in cases of ball-valve gall-stone in the duct it will be mitigated from time to time (see page 1189). The patient suffers from septic fever and there is very rapid loss of flesh.

The condition is generally fatal unless operation is performed early. There is a strong tendency for abscess of the liver to form, and in 1 case upon which I operated a subphrenic abscess had developed.

Treatment.—Cholecystostomy with free and prolonged drainage. If an abscess of the liver exists it should also be drained. If gall-stones are gathered in the common duct they should be removed.

Typhoid Cholecystitis.—Typhoid bacilli were first found in the bile by Futterer in 1888, and typhoid cholecystitis was first described by Girode in 1890. As previously stated, typhoid bacilli are usually present in the bile during, and perhaps are present months or years after, an attack of typhoid fever. They are not always present, however, for in a case of cholecystitis following typhoid on which I operated an unidentified bacillus was found ("New York Med. Jour.," April 8, 1905); in a case on which I had made an artificial anus for typhoid perforation and subsequently performed intestinal resection I drained a greatly distended gall-bladder at the second operation and cultures of the bile remained sterile; and in a case of typhoid with distended and apparently inflamed gall-bladder on which I operated the bile was reported to be sterile. Because typhoid bacilli are usually present in the bile during typhoid does not mean that most cases of typhoid have cholecystitis. Cholecystitis is not very common, and arises when bacilli are very numerous or very virulent, when vital resistance is lowered, when there is antecedent inflammation of the gall-bladder, when there are gall-stones, and particularly if there is a block of the duct causing stagnation of bile. Bacilli in bile may do no harm at all, but they may cause catarrh, purulent catarrh, suppuration of the gall-bladder walls, suppuration outside of the gall-bladder, or perforation. When bile or inflammatory exudate contains typhoid bacilli, agglutinins are present and may precipitate masses which become nuclei for gall-stones.

The usual period for cholecystitis to arise is during the third week of the fever, but it is not uncommonly met with during convalescence and is perhaps mistaken for a relapse.

The condition may arise months or a year after the attack of typhoid, and yet a pure culture of typhoid bacilli may be obtained from the gall-bladder. Strange to say, cases of cholecystitis have been operated on in persons giving no history of having had typhoid, and typhoid bacilli have been obtained from the gall-bladder. I operated upon such a case. Such a person may have had a very mild attack of typhoid, or he may be immune to typhoid fever and yet the bacillus may be capable of causing inflammation. Many cases of typhoid cholecystitis are probably unrecognized because of the trivial symptoms, or because a high position of the liver renders the real seat of pain obscure, because the general symptoms are uncertain, because toxemia blurs perception of pain, or because the condition is confused with appendicitis. It is rare in children, more common in adults. Most infections result from the bacilli ascending the common duct, some are by way of the lymphatics (Charles H. Mayo), some by an adhesion of the gall-bladder to the bowel, some by way of the portal circulation and the bile-ducts. Mixed infection may occur, and a secondary staphylococcus infection may be followed by disappearance of the typhoid bacilli. The symptoms of typhoid cholecystitis are pain and tenderness in the gall-bladder region, rigidity of the upper half of the right rectus muscle, perhaps a palpable mass, an elevated and remittent temperature, sweats, perhaps jaundice, and sometimes leukocytosis. In some cases perforation occurs. Erdmann reported 1 case and collected from literature 34 cases of perforation ("Annals of Surgery," June, 1903).

Treatment.—In an ordinary case without perforation incise and drain the gall-bladder. If perforation exists, do cholecystectomy if possible; if not, drain. No attempt should be made to suture the perforation. If perforation exists and operation is not done, death is practically certain. Of 27 cases not operated upon, all died; of 7 cases operated upon, 4 recovered (Erdmann).

Gall-stones are formed during life in the gall-bladder or bile-ducts by the agglutination of materials which have been precipitated from bile. The nucleus of a gall-stone may be a mass of bacteria, a blood-clot, epithelium, crystals of cholesterin or carbonate of lime, or a cast of a small duct.[1] A condition of the body thought to lead to the formation of gall-stones is designated by the term *cholelithiasis* (Brockbank). But one stone may be present or great numbers may exist. Solitary stones may be nearly round or cylindrical. When several stones or many stones exist the mutual pressure often leads to the formation of facets (Naunyn). In color, calculi may be pale yellow, green, black, or brown. Some are heavier than bile and some are lighter. Brockbank gives the following varieties of gall-stones: pure cholesterin stones, stratified cholesterin stones, common or gall-bladder calculi, mixed bilirubin-calcium calculi, pure bilirubin-calcium calculi, and certain rare forms.[2] Gall-stones usually take origin in the gall-bladder, but may arise in the common duct, the cystic duct, the hepatic duct, or the smaller ducts of the liver. As a rule, however, calculi in the common or cystic duct were not formed there, but were transported from the gall-bladder or hepatic ducts.

Causes.—Gall-stones are very commonly found postmortem. In Germany it is estimated that they are found in 12 per cent. of all cases. In 1655 autopsies in the Johns Hopkins Hospital gall-stones were present in 6.94 per cent. of all cases.[3] The usual estimate is 5 per cent. of autopsies. The cause is a catarrhal condition of the bile-ducts, due particularly to the entrance of bacteria from the intestine (colon bacilli, typhoid bacilli, pus organisms, pneumococci). This catarrhal condition causes stagnation of bile. Healthy bile is sterile, but not germicidal, and bacteria will grow in it. Bacteria have been found in bile years after the termination of an attack of typhoid fever. Experimental infection

[3] C. D. Mosher, in "Johns Hopkins Hosp. Bull.," Aug., 1901.

of the gall-bladder producing mild cholecystitis is almost always followed by gall-stone formation.[1] Welch pointed out that recent gall-stones have bacteria in their center. Cushing tells us that 30 per cent. of gall-stone cases operated upon in the Johns Hopkins Hospital had previously suffered from typhoid fever, but the experience of the Mayos is not in accord with this opinion. In view of the fact that bile containing typhoid bacilli may contain agglutinins we can understand how masses could be precipitated to form nuclei—30 per cent. of Ochsner's cases had had appendicitis.

The chief predisposing causes are advancing years, insufficient exercise, the daily consumption of unnecessarily large quantities of food, gouty tendencies, and conditions which interfere with the emptying of the gall-bladder. Cardiac disease and cancer of the liver predispose. Gall-stones rarely form before the age of thirty-five. The youngest patient from whom I have removed stones was a girl of twenty. The disease is more common in the insane than in the mentally sound, in the white race than in the black, and in women than in men. In 25 per cent. of all females beyond sixty years of age gall-stones are present (Naunyn). The special liability of women may be brought about by tight lacing, pregnancy, inactivity, or movable right kidney. Stout and lazy women are particularly liable to gall-stone formation, and women who have borne children are far more liable than those who have not. Total abstainers seem to possess a greater predisposition than users of alcohol, probably because they are more apt to be large eaters (Herbert F. Waterhouse, in "Lancet," May 8, 1909). There are two forms of the condition to be considered: the acute type, due to efforts made by the gall-bladder or duct to expel the concretion; and the chronic condition, in which a calculus is lodged for a long time, or in which, as soon as one calculus is passed into the intestine, "another begins its journey" (Brockbank's treatise on "Gall-stones"). The fact that bacteria may cause the condition must not lead us to infer that pus is of necessity formed. If the bacteria are present in small numbers, or if their virulence is greatly mitigated, they produce catarrhal inflammation only, the bile stagnates, and a stone forms. There may be one stone, two, several, or many stones. I have removed 200 from a patient. Multiple stones are usually faceted. Solitary stones are not faceted.

Many observers believe that inflammation of the mucous membrane causes the secretion of quantities of cholesterin, which material forms a large part of most gall-stones. Others maintain that cholesterin is a normal constituent of bile and is not obtained from the mucous membrane.

Bachmeister ("Münch. Med. Woch.," Feb. 18, 1908) demonstrates that if pure sterile bile is permitted to stand for a considerable time cholesterin will be precipitated, and that if epithelial cells are added to this the cholesterin is precipitated much more rapidly. The catarrhal inflammation furnishes quantities of epithelial cells and the cells precipitate cholesterin, and in this way inflammation causes gall-stones. Aschoff ("Progressive Med.," June, 1914) maintains that gall-stone predisposition depends on the amount of cholesterin in the blood and bile.

The blood certainly contains cholesterin (0.16 to 0.18 per cent.). The cholesterin content is increased by a diet of meat, eggs, fat, fish, etc. It is increased by nephritis, diabetes, arteriosclerosis, pregnancy and lactation. When the blood holds an excess of cholesterin a first attack of colic may be due to sudden precipitation of cholesterin in a normal gall-bladder. Such an attack is afebrile and the solitary stone is round (Aschoff's theory, Ibid.). Pigmented stones and layered stones prove that inflammation has existed. This theory asserts that stones may form originally without inflammation but that the presence of a stone favors inflammation. It is probable that when gall-stones exist they are all due to a common cause and all have begun to form at the same time.

[1] Gilbert, in "Archives générales de méd.," Aug. and Sept., 1898.

It is not likely that one begins and then another, and so on. After a stone once begins it may progressively increase in size. In many cases the stone or stones never cause trouble. A gall-stone may begin to descend because of violent muscular exertion, external pressure, or at the onset of a fresh inflammation which leads to loosening of the stone. A very small stone usually passes freely. A larger stone in passing causes colic. A still larger stone remains in the gall-bladder, or becomes fixed in the cystic duct or in the common duct. In most cases gall-stones form in the gall-bladder. In some they form in the common duct if stones have previously existed in the gall-bladder. When the common duct retains a stone and is suffering from some degree of obstruction and from infection, stones not very unusually form in the hepatic ducts (Wm. J. and Chas. H. Mayo, in "Am. Jour. Med. Sciences," March, 1905). Stones are occasionally found at necropsy in the radicles of the hepatic duct.

Symptoms.—The formation of a stone requires several months, and during the antecedent period of gastro-intestinal catarrh, *the prodromal state* of Kraus, certain symptoms may exist, viz.: constipation, flatulence, loss of appetite, migraine, uneasy sensations in the epigastrium or right hypochondrium, sallowness of the skin, slight yellowness of the conjunctivæ, scantiness of urine, which is saturated with uric acid, and may after a time contain a little bile. If this condition is not arrested by treatment, it grows worse. The abdomen becomes decidedly distended; pressure over the stomach or liver may cause distinct uneasiness or even pain; acid indigestion is very troublesome; violent attacks of migraine occur; constipation becomes more decided, the feces become clay colored, gastralgia may occur, the skin is apt to be slightly jaundiced, itching is complained of, the patient is irritable and sleeps poorly. The liver is found to be enlarged and the urine contains distinct amounts of bile. When the patient reaches this stage, gall-stones have formed or are very liable to form. These symptoms may pass away even if a concretion forms. It is quite true that in some cases a stone exists for years without causing trouble. This is particularly true in elderly people. A stone seldom fails to cause symptoms, but often the symptoms are unrecognized. In many cases the symptoms which stones cause are thought to be due to disease of the stomach (indigestion, flatulence, pain after eating, pyloric spasm, etc.). Most of the cases I have seen long thought they had stomach trouble, and the real condition was recognized only when there was a seizure of colic or an attack of inflammation.

As Waterhouse ("Lancet," May 8, 1909) says, the symptoms do not bear any relation to the size or the number of the stones. In fact, gall-stones give rise to active symptoms only when infection occurs or when the ducts become occluded and cease to drain, or when a stone starts to pass. If infection occurs, it may pass away spontaneously, but seldom does so. When a stone forms, pain is apt to become a marked feature of the case. John B. Murphy ("Med. News," Nov. 2, 1903) points out that in a person with stones in the gall-bladder there may be:

1. The pain of acute inflammation, the result of a severe infection. In this condition there are abdominal rigidity and contracted gall-bladder.

2. The pain of tension. In this there is not persistent abdominal rigidity, but pressure always causes sudden and transient tension of the belly muscles. Murphy's method of demonstrating tenderness of the gall-bladder is most valuable, and I always use it. It is as follows: hook the fingers well up under the liver and tell the patient to take a deep inspiration. On inspiration pain becomes acute and respiration suddenly ceases.

3. Referred pain may exist with either of the above conditions. *Colic* is spasmodic pain, and means that a stone has left or is trying to leave the gall-bladder, and is in or is trying to enter a duct. Many persons with a stone or with stones in the gall-bladder never have colic. A sense of pressure or of

soreness in the hepatic region, the result of cholecystitis, has added to it sudden and transient paroxysms of pain, due to the passage of thick bile from the gall-bladder and small ducts, or of gravel from the small ducts, urged on by bile pressure. When any stone but the very smallest begins to pass from the gall-bladder, violent colic is experienced. Such a colic usually comes on very suddenly, and often about three hours after a meal. It may, however, come on gradually, the patient complaining greatly of flatulence. In some cases it is so sudden and violent as to simulate perforation of the stomach or duodenum. The reason colic is particularly apt to come several hours after a heavy meal is that at that time bile is passing down into the intestine. A bladder containing calculi often tolerates the presence of the foreign bodies for an indefinite length of time, and then suddenly resents their presence and ejects them forcibly or tries to eject them. The pains are violent, spasmodic, and paroxysmal, and over the hepatic and epigastric regions, "radiating upward over the right half of the thorax" (Kraus), and passing particularly from the epigastrium to the right shoulder-blade. The patient is profoundly nauseated and usually vomits. In many cases the vomiting is violent. The abdomen is distended and a condition almost of collapse is soon reached. The temperature is usually normal or subnormal, but is occasionally somewhat elevated. The patient may shiver and sweating may follow, but rigors are rare. The respirations are shallow, the patient groans, cries out, flings himself about in the bed, and often, in seeking relief, assumes some strange or contorted position. He frequently holds one hand over the liver region. His expression is indicative of intense suffering and apprehension and sometimes of abject terror. The pain is one of the most awful a human being can feel, and women who have felt it assert that the pains of parturition are trivial in comparison. The attack lasts a variable time, and terminates when the stone passes into the intestine or drops back into the bladder. The usual duration of an attack is from four to twenty hours. I have seen attacks that lasted three days, four days, or even five days, almost without intermission. It terminates suddenly if the stone passes or falls back in the gall-bladder. It abates very gradually if the stone becomes wedged in a duct. In many cases at the termination of the attack an enormous amount of clear pale urine is passed. During and for a time after the attack the gall-bladder may be very tender. After the cessation of colic, if the feces are examined carefully during several days, the stone may be discovered. The fact that no stone is discovered does not prove that one was not passed, because a cholesterin stone may be broken up in the intestinal canal. If the stone is passed, jaundice almost invariably follows the colic in from twenty to thirty-six hours and lasts several days. The jaundice results from the stone being in or having passed through the common duct. If stones do not pass from the cystic duct so as to enter or protrude into the common duct, jaundice does not occur. In 80 per cent. of my cases of gall-stones (excluding common duct cases) there was no history of jaundice. Even when a stone is lodged in the common duct jaundice may be slight or absent. When jaundice arises after a colic, it comes on gradually, bile appears in the urine, and often, but not always, the stools become clay colored from absence of bile. Jaundice may be first noticeable in the urine or in the conjunctiva. The skin is apt to itch annoyingly, even atrociously. The patient is constipated and very thirsty. The liver is enlarged and tender and the spleen is enlarged. Some writers state that the pulse is slow in jaundice. My experience is in agreement with the much larger experience of Moynihan, who says: "I have not found any reduction in the pulse-rate in jaundice unless a degree of chronic pancreatitis is present" ("Gall-stones and Their Surgical Treatment"). If the stone becomes impacted, after a time the pains become gradually less violent, and may entirely cease. If it ceases and the stone does not move, pains do not recur; if the stone moves pains recur, and, usually, again and again the patient suffers from severe

pain. An individual may get about when a stone is impacted, but again and again fierce attacks of colic occur, and if the stone is wedged immovably in the common duct, producing absolute obstruction, the patient becomes and remains deeply jaundiced. Continued deep jaundice is seldom seen when stones are lodged in the common duct, because they are not often absolutely fixed and hence rarely produce complete obstruction. Usually the stone moves from time to time or is at least lifted, so that bile gets by it at intervals. This condition constitutes the *ball-valve stone*, and in it jaundice, though present more or less, is at times much more intense than at other times. It is a jaundice in which the hue is yellow, not deep brown, and it is a jaundice that wanes and deepens. It deepens after each colic and later wanes, but seldom entirely disappears while the stone remains in the duct.

In persistent jaundice due to gall-stones the gall-bladder is seldom enlarged. Courvoisier showed that when persistent jaundice is associated with enlargement of the gall-bladder the cause is usually pressure on the duct from without (malignant disease of the pancreas).

Slight jaundice is not always easy of recognition. Recognition is particularly difficult in sallow individuals and by artificial light. Moynihan praises Hamel's test for slight jaundice. It is made by drawing a little blood from a puncture of the lobe of the ear into a capillary tube and permitting the tube to stand for a few hours. If any jaundice is present the serum, which collects in the upper part of the tube, will be yellow (Moynihan).

In certain cases when a stone is in the common duct an attack of colic is followed by or accompanied by a chill or chills, which may be very violent, moderate, or slight, and by a febrile seizure resembling malaria and called *hepatic fever* or *Charcot's fever*. The temperature rises rapidly, and in an hour becomes 104° F. or more, remains high for several hours and then, with a profuse sweat, drops suddenly to normal. It may remain normal for a few hours, a day, two days, several days, or weeks. In this condition there are jaundice and tenderness of the liver. Charcot's fever is brief in duration. It usually means stone in the common duct. If stones are in the bladder, we are more apt to get a persistent slightly elevated temperature. These intermissions distinguish Charcot's fever from the remittent fever of sepsis, and the absence of the plasmodium in the blood and the history of colic distinguish it from malaria. The fever is due to intoxication with toxins from infected bile retained in the ducts by obstruction. The condition is ominous because it is due to infection, and may lead to inflammation of the large ducts (*cholangitis*).

The chart of Charcot's fever shows sudden elevations, precipitate descents, and complete intermissions. Moynihan calls it the "steeple chart" ("Gall-stones and Their Surgical Treatment"). When infection spreads widely in the smaller intrahepatic ducts the temperature is high and does not intermit. Continuous fever of this type has usually been preceded by Charcot's fever.

If a stone lodges in the cystic duct, it does not cause jaundice unless an end of the stone projects into the common duct. It grows in size from incrustation, prevents the entrance of bile into the gall-bladder, and the bladder may shrivel and thicken or become distended and filled with mucus, the bile being absorbed (*hydrops* of the gall-bladder). If a bladder so blocked becomes infected, pus forms, and the condition known as *empyema* of the gall-bladder arises. An empyema of the gall-bladder may rupture into the bowel, the peritoneal cavity, or even through the skin.

The common duct is involved in 1 out of 5 or 6 cases of gall-stone disease.[1] Brewer points out that in 67 per cent. of common duct cases the stone is in the duodenal extremity, in 15 per cent. in the hepatic extremity, and in 18 per cent. in the middle. If a stone *blocks* the common duct, jaundice always exists and persists. Blocking may be complete and the stone may ulcerate into the bowel

[1] Robson, in "Lancet," April 12, 1902.

or the peritoneal cavity. Blocking may be incomplete, the stone acting as a ball-valve and producing *intermittent* colic and jaundice, which wanes and deepens (see page 1189). Fenger pointed out that if a stone remains fixed in the common duct the liver becomes tender and enlarged, but if a stone floats about in the common duct the gall-bladder undergoes atrophy. In complete obstruction the stools become clay colored and bilirubin is found in the urine. Fluctuating jaundice, with attacks of pain and fever, and a shrunken gall-bladder are strongly suggestive of a "ball-valve" stone in the common duct. Persistent deepening, painless jaundice, the color of the skin becoming brown or even of a mahogany hue, associated with a distended gall-bladder, is strongly suggestive of malignant disease compressing the common duct. The above statements constitute *Courvoisier's law.* It is found true in 90 per cent. of cases. We may add that a persistent jaundice, varying somewhat, and associated with pain or with actual colic, suggests blocking of the duct by an immovable stone.

Gall-stones may lead to suppurative inflammation of the gall-bladder or bile-passages, ulceration, occlusion of the neck of the gall-bladder, dilatation of the stomach from the formation of adhesions which kink the pylorus, pericystic abscess, peritonitis, empyema of the gall-bladder, and cancer of the gall-bladder. In cancer of the ducts gall-stones are seldom found, at least are seldom found in the ducts. Eddes collected 22 cases of cancer of the papilla. In 3 of these cases there were stones in the gall-bladder, in 1 there was a stone in the common duct ("Boston Med. and Surg. Jour.," March 7, 1901). If the patient develops distinct infection of the gall-bladder or bile-ducts, he will suffer from chills, fever and sweats.

Gall-stones may lead to cirrhosis of the liver. A stone may ulcerate into the bowel and cause intestinal obstruction. It may be difficult to make a diagnosis between gall-stones with icterus and cirrhosis of the liver with icterus. In the former case the urine contains bilirubin and in the latter case urobilin. In less then half the cases gall-stones can be detected by the *x*-rays.

Treatment.—In the prodromal stage and after recovery from an attack insist on the patient taking considerable outdoor exercise. Direct him to take a cold sponge-bath every morning, to move the bowels freely every day, and to employ a simple diet. He should avoid all highly seasoned foods, pastry, rich soups, fatty food, cheese, alcohol, and sweets. Alkalis internally are of value. Those who believe that excess of cholesterin in the blood is responsible for gall-stone formation treat the condition as follows:

Rothschild's Diet (John C. A. Gerster, "Virginia Med. Semi-Monthly," August, 11, 1916).—Fast for three or four days. During the fast give all vegetables except peas, beans, and lentils. Give cereals, sugar, buttermilk free of fat, and skimmed milk. This diet is too rigid to be maintained, so feast for three or four days, adding lean meat, fish (except salmon, shad and blue fish), and oleomargarine but not butter. So periods of feast and periods of fast alternate.

During colic give a purgative enema, apply hot turpentine stupes over the hepatic region, and administer hypodermatic injections of morphin and atropin. If vomiting does not occur, let the patient drink a large amount of warm water to favor it. After the attack administer a saline purgative.

When the attack has terminated, examine carefully for any evidence of inflammatory trouble in the hepatic region.

In certain cases operation becomes necessary. Mr. A. W. Mayo Robson[1] advises operation in the following cases: in frequently recurring biliary colic without jaundice, whether the gall-bladder is enlarged or not; in cases of enlargement of the gall-bladder without jaundice, even if there is no pain; in persistent jaundice which was ushered in by pain, painful seizures occurring,

[1] On the "Gall-bladder and Bile-ducts."

whether or not febrile attacks occur; in empyema of the gall-bladder; in peritonitis beginning in the gall-bladder region; in intrahepatic abscess and in abscess about the liver, gall-bladder, or bile-ducts; in some patients in whom the stones have been passed, but adhesions remain and produce pain; in fistula cases; in some cases of persistent jaundice due to obstruction of the common duct, although there may be a possibility of cancer existing; in phlegmonous cholecystitis and gangrene of the gall-bladder. Besides these conditions, which may be produced by gall-stones, Robson operates for wounds of the gall-bladder, infective and suppurative cholangitis, and for some conditions of chronic catarrh of the bile-ducts and gall-bladder.[1] The tendency to operate early for gall-stones is growing. It is true that stones *may* cause no trouble, but sooner or later they are apt to cause it, there is no tendency whatever to spontaneous cure, and medicine cannot dissolve them in the bladder. Early operations are easy and comparatively safe; late operations are difficult and dangerous, and by early operation dangerous complications (infection, adhesions, obstructive jaundice) are avoided. As Maurice H. Richardson[2] says: An early operation is less dangerous than the passage of a stone; complications are avoided or lessened; even if the diagnosis is wrong, the real condition may be found and removed. If obstructive jaundice exists operation is dangerous because of the possibility of fatal oozing of blood.

The common operation is *cholecystostomy*, which consists in opening the gall-bladder, removing the stones, and making a temporary fistula in the gall-bladder. The drainage cures the diseased mucous membrane. The fistula is permitted to heal after a time, hence many call the operation cholecystotomy rather than cholecystostomy. Operation should be done promptly and should not be delayed. Delay permits the gall-bladder to thicken and shrink, and allows the stone to enter the duct. After removing stones and draining the gall-bladder, symptoms may recur. Recurrence of symptoms may be due to a stone or stones having been overlooked, to renewed formation of stone, or to cholecystitis and bile-sand. After drainage gall-stones rarely re-form. Wm. J. Mayo collected 1000 operations done by six surgeons, and in not 1 case did stones re-form. Kocher has seen stones recur in 3 out of 31 cases of cholelithiasis after ideal cholecystotomy (suturing the gall-bladder after removing stones). The operation of incision, removal of the stone, and suture of the gall-bladder is known as *ideal cholecystotomy* or *cholecystendysis*. It is not a proper procedure, as it does not cure the diseased mucous membrane and stones are apt to re-form. *Cysticotomy* is incision of the cystic duct. If calculi exist in the common duct, it may be possible, after celiotomy, to manipulate them back into the bladder and extract them from that viscus by a scoop, but this maneuver is impossible unless the cystic duct is dilated. In some cases the gall-bladder is incised, a fistula is made, and the duct and bladder are frequently irrigated. In other cases the stone may be crushed by the fingers manipulating the duct and the concretion within it (*choledocholithotrity*). Robson points out that crushing of the stone is apt to leave fragments which may cause trouble, and it should be done only when the stones are soft. It is wrong to endeavor to force a stone from the common duct into the duodenum. The attempt will fail, and in some cases the patient will be placed in a worse condition by the stone lodging in Vater's diverticulum.[3] The duct may be opened, and after the removal of the stone closed by sutures (*choledochotomy*) or drained for a time (*choledochostomy*), strands of gauze being carried down to the opening and in some cases a tube being carried up a dilated duct toward the liver. If the stone be impacted near the outlet of the duct, it may be necessary to incise

[1] Robson's treatise, from which the above is taken, is a valuable exposition of the surgery of the gall-bladder and bile-ducts.

[2] "Boston Med. and Surg. Jour.," Sept. 5, 1901.

[3] See A. W. Mayo Robson, in "Lancet," April 12, 1902.

the duodenum in order to remove the stone (*duodenocholedochotomy*). A dilated common bile-duct may be anastomosed to the bowel (*choledocho-enterostomy*) or to the surface (*choledochostomy*). The obstruction may be side-tracked by anastomosing the gall-bladder to the bowel (*cholecystenterostomy*) (see page 1266). Cholecystenterostomy affords drainage, but does not remove the cause of trouble, and infection is apt to be received from the bowel. In some rare cases of common duct obstruction, in which the gall-bladder is distended and the condition of the patient is desperate, anastomose the gall-bladder to the colon (Robson). In some cases of diseased gall-bladder the viscus is removed (*cholecystectomy*). Wm. J. Mayo and others have pointed out that a danger in operations on the common duct is a sudden fall in blood-pressure when the duct is being manipulated. All operators have observed it. Ransohoff maintains that it arises only when the portal vein is compressed.

Carcinoma of the Gall-bladder and Ducts.—In 405 operations on the gall-bladder and biliary passages the Mayo brothers found malignant disease 20 times (5 per cent. of cases). (See Wm. J. Mayo, in "Med. News," Dec. 13, 1902.) Malignant disease may be primary or secondary. It may arise from carcinomatous changes in papillomata. We know that papillomata may spring up in any diseased gall-bladder. In 107 of the 2538 cases of cholecystectomy in the Mayo clinic (from Jan. 1, 1907 to June 1, 1915), papillomata were found (Wm. J. Mayo, in "Trans. Amer. Surg. Assoc.," 1915). Papillomata are not cured by a drainage operation. Cholecystectomy is necessary. In primary carcinoma calculi are practically always present, and are apparently the cause of cancer by maintaining chronic irritation. Stones are seldom present in secondary malignant disease. Not very infrequently cancer of the common duct is encountered. Now and then a surgeon discovers cancer of the ampulla of Vater.

Carcinoma of the gall-bladder can usually be palpated. It is hard and nodular, and seldom accompanied by much abdominal rigidity. There will be a long history of attacks of biliary colic and of recent or comparatively recent grave loss of flesh. Sooner or later jaundice arises, deepens, and persists. In cancer of the ampulla or ducts jaundice develops but ulceration opens a way for the bile and jaundice fades, perhaps to recur again. So it may disappear and reappear. In cancer of the duct above the ampulla jaundice arises. There is no bile but there is pancreatic juice in the intestine. In cancer of the ampulla during jaundice there is neither bile nor pancreatic juice in the intestine.

Cholecystectomy has been employed for this condition, but offers but little hope. A wedge-shaped piece of liver-tissue should be removed with the gall-bladder and hemorrhage should be arrested by sutures or gauze packing. In 2 cases in which I opened the abdomen without suspecting malignant disease of the gall-bladder the liver was hopelessly involved. In 1 case in which I operated for a supposed impacted stone in the common duct an inoperable cancer of the common duct was found. In cancer of the common duct it may be possible to excise the growth and suture the ends of the duct as has been practised by Moynihan, the Mayos and others. If this is impossible, follow the advice of the Mayo brothers: Ligate the distal end of the duct and implant the proximal end in a portion of the duodenum which is covered by peritoneum ("Keen's Surgery," vol. iii). Cancer of the ampulla has been excised successfully.

Injuries and Diseases of the Pancreas

Injuries of the Pancreas.—The pancreas is very rarely ruptured alone, although this sometimes occurs as the result of blows or crushes. In the majority of cases in which the pancreas is damaged other organs are involved; for instance, the stomach, the spleen, and the liver. A gunshot wound of the

pancreas is almost certain to injure the left kidney, the stomach, or the vertebral column. It will be remembered that in the case of President McKinley the bullet passed through the stomach, damaged the left kidney, and injured the pancreas. Becker reported an isolated gunshot wound of the pancreas, the only case on record (Stephen H. Watts). Garré ("Beiträge zür Klinische Chirurgie," xlvi, No. 1) collected 30 cases of subcutaneous rupture of the pancreas, and in only 8 of these cases was the pancreas alone damaged.

Symptoms.—When the pancreas is injured alone, hemorrhage is not usually severe; but if adjacent organs are also damaged, it is sure to be profuse. Hence when adjacent organs are damaged immediate symptoms of severe intra-abdominal hemorrhage appear; but profound collapse is not often present when the pancreas alone is injured. In fact, symptoms may not arise for a considerable length of time after injury of the pancreas. A diagnosis at this stage is impossible without exploratory operation. Wohlgemuth and Noguchi claim that within a few hours of a pancreatic injury there is an increase of diastase in the blood and urine ("Berlin. klin. Wochen.," xlix, 1912). If this observation be correct we have a very valuable diagnostic test. Severe injury of the pancreas is usually, but not invariably, fatal. After slight damage of the gland the patient may completely recover; but, as a rule, he partly recovers, and, after a number of weeks, a smooth enlargement, palpable in the epigastric region, is formed. When operation is performed this mass is found to be back of the stomach. It contains a quantity of fluid blood, clot, and pancreatic fluid. Such a fluid collection is in the lesser peritoneal cavity and is called a cyst, though it is not a true cyst of the pancreas. It is a pseudocyst. Robson and Moynihan, in their valuable treatise on "Diseases of the Pancreas," explain the formation of this collection of fluid as follows:

The injury lacerates the posterior layer of the lesser sac of the peritoneum and the pancreas, to which it is adherent. Blood and pancreatic fluid enter the lesser peritoneal sac. Peritonitis follows. The foramen of Winslow becomes blocked by adhesions; and the lesser peritoneal cavity, being now a closed sac, is distended by a serous exudate mixed with blood and pancreatic fluid. Collections of this character form very rapidly, and several pints may gather in a few days. Other results of injury to the pancreas are abscess, pancreatitis, and true cyst formation. A fistula may follow operation for rupture of the pancreas. Such a fistula is very troublesome, often refuses obstinately to heal, and the pancreatic fluid macerates the skin severely.

Treatment.—Operation is imperatively demanded, although the prospects are bad. Garré collected 8 cases, 3 were operated upon, and all died. He reported a successful case of his own (loc. cit.). The pancreas was torn in two and the pieces were separated. The splenic vessels were uninjured. The two portions of gland were sutured together. This stopped the bleeding. Gauze-packing was introduced. Mikulicz ("Proceedings of Amer. Surg. Soc.") in 1903 collected 21 wounds and 24 crushes of the pancreas. Twelve of the wounds were due to bullets and 9 were stabs. Five of the 12 gunshot wounds were operated upon, with 2 deaths. All unoperated upon died. The 9 patients who had been stabbed were all operated upon and only 1 died. In a gunshot wound of the abdomen, when exploration leads the surgeon to surmise that the pancreas has been injured, this organ is usually approached by dividing either the gastrocolic omentum, the transverse mesocolon, or the gastrohepatic omentum. It can be easily exposed by separating the great omentum and its mesentery from the colon (the epiplo-enterocolic method). Accessory injuries must be carefully noted, and if a bullet has penetrated the posterior wall of the stomach, the pancreas is almost certain to be damaged. One should remember that, as Park says, even after opening the abdomen it is difficult to explore the pancreas, especially in a stout person. If there is no evidence of posterior perforation of the stomach by a foreign body, one may

assume that the pancreas has escaped. When the pancreas is exposed, if it is found to be bleeding, the bleeding vessels should be ligated and the tear in the gland should be sutured with catgut, care being taken not to puncture the main duct of the gland. If this duct has been cut, it should be carefully sutured. In some cases of gunshot wound it is necessary to resect a portion of the gland. At the termination of an operation upon the pancreas posterior drainage, preferably at the costovertebral angle, should always be obtained. It is necessary to drain away all escaping pancreatic fluid, as it tends to cause necrosis of tissue with which it comes in contact.

In cases of crush with pancreatic injury the associated injury to other structure usually proves rapidly fatal, but in a less severe case the abdomen may be opened for exploration, and if this is done, the surgeon should proceed as previously directed.

The question of excising a lacerated portion of the pancreas is one of great interest. It is known that dogs have lived for some time after complete excision of the pancreas. Four-fifths of the pancreas can be removed from a dog without producing permanent glycosuria, but if more than this is removed the dog develops saccharine diabetes and eventually dies of it. In man, quite large-sized pieces of the gland have been removed and recovery has followed. Hence it is justifiable to excise a hopelessly damaged portion, bearing in mind Park's caution that the chief danger in excising a portion of the pancreas is injury to the splenic artery.

Wounds of the Pancreas During Operations on the Stomach and Spleen.—In the performance of gastrectomy, partial or complete, the pancreas will be injured if the growth or ulcer be adherent to it. Such an accident is held by most operators to increase mortality greatly. The Mayos report 448 resections of the stomach for benign and malignant disease. The average mortality was 10 per cent. In 8 per cent. of these cases the pancreas was injured, and the average mortality of such cases was only 11 per cent. (Wm. J. Mayo, in "Annals of Surgery," August, 1913). The injuries reported by the Mayos were superficial at the point to which the stomach adhered. In no case was the main duct opened. It was noticed in these cases that local peritonitis had caused the formation of a fibrous capsule. Bleeding was controlled by suture-ligatures of catgut. The pancreatic wound was not sutured. As stated on page 1224, if the pancreas is wounded during pylorectomy, the closed end of the duodenum is placed in the pancreatic wound and the anterior peritoneum and adventitious sheath is sutured to the anterior portion of the duodenum. If an ulcer of the posterior wall of the stomach is adherent to the pancreas, transgastric excision removes considerable pancreatic tissue. Such a wound is not sutured, but the gap is filled by a mobilized bit of gastrohepatic or gastrocolic omentum (Wm. J. Mayo, Ibid.). In 2 of my cases of splenectomy I damaged the pancreas, tying off a bit of the tail with the splenic vessels. In 1 case leakage occurred and death followed, anterior drainage having been employed. In the other case there was profuse drainage for several days, which was carried off by a posterior drain. This patient recovered. Both were cases of Banti's disease.

Pancreatic Fistula.—A fistula may follow a wound of the pancreas. It is a very troublesome condition, often refuses most obstinately to heal, and the pancreatic secretion causes maceration and violent irritation of the adjacent skin. The usual treatment is to keep the way open for easy drainage. Wohlgemuth's plan is promising ("Berliner klin. Wochen.," 1908, No. 8). He reported 5 successful cases. I have had 2 cases. Each followed operation upon a pancreatic cyst. The treatment consists in feeding upon strict antidiabetic diet and in giving large doses of bicarbonate of soda before and after meals. By cutting off carbohydrates a powerful stimulus to the flow of pancreatic juice is removed. The bicarbonate of sodium lessens the acidity of the

stomach contents. The more acid the contents which enter the duodenum, the greater the flow of pancreatic juice; the less acid, the less the flow.

Displacement of the Pancreas.—In cases of splanchnoptosis the pancreas may become considerably displaced, though this condition cannot be recognized without opening the abdomen. It may be a portion of the pedicle of a movable spleen. So far, I know of no case in which fixation has been attempted, though, of course, theoretically it could be done. The pancreas has been found in umbilical herniæ. In 10 per cent. of diaphragmatic herniæ the pancreas constitutes part of the contents. Körte collected 8 cases in which the pancreas prolapsed through an abdominal wound. In several cases in which the pancreas prolapsed into an abdominal wound the protruding part has been excised. In other cases it has been restored.

Pancreatitis often leads to the production of jaundice; always to very rapid loss of weight; occasionally to the presence of fat and sugar in the urine; sometimes to the presence of fat in the stools, and frequently to the condition known as fat necrosis. Robson and Moynihan[1] point out that when there is no diarrhea and the stools contain undigested muscle-fiber, one may assume that there is a deficiency in pancreatic juice. When there is a blockage to the secretion from the pancreas, if salol be given by mouth, salicyluric acid does not appear in the urine. The test is made by putting 15 gr. of salol into gelatin capsules hardened with formalin (Sahli) and giving them with a roll and a cup of water. If pancreatic ferment is in the intestine, salicyluric acid appears in the urine in from three-quarters of an hour to one hour; if the ferment is absent from the intestine, salicyluric acid is not found in the urine because the salol is not split up and absorbed. The test for the acid is ferric chlorid, which, in the presence of the acid, turns the urine violet. The general cause of pancreatitis is infection. Often obstruction of the common duodenal outlet of the pancreatic duct and common bile-duct is followed by infection and suppuration of the pancreatic ducts and pancreatitis. Besides the general cause, which is infection, various exciting causes may be named, among which are gall-stones in the common duct and calculi in the pancreatic ducts, traumatism, cancer of the stomach or duodenum, catarrh of the stomach or duodenum, and many infectious diseases. It thus becomes evident that the infection may be by way of the blood; but, undoubtedly, in the vast majority of cases, the infection comes from the duct, or gall-bladder by way of the lymphatics. One manner in which the disease may be produced was suggested by Halsted and Opie, of Baltimore: A stone becomes impacted in the duodenal outlet of the common duct and pancreatic duct, the pancreatic duct, where it emerges above the common duct, not being blocked. The bile and pancreatic juice are thus prevented from entering the duodenum, and the bile flows back into the pancreatic ducts. Swelling of the papillæ could act in the same way. So could a plug of mucus. It is thought that overacid duodenal contents may enter the duct and produce pancreatitis. Deaver and Pfeiffer ("Annals of Surgery," 1913, 58) believe that pancreatitis is lymphangitis. J. E. Sweet ("Internat. Clinics," vol. iv, Series 25) makes the subject clear. According to that investigator not all acute cases are due to stones in the ampulla but whether caused by stones or not infection is the real cause. Infection kills cells, sets free in the tissues an agent which activates trypsinogen into trypsin, trypsin digests living tissue, erodes blood-vessels, causes hemorrhage and perhaps gangrene. If infection takes place without activating the proteid ferment, an abscess forms. Infection of the interlobar connective tissue is chronic pancreatitis. It is lymphangitis. Pancreatitis is predisposed to by obesity and arteriosclerosis (Balch and Smith, "Publications of the Mass. Gen. Hosp.," Oct., 1911).

That strange condition known as *fat-necrosis* is often present in pancreatitis. In fat-necrosis the fat is decomposed into fatty acids and glycerin. The

[1] Robson and Moynihan, on "Diseases of the Pancreas."

glycerin is absorbed, but the fatty acids unite with calcium salts and remain in the tissues, forming patches of yellowish-white color and varying size. These patches are found in the fat beneath the peritoneum, in the omentum, and in the mesentery, and even in distant parts (for instance, the pericardium).[1] It is an undoubted fact that fat-necrosis is not uncommonly found after diseases and injuries of the pancreas; and many assume that it is produced by the entrance of the ferment of the pancreas into the fatty tissue. How the ferment gets there is a matter of some doubt. In the case of a wound of the pancreas one can understand the flow of the secretion and its imbibition by adjacent parts; but in other cases one must assume that it has been absorbed by the lymphatics and distributed to more distant parts. When one reflects that in some conditions of the pancreas there is no fat-necrosis, while in others this condition arises, it is presumable that the pancreatic conditions associated with it are such as to permit the fat-splitting ferment to diffuse into neighboring tissues.

In pancreatic disease *hemorrhage* into that organ is common. The hemorrhage is not, of necessity, fatal, but frequently is so. Occasionally death takes place as the result of sudden pancreatic hemorrhage in a person apparently in excellent health. It is thought by Robson and Moynihan that during the existence of cancer of the pancreas there is a strong tendency to excessive hemorrhage after any operation. In 1 case of my own the patient bled to death after the performance of cholecystostomy for obstructive jaundice. The oozing of blood in this case was from the margins of the gall-bladder and the adjacent peritoneal surfaces. We, therefore, conclude that in certain conditions of the pancreas there is a tendency to local hemorrhage in that organ; and that there may also be a tendency to the development of a general hemorrhagic diathesis, the general hemorrhagic tendency being much increased if jaundice exists. During acute inflammation of the pancreas hemorrhage is almost certain to occur into that gland; in other varieties of inflammation hemorrhage may occur or may be absent. In degenerative lesions of the pancreas a material like unfermented pentose is frequently present in the urine. When the reaction for this material is obtained we speak of it as the *Cammidge reaction*, after its discoverer. (For Cammidge's improved method, see "Brit. Med. Jour.," May 19, 1906.) The Cammidge reaction is not by any means conclusive proof of organic pancreatic disease. It may be found in a great variety of other conditions (gall-stones, cholecystitis, gastric carcinoma, burns, etc.). In most patients who exhibit it there is arteriosclerosis and, of course, this condition might affect pancreatic secretion (Watson, "Brit. Med. Jour.," April 11, 1908). My own views coincide with those of Swan and Gilbride ("New York Med. Jour.," April 23, 1910). They believe a positive reaction indicates disturbed pancreatic function, but not, of necessity, organic disease.

Forms of Pancreatitis.—This disease is divided by Robson and Moynihan into the acute, the subacute, and the chronic forms; and they say that recorded cases demonstrate the fact that three distinct classes of inflammation may arise: (1) Cases that die within forty-eight hours from the beginning of the trouble. In this group hemorrhage is usually found, and if fat-necrosis is present, it is limited in area. (2) Those that live for some weeks after the beginning of the trouble. In these cases the pancreas may become necrotic or suppuration may occur. Fat-necrosis is usually widespread. (3) In the third class of cases long-continued inflammation or repeated attacks produce sclerosis of the pancreas.

Acute Pancreatitis.—Normal pancreatic juice does not digest living pancreatic tissue. In acute pancreatitis the tissue is digested. Bacterial infection reaches the pancreas and kills cells. The dead cells furnish a substance which activates trypsinogen into trypsin and trypsin digests living tissues. If material from the duodenum reaches the pancreas trypsinogen will be activated. If

[1] Robson and Moynihan, on "Diseases of the Pancreas."

pancreatic drainage is blocked (as by a stone in the diverticulum) infection may be inaugurated and existing infection intensified. It digests or ruptures the walls of the small ducts and diffuses through the gland, producing necrosis of gland tissue, exudation into gland tissue, necrosis of the blood-vessels, and, in consequence, hemorrhage (Balch and Smith, in "Publication of Mass. Gen. Hosp.," Oct., 1911). Hemorrhage usually but not invariably occurs. It is apt to be profuse. A part of the gland or the entire gland may be involved. Fat-necrosis occurs from the action of the fat-splitting ferment which does not require activation. A part of the pancreas or the entire gland may become gangrenous.

The *symptoms* of this condition come on suddenly and consist of violent pain in the epigastric region, but seldom marked tenderness, usually vomiting, constipation, weakness of the circulation, slow or moderately rapid pulse, cold extremities, and collapse, with a great fall in blood-pressure. The temperature is normal or moderately elevated. Some maintain that collapse is due to trypsin; others, that it results from the absorption of toxic products from the gland. The pain is extremely violent and is intensified in paroxysms, and there is rigidity of the epigastrium. In some cases there is appreciable tenderness. The patient vomits the contents of the stomach and then bilious matter. Distention soon becomes distinct in the upper portion of the abdomen. The patient presents the appearance of one suffering from peritonitis. This condition is not unusually mistaken for intestinal obstruction, but in acute pancreatitis the constipation is not absolute; the patient passes gas, and may even have a bowel movement as the result of the administration of an enema. The condition is usually fatal within a few days but may last for many days, but in very rare instances recovery takes place. In acute pancreatitis from stone in the common duct there is no leukocytosis (Murphy). In some cases of pancreatitis from other causes there is high leukocytosis.

The *diagnosis* cannot be made with certainty and is merely an inference. Reginald Fitz told us that the existence of this disease should be suspected when a person previously in good health, or who has complained only of occasional attacks of digestive disorder, is suddenly seized with severe pain in the epigastric region, followed by vomiting and collapse; and when, within twenty-four hours or more, there appears a circumscribed swelling in the epigastrium which is resistant or tympanitic. Visible oil in the stools, a Cammidge reaction, or sugar in the urine add probability to a diagnosis of pancreatitis. When an exploratory incision is made in the abdomen, if fat-necrosis is detected, the diagnosis becomes certain. The peritoneal cavity may contain thin, bloody fluid.

Treatment.—Operation was suggested by Naunyn in 1903. Just as soon as the patient has been roused from shock, exploration is made by way of the abdomen. Robson operates at once, even in shock. It is quite true that the patient might, if let alone, pass through the acute stage, and that a local abscess might then form, the treatment of which would be obvious. But the danger of waiting is too great to justify delay, and if suppuration should occur it might not remain local, but might spread widely in the retroperitoneal tissues. When observation after exploratory incision into the greater cavity of the peritoneum suggests the existence of acute pancreatitis, the infected area should be exposed, preferably above the stomach, through the gastrohepatic ligament. The pancreas should be incised, necrotic tissue should be removed, hemorrhage should be arrested by ligation or packing, the gauze pack emerging above the lesser curvature, a stab incision should be made at the costovertebral angle, and posterior drainage should be made from the lesser peritoneal cavity. One should follow the rule laid down by Roswell Park, and explore in every case in which the disease is suspected to exist. Of Körte's 16 cases operated on during the first week 11 recovered ("Annals of Surgery,"

1911, vol. lv). Of Balch and Smith's cases ("Publication of Mass. Gen. Hosp.," Oct., 1911), 11 were operated upon within three days, and 3 recovered. The two authors just quoted state that the Massachusetts General Hospital records for twenty-one years show only 1 victim who recovered without operation. Mikulicz ("Annals of Surgery," 1903,) recorded 75 operations for acute pancreatitis. In 36 the pancreas was attacked surgically with 25 recoveries. In 41 the pancreas was not directly attacked and only 4 recovered.

Subacute pancreatitis comes on suddenly, with violent pain, vomiting, and constipation, but there is far less exhaustion and weakness than in the acute form. The vomiting is less marked and the swelling in the epigastric region is not so rapid. The symptoms are similar to those of the acute form, but not so violent nor so rapidly progressive. The temperature frequently rises higher than in the acute form, and it may become irregular or chills may occur. In many cases the patient seems to grow better after a time, the violent pain abating, though distinct pain may remain, but he does not gather strength and continues to lose flesh, and there is usually albumin and there may be sugar in the urine. In rare instances fat is found in the urine. In subacute pancreatitis abscess is prone to form. The abscess may make a distinct swelling in front, and may lead to the development of a subphrenic or of a perirenal abscess. In rare cases an abscess of the pancreas tracks its way for a long distance in the subperitoneal tissue; occasionally it opens into the stomach or bowel. Cases of subacute pancreatitis usually die, but occasionally recover after a long illness.

Treatment.—Exploratory incision. Expose the pancreas, preferably by dividing the gastrohepatic ligament; determine its condition; remove purulent matter and necrotic areas; arrest hemorrhage with packing, and insert posterior drainage at the costovertebral angle. Leave the anterior wound open for the emergence of the gauze packing.[1] Drainage of the gall-bladder has been recommended, but, as a matter of fact, it gives, as a rule, but temporary relief.

Chronic Pancreatitis.—There are many causes which favor the development of chronic pancreatitis, viz., syphilis, alcohol, bacteremia, block of the common duct (stenosis, stone, etc.), extension of inflammation from the bile-ducts, and ascending infection from the duodenum. It is a lymphangitis of the interlobular tissue and is due to infection. It usually results from disease of the bile-passages and is often associated with gall-stones. In 2200 operations performed by the Mayo brothers on the gall-bladder and bile-ducts, the pancreas was found diseased 141 times (6.4 per cent.).

In 168 cases of pancreatic disease on which they operated 81 per cent. were caused by or, at least, associated with gall-stones. In operations upon the common or hepatic ducts the pancreas was diseased in 18.6 per cent. of cases. It was diseased in 4.45 per cent. of cases of operation upon the gall-bladder. Chronic pancreatitis produces enlargement of the organ, and the enlarged area is hard and feels like a malignant growth. This condition is more common than the acute or subacute form. Robson and Moynihan have operated upon 30 cases. This disease is frequently associated with gall-stones or with stones in the pancreatic duct, and occasionally with ulcer of the stomach or of the duodenum. In some cases symptoms of the condition come on acutely. Pain, nausea, and vomiting occur, and jaundice develops rapidly, as it does after the passage of a gall-stone. It is noted, however, that the pain is not in the region of the gall-bladder, but is in the middle of the epigastrium, and it passes to the left rather than to the right. The tenderness, too, is in the middle of the epigastrium and not in the gall-bladder region. There is either constipation or diarrhea. A series of these attacks may occur, the jaundice growing worse after each attack. In some cases, however, the condition comes on gradually and insidiously, the pain slowly developing, but no violent seizures taking

[1] Roswell Park, "Annals of Surgery," December, 15, 1901

place. There are rigidity of the rectus muscles, rapid loss of flesh, anemia, sometimes bronzed skin, usually vomiting, and considerable flatulence. The gall-bladder is enlarged and commonly palpable.

In some cases it is possible to palpate the inflammatory mass. There may be irregular fever and chills with episodes of subnormal temperature. None of the above indications are conclusive signs of disturbed pancreatic function. Signs of disturbed function of the gland are of great importance in making the diagnosis, and these signs are glycosuria and impaired power of digesting fats and proteins (Walko, in "Archiv. f. Veranungskrankheiten," 1907, xiii). Fatty stools containing unsaponified neutral fat are very significant.

The jaundice in chronic pancreatitis results from compression of the duct by the hyperplastic mass, or blocking of the duct by a stone. Stenosis of the duodenum may occur. In jaundice from chronic pancreatitis capillary hemorrhage is particularly common (Robson). Mayo Robson attaches much importance to the Cammidge reaction. In the Jefferson Hospital we regard it as often of decided use, but we do not as yet attach as much importance to it as do some other clinicians. This reaction, when present, indicates degenerative disease of the pancreas. It is obtained when the urine contains a substance having the characteristics of unfermented pentose.

Treatment.—Drainage of the gall-bladder has been the usual treatment either by cholecystostomy or cholecystenterostomy. It may cure a case but in many cases the benefit is temporary and after a time the symptoms are apt to return.

Wm. J. Mayo ("Am. Jour. Med. Sciences," 1914) says: "In at least half of the cases operated on in our clinic the following sequence has occurred: Cholecystostomy had been done for chronic cholecystitis without stones, and with a complicating chronic pancreatitis. The patient was relieved for some weeks or months and then the symptoms returned." Drainage was again instituted and there was perfect relief so long as drainage was continued but when the fistula closed the symptoms returned. Mayo now removes the gall-bladder and finds that a permanent cure is obtained.

Pancreatic Calculi.—When the pancreatic secretion is blocked, stones tend to form; and the blocking may be due to inflammation of the duct of Wirsung, or may result from chronic pancreatitis. The stones may be single or multiple.

Symptoms.—There is pain in the epigastric region, which usually comes on in paroxysms that resemble those due to gall-stones, though they are not so violent. Pain is accompanied by vomiting, exhaustion, and sometimes actual collapse, and may be followed by rigors. Portions of stone are sometimes recovered from the feces, and sugar is occasionally found in the urine. Fat has also been noted in the stools in some cases. Sometimes jaundice develops because the calculus presses upon the common duct. Pancreatic calculi are composed of lime salts and can be skiagraphed.

Treatment.—Pancreatic calculi have, in rare instances, been removed by operation; and this is the proper procedure when the diagnosis can be made. The diagnosis is, however, possible only after exploratory incision. As a rule, no operation is performed until a cyst results or an abscess forms; and when the cyst or abscess is opened fragments of stone may be found in the fluid, and stones may subsequently come away in the resulting fistula. My colleague, Prof. Nassau, removed successfully a pancreatic calculus.

Pancreatic Cysts.—Pancreatic cysts are rare. In 5000 consecutive abdominal operations performed at the Mayo clinic there were 2 for pancreatic cyst. Many forms of cyst may develop in the pancreas; the following are set forth by Robson and Moynihan: (1) Retention cysts; (2) proliferation cysts, including cystic adenoma and cystic epithelioma; (3) hydatid cysts; (4) congenital cysts; (5) hemorrhagic cysts; (6) pseudocysts. What we speak of as pseudocysts have already been considered in discussing effusions into the lesser peri-

toneal cavity. They result from lacerations of the pancreas (see page 1193). Retention cysts are due to blocking of the duct of Wirsung or of smaller ducts. The block may be due to stricture, calculus, or primary chronic inflammation. Undoubtedly chronic pancreatitis plays a great part in the production of retention cysts. Blocking causes dilation, acini fuse, and a cyst forms. Such a cyst is accompanied by diffuse pancreatitis involving a considerable portion of the pancreas and seriously affecting metabolism and secretion. One-third of such cysts follow traumatism. Proliferation cysts are neoplastic and are very rare. In 1907 Kleinschmidt could collect from literature 21 cases only. Fifteen of these cases involved the tail alone. Any chronic pancreatitis is limited and disturbances in secretion and metabolism are slight or absent until late in the case. Proliferation cysts are not caused by traumatism. Congenital cystic disease is extremely rare. Hemorrhagic cysts result from hemorrhage into the substance of the pancreas itself.

Symptoms.—Cysts are somewhat more common in men than in women. A cyst of the pancreas proper is more often met with in the head of the organ than in its body or tail. The cyst may be single or multiple. In its growth it either destroys the substance of the pancreas or it grows away from the pancreas and damages it but little. In some cases the cysts grow to a very large size; and Robson and Moynihan refer to a case in which the cyst attained the size of a man's head, and to another in which it was the size of a full-term pregnancy. A pancreatic cyst is smooth, round, elastic, and rather tense (Robson and Moynihan). The contained fluid varies greatly. As a rule, it is brownish-red in color; in 1 case upon which I operated it was clear yellow; in some cases it is milky, and in others it is nearly black. The fluid is always albuminous. Urea may be present, and in many cases pancreatic ferments are found. In most cases the cyst adheres so closely to the surrounding structures as to render extirpation practically impossible. A pancreatic cyst of considerable size causes epigastric discomfort, pain during digestion, and frequently vomiting. In some cases the pain is trivial, in others it is very violent. As a general rule, the patient is constipated, but sometimes diarrhea occurs, and the movements may even contain blood. If the tumor presses upon the common bile-duct, jaundice will develop. In some cases the patient loses flesh markedly and with considerable rapidity, and he becomes very weak. A large cyst causes marked pressure symptoms. Joseph Ransohoff ("Surgery, Gynecology, and Obstetrics," March, 1916) had charge of a case in which the pressure of a cyst upon the left renal vein caused unilateral hematuria. In rare instances fat is present in the stools, and in other unusual cases sugar is found in the urine. A test should always be made with salol, to see whether pancreatic ferment is present in the intestine (see page 1195). In the beginning the pancreatic cyst is behind the stomach; but it enlarges and, as a rule, pushes the stomach upward and to the right side, and the transverse colon downward. The cyst approaches the surface of the abdomen below the greater curvature of the stomach (Robson and Moynihan). The same authors tell us that in rare cases the cyst appears at the upper border of the stomach, and that in others it inserts itself between the layers of the transverse mesocolon. In a case upon which I operated it had worked its way through the subperitoneal tissue into the right loin, and was looked upon by Professor Montgomery and myself as a hydronephrosis. As a rule, the pancreatic cyst is immovable, but in rare instances it is movable. When a hand is placed in the loin and another on the abdomen, ballottement may be appreciated. If the distended stomach or colon overlies the tumor there will be a tympanitic percussion-note, but when the tumor reaches the abdominal wall there will be a dull percussion-note. On inquiring into the history of these cases it will be found frequently that there has been a severe injury to the upper abdomen.

Treatment.—Exploratory incision makes the condition clear. In the majority of cases the cyst is incised, emptied, and stitched to the wall of the abdomen. This operation may be done in two stages—first, exposing the cyst and fixing it to the abdominal wall; second, when adhesions have formed, opening it. As a rule, however, it is performed in one stage, the abdominal cavity being carefully protected by gauze. Some authors advocate exposing the cyst, opening and evacuating it through the abdominal wound, and draining through the loin. Complete extirpation is usually impossible because of the adherence of the cyst. If the cyst is movable, extirpation may be carried out, but the safest operation consists of incision and drainage.

Tumors and Other Growths of the Pancreas.—The pancreas may be affected by sarcoma, carcinoma, adenoma, tuberculous disease, or syphilis. Primary tumors are very rare. In two-thirds of the cases of pancreatic cancer the growth involves the head. The body and tail seldom suffer. Most pancreatic cancers have an abundance of fibrous tissue. Billroth in 1884 removed an adenocarcinoma. Finney reported 1 case and collected 16 from literature which came to operation ("Annals of Surgery," June, 1910). He says the diagnosis can only be made by exclusion and that in 25 per cent. of cases the mass is not fixed, but is movable. In Finney's series of cases there were 9 recoveries and 8 deaths. Wm. J. Mayo reports the successful removal of a cyst with sclerosed pancreatic tissue (Ibid., August, 1913).

Treatment.—Attempts have been made to remove tumors of the pancreas. After an exploratory incision has determined the condition, the pancreas is exposed at the point at which the tumor projects. This is usually done by opening through the gastrocolic omentum. If the tumor is in the tail of the pancreas, however, the exposure may be effected in the flank. When the tumor has been exposed an attempt may be made to enucleate or resect it. Coffey ("Annals of Surgery," Jan., 1911) shows that ligation of the duct does not occlude it permanently. Tumors of the splenic portion of the pancreas have been removed. Total pancreatectomy or complete resection of the head of the gland should not be attempted.

In a large tumor of the head of the pancreas palliate the condition by cholecystenterostomy. Villar reports 13 cases of partial resection of the pancreas for tumors, with 5 recoveries from operation (French Surgical Congress of 1905). Finney's paper deals with 17 cases (see above).

Injuries and Diseases of the Spleen

Wounds of the Spleen.—Stab wounds of the spleen alone are rare. Those by way of the pleura are more common than those by way of the abdomen, hence in most stab wounds of the spleen the pleura and diaphragm are injured. A considerable wound of the spleen causes great hemorrhage and, if surgical aid is not soon at hand, will almost inevitably produce death. It is caused by a bullet or a stab and, as a rule, other viscera are also damaged. Immediate operation is indicated. Laparotomy alone is suited to few cases. In most cases the damaged structures can be reached by opening the abdomen through the diaphragm (that is, by enlarging the original wound). If the injury is from the front, and there are evidences of intra-abdominal hemorrhage, open the abdomen, divide the eighth, ninth and tenth costal cartilages to enter the pleural cavity and enlarge the wound in the diaphragm. In some cases remove the spleen. In some arrest bleeding by packing, by suture or by transplantation. If operation be performed promptly the mortality is under 20 per cent.

Rupture of the Spleen (Fig. 707).—Rupture may be spontaneous from distention if the organ is much congested and enlarged. Sometimes bleeding takes place beneath the capsule and at autopsy nothing can be found to account for it. If the capsule ruptures a subphrenic hematoma forms. In some cases a

cyst forms and bleeding takes place into the cyst. Rupture may occur in diabetes. Malarial spleens are prone to rupture. Traumatic rupture is far more common than spontaneous rupture. It is unusual if the organ be healthy, but does occasionally occur from crushes. It is rarely found unassociated with other injuries. The spleen may be dislocated as well as ruptured. An enlarged spleen is particularly liable to rupture not only from a crush, but from a kick, a blow, or a fall. Rupture of the spleen produces pain in the lower part of the left side of the thorax and in the left hypochondriac region, and rigidity in the left hypochondriac region and the signs and symptoms of intra-abdominal hemorrhage. There is tenderness over the spleen, pain over the heart, and great shortness of breath. The bleeding is profuse, but sometimes slow. The splenic blood contains numerous leukocytes and clots rapidly, hence the bleeding may be arrested for a time, and if it should be the patient will not bleed to death rapidly and reaction will generally occur (Ballance). The blood in some cases clots so rapidly that it gathers in the left loin, and is not commonly diffused throughout the abdomen. A subphrenic hematoma forms. It gives rise to an increasing area of dulness on percussion in the left flank, which, Ballance points out, seldom shifts when the position of the patient is shifted, as it does in bleeding from other intra-abdominal structures. In some cases, however, the blood remains fluid and spreads throughout the belly, and then there is rising dulness in each flank. The cases reported by Le Dentu and Mouchet show that the blood may remain fluid ("Bull. de l'Academie de Med.," June 16, 1903). In some cases the signs of hemorrhage are late and they may even be deferred until the fourth day (Eisendrath, "Annals of Surgery," Dec., 1902). In some cases there is violent pain in the left shoulder (*Kehr's sign*). Exploratory incision will be required to recognize the condition positively. In Elder's table there are 52 uncomplicated cases, not a case was operated upon (operation was not the rule until 1890), and 84.6 per cent. died. Eisendrath[1] has collected 50 cases operated upon: 56 per cent. recovered and 44 per cent. died. Février[2] has collected 56 ruptures of the spleen. In 46 cases operation was performed and the mortality was 50 per cent. E. Berger ("Archiv. für klinische Chirurgie," Bd. 28, Heft 3) collected 168 fatal cases of rupture of the spleen: 145 died during the first day and every one of them died from hemorrhage. After the first day 23 died. In 90 per cent. of the entire series hemorrhage caused death; in 10 per cent. infection was responsible for death. Vedova collected 194 cases of splenectomy for traumatic rupture, with 65 deaths, a mortality of 33.5 per cent. ("Practical Medicine Series," vol. ii, 1913). Hemorrhage is the great danger in ruptured spleen—hemorrhage from the parenchyma rather than from the great vessels. The parenchyma is friable and contains multitudes of capillaries and veins, there is no muscular tissue, divided vessels do not tend to contract,

FIG. 707.—Fauntleroy's case of ruptured spleen. External surface.

[1] "Jour. Am. Med. Assoc.," Oct. 25, 1902.
[2] "Rev. de Chir.," Nov., 1901.

and the capsule is thin (the elder Senn, in "Jour. Am. Med. Assoc.," Nov. 21, 1903).

Treatment of Wounds and Rupture.—The treatment is evident from the previous remarks. It is as follows: Open the abdomen immediately, the patient being surrounded with hot bottles and hot salt solution flowing into a vein. Explore the spleen and other viscera. If the spleen is damaged, we may do splenectomy (total or partial), may use the suture, the cautery, or the tampon, and any other visceral injuries are, of course, attended to.

The usual operation has been total splenectomy. In partial splenectomy only the injured part is excised and the wound margins are sutured.

The arrest of hemorrhage by suture is known as *splenorrhaphy*. Lamarchia, in 1896, was the first to perform this operation. The tear or wound is sutured with catgut and the suture line is covered with omentum. Berger collected 14 cases of suturing, with 2 deaths, but these were injuries of less severity than those requiring splenectomy. In some cases the tampon can be used. Berger collected 10 cases, with 1 death. Another method is to crush the splenic structure slowly with broad forcipressure forceps and suture the crushed margins with catgut. Senn followed this plan. George Ben Johnston (paper read before Johns Hopkins Med. Soc., March 2, 1908) has collected 150 cases of splenectomy for wounds or ruptures, with 99 recoveries and 51 deaths, a mortality of 34 per cent.

Abscess of the spleen is a rare condition which is usually metastatic in origin. It may follow pneumonia or typhoid, may develop during pyemia, or may result from injury. Chronic suppuration may be due to tuberculosis or actinomycosis. Some chronic cases are almost free of symptoms. There are pain and tenderness if the serous membrane be involved, otherwise they may be absent. There may be simply a feeling of heaviness. In many cases enlargement is noted in the splenic region, and the symptoms of pyemia exist. In acute cases there will be chills, fevers and sweats. Leukocytosis exists but may not be excessive. The abscess may become adherent to the belly wall, may become encapsulated, or may rupture into a viscus or the peritoneal cavity. Fluctuation can seldom be obtained. What is known as a tropical abscess (Fontoynant and Jourdrau, in "Archiv. Prov. de Chir.," No. 11, 1902) may develop during a malarial attack as a result of severe exertion. There are severe pain in the left hypochondrium, dyspnea, and dry tongue. There may or may not be fever. The pus may be sterile.

The **treatment** of abscess of the spleen consists in incising the abdomen at the outer edge of the left rectus muscle, suturing the spleen to the abdominal wall, opening the abscess, and providing for drainage (Tédenat[1]). If the abscess is adherent to the abdominal wall, incise it directly. Splenectomy has been performed for abscess. In 9 recorded cases of splenectomy for abscess there was 1 death (George Ben Johnston, paper read before Johns Hopkins Med. Soc., Mar. 2, 1908).

Enlargements and Tumors of the Spleen.—(See Royale H. Fowler, in "Long Island Med. Jour.," July, 1911.) The spleen undergoes hypertrophy in the course of infectious disease, from amyloid disease, from malaria, from splenic anemia, from tuberculosis, from leukemia, and from Hodgkin's disease. Secondary cancer is seen after cancer of the stomach. Genuine primary tumors are extremely rare. Fibroma, enchondroma, hemangioma, lymphangioma, angioma, and sarcoma occasionally develop. Jepson and Albert reported a case of primary sarcoma of the spleen and collected 31 others from literature ("Annals of Surgery," July, 1904). Primary carcinoma can only arise from fetal inclusion. It is usually medullary and is sometimes melanotic. Secondary carcinoma and secondary sarcoma are more common. Echinococcus cysts, dermoid cysts, lymph cysts, serous cysts, and blood cysts occasionally

[1] "Rev. de Gynéc. et de Chir. Abd.," July, August, 1901.

develop. The spleen alone may suffer from hydatid disease. The liver is apt to be also involved. "There is but a single recorded case of dermoid cyst. It was reported by Andral in 1830" (Royale Hamilton Fowler, in "Surg., Gynec., and Obstet.," August, 1910).

Non-parasitic cysts may be unilocular or multilocular.

A blood cyst is usually preceded by injury or an infectious disease. A serous cyst may result from a hemorrhagic cyst, and a blood cyst may be due to hemorrhage into a serous cyst (Fowler, Ibid.). There are on record 12 cases of splenectomy for sarcoma: 9 recovered and 3 died (George Ben Johnston, Loc. cit.).

Treatment.—The condition may become clear after exploratory laparotomy only. For some tumors splenectomy is indicated. A hydatid cyst is treated as is a hydatid cyst of the liver (see page 1172). A blood cyst is sutured to the incision in the abdominal wall and is drained.

Splenoptosis, or Wandering Spleen.—The spleen may wander into any part of the general peritoneal cavity. This condition is seldom met with except in women. It is most common in women who have borne children. A wandering spleen may undergo atrophy, engorgement, or axial rotation (Sir J. Bland-Sutton). The spleen may be healthy or enlarged from malaria or leukemia. As a matter of fact, it is usually diseased. The organ when displaced drags upon the stomach, producing dilated stomach; it may interfere with the bile-duct, causing jaundice; it may cause intestinal obstruction by forming adhesions, or may cause uterine retroflexion or prolapse by passing into the pelvis.

Sir J. Bland-Sutton[1] says this condition may endanger life, as it may lead to rupture of the stomach, intestinal obstruction, splenic abscess, or splenic rupture. A wandering spleen can be identified by the fact that it has a notch upon its edge, and can be pushed about the abdomen. When the spleen wanders it may be missed from its normal situation. Always examine the blood in order to determine if leukemia or malaria exists.

Treatment.—Greiffenhagen advocates suturing the organ in place (*splenopexy*). Most surgeons prefer to perform splenectomy. In a case without leukemia the operation is very successful. Splenectomy for wandering spleen is rarely followed by serious blood changes or other trouble. The reason is that a wandering spleen is usually a diseased organ, having undergone hypertrophy or fibroid change, and other structures have taken on splenic function. Splenectomy should not be undertaken if leukemia exists. In such a case surgeons usually apply a support and employ medical treatment for the existing disease, but some endeavor to suture the organ in place. If the wandering spleen were enlarged by malaria, I would perform splenectomy. If the spleen were healthy I would surround it with gauze exactly as is done with the kidney in a case of movable kidney. If the spleen were enlarged by leukemia I would not operate at all.

Operations upon the Abdomen

Abdominal Section (*Celiotomy; Laparotomy*).—There are many different methods of opening the abdomen. The plan selected depends upon the nature and the situation of the disease, and upon the inclinations and the custom of the operator. The abdomen may be opened to attack a recognized seat of disease or injury or to determine what the disease or injury is and where it is situated. Abdominal section performed for the latter purpose is spoken of as exploratory section or exploratory incision.

An incision should not be unnecessarily lengthy, but it should be long enough to permit of thorough exploration and rapid and safe work. A very

[1] "Brit. Med. Jour.," Jan. 16, 1897.

lengthy incision favors visceral prolapse and renders the patient liable to hernia. Again, a lengthy incision requires longer to suture than a short one, and so operation is prolonged. James E. Moore protests against too small incisions, which are often made as a matter of pride ("Jour. Am. Med. Assoc.," Sept. 16, 1911).

Of recent years exploratory operations have become extremely common, and many abdominal conditions would be unrecognized without such exploration, or would be recognized at so late a period as to be beyond the reach of surgery after diagnosis. This is notably true of the surgical diseases of the stomach. The wise surgeon will not be too radical in employing exploratory operations. The fact that he can explore with such comparative impunity does not release him from the obligation to endeavor by every proper method to make a diagnosis before resorting to operation. I fancy that of recent years the belief that it is almost waste of time to make prolonged efforts to diagnosticate many intra-abdominal troubles because the solution is so much easier by section, has become so common as to have led young and unskilled operators to perform section in cases in which the diagnosis might have been made without this procedure.

Before opening the abdominal cavity for exploratory purposes or to gain access to some area of abdominal or pelvic disease the patient is carefully prepared as for any other operation. In an appendicitis case the patient is moved with the utmost care and is prepared for operation most gently, because of the possible danger of rupturing an abscess. In an emergency case no prolonged or complicated method of cleansing can be employed. The abdomen and loins are scrubbed carefully with soap and water, special attention being given to the umbilicus; the pubic region is shaved, the soap-suds are washed away with sterile water, the surface is gently scrubbed with alcohol and then with a hot solution of corrosive sublimate (1 : 1000), and is covered with gauze wet with the sublimate solution. In emergencies the iodin method can be used after dry shaving (see page 77). As previously stated (see page 76), we no longer regard it as necessary to "prepare" the abdomen the day before. The patient can be prepared antiseptically the morning of the operation, or can be shaved just before etherization, and be cleaned when under ether. The instruments required depend upon the nature of the case. Have at hand an electric light and appliances for throwing salt solution into a vein. Always have the instruments, sponges, and pads counted twice by two people, write down the number, and have two people count them twice after operation. This rule is adopted so that no instrument, sponge, or pad will be left in the abdomen. Some surgeons do not use abdominal pads and sponges when dry, believing that dry gauze injures the peritoneum and favors the subsequent development of adhesions (Sanger). Believers in this hold that pads and sponges should be wrung out in hot normal salt solution before being used. I find moist pads and sponges satisfactory, but moist packs cannot be satisfactorily adjusted. If dry packs are used, dry pads and sponges may as well be.

Operation.—An anesthetic is given. In some cases the patient is placed recumbent. A blanket, made into a roll, is placed in the hollow of the back to prevent sprain of the sacro-iliac joints, a common cause of postoperative backache. In some cases the *position of Trendelenburg* is employed (Fig. 708). In the Trendelenburg position the pelvis is elevated, the intestines fall toward the epigastrium, are removed from the necessity of being handled and from the danger of being bruised, the pelvis is thoroughly exposed, and pelvic work becomes easier and safer. This position should not be used if there is myocardial disease, as the increased pressure in and flow of blood from the inferior cava may cause fatal acute dilatation of the heart (Kraske, of Freiburg, in "Proceedings of German Surg. Congress," 1903). The position is of little use in very fat people (Trendelenburg), and in such subjects may cause intestinal obstruction (Kraske). When this position is employed, the table should be lowered as soon

as possible, to avoid gastric hemorrhage (von Eiselsberg). The normal position should not be suddenly assumed, as this may cause intestinal obstruction, the omentum being mixed with coils of intestine, pulling the colon down (Pasteau, in "Bulletins and Mém. de la Soc. Anat. de Paris," July, 1905). The position should not be used in a pelvic abscess (König), as it may lead to a flow of pus from the pelvis into the far more dangerous regions above.

Volvulus or kinking of the ileum and of the large intestine have followed the use of the position. Organic disease of the blood-vessels, heart, lungs or kidneys adds to the risk of ill effects from the position. The flexion of the legs often causes much pain and stiffness and may predispose to pulmonary embolism. If the Trendelenburg position has been employed, before closing the belly return the omentum to its proper position and spread it out (Lauenstein). In every abdominal operation the patient is to be carefully protected from cold, the extremities and the chest are covered with blankets, and sterilized sheets are placed well around the field of operation. The skin is sterilized anew immediately before operating. The surgeon steadies the skin of the belly with the fingers of his left hand, and, holding the knife free in the right hand, makes an incision. Incision may be in any region, and is made as long as is necessary. Incisions may be straight, curved, angled, vertical, transverse, or oblique. The vertical incision is most commonly used. For purposes of exploration the incision is made about 2 inches in length, and it is lengthened if it is found necessary. The abdomen may be opened in the median line above or below the umbilicus. This incision is advantageous for operations on the pelvis, for general exploration, and for certain procedures upon the stomach, the intestines, and the left lobe of the liver. The closure of such an incision, however, lacks strength, as compared with the closure of an incision where strong muscles will overlie the scar through the peritoneum and the transversalis fascia. Incision through the semilunar line is practised by a number of operators. A favorite incision is through the rectus muscle. The fibers of this muscle are separated, the structures beneath it are divided, and, after the completion of the operation, the deeper structures are sutured and the parts of the separated muscle are allowed to fall together. The scar resulting from such an incision is well supported and solid, hence the likelihood of hernia developing is diminished. A favorite method with some is to open the sheath of the rectus muscle, retract the entire muscle aside, incise the posterior portion of the sheath and the structures back of it, and, when the operation has been completed, allow the entire muscle to come back into place, thus strengthening the deep-seated scar. When the abdominal trouble is in a region that admits of it, I almost invariably go through the rectus muscle or retract the entire muscle. Besides these methods, there are special incisions, suitable for particular cases: An oblique incision along the costal margin, for reaching the gall-bladder; an incision shaped like the italic letter *f*, for the same purpose; special incisions for certain operations upon the stomach, for abdominal nephrectomy, etc. Some operators have even used a transverse incision in certain pelvic operations especially. Years ago Billroth at times divided the rectus muscles transversely. Many surgeons object to a transverse incision which divides the rectus muscles (the Mayos and Moynihan). Murphy did not object to the procedure. Moschowitz and Lilienthal warmly advocate it for certain cases. I never hesitate to divide one rectus for a gall-bladder operation. Retraction ceases at the nearest transverse lines. G. G. Davis makes a transverse incision outside of the rectus for appendectomy (page 1211). Farr (Ibid.) points out one advantage in the closing of a transverse incision. If there is any tension it can be greatly lessened by raising the

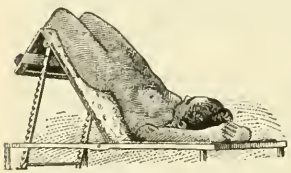

FIG. 708.—The Trendelenburg position.

shoulders in order to curve the dorsal and lumbar spine. (A full discussion of abdominal incisions will be found in an article by R. E. Farr, "The Journal Lancet," Nov. 1, 1912.)

In an operation through the median line the first cut goes to the aponeurosis of the external oblique muscle. Clamp the vessels. Do not hunt for the linea alba below the umbilicus, but go right through or between the recti muscles. Above the umbilicus the linea alba is very distinct and the surgeon often cuts through it. Divide the transversalis fascia, beneath which is a little fat, and expose the peritoneum. The latter structure is recognized by its glistening appearance, by the ease with which it can be pinched up between the finger and thumb, and by the readiness with which its opposed surfaces may be made to glide over each other. On identifying the peritoneum, catch it at each side of the incision with forceps, raise a fold, nick it with a knife, and open the layer by scissors to the length of the external wound. To prevent stripping of the peritoneum a good plan is to anchor it to the belly wall with a stitch on each side of the incision. Through the wound thus made the abdomen and its contents are explored, the trouble located, and determination made as to whether or not further operation be advisable, and, if it be advisable, what form it shall take. It may be necessary to enlarge the wound. This is done by placing the index and middle fingers of the left hand in the belly, with their pulps against the peritoneum, in the line where the surgeon will cut, to serve as supports to the scissors and as guards to intraperitoneal structures. The scissors are introduced and the wound is enlarged upward or downward, going around the umbilicus if necessary. As soon as the incision is complete for work in the lower abdomen or pelvis it is a good plan to push a large pad into Douglas's pouch and leave it there until the operation is finished, when it must be removed. Slender adhesions are stripped off with the finger or are pushed off with gauze; firm adhesions are tied in two places and cut between the ligatures.

The *toilet of the peritoneum* is important after the operation is completed. Following a clean laparotomy, when but little blood has flowed into the cavity, flushing is not required; if much blood has flowed or if septic matter has passed into the peritoneal cavity, after removing the pad from Douglas's pouch flush the belly thoroughly with hot normal salt solution. In a clean case empty out most of the fluid, but let a pint or more remain in the abdomen. In flushing the abdomen bear in mind Monks's observations as to the mesentery. It is a sort of shelf. If we follow down the left side of it with the finger the finger must enter the left iliac fossa; if we follow down the right side of it the finger must enter the right iliac fossa. Hence in order to flush the right cavity carry the nozzle down the right side of the mesentery to its root, and in order to flush the left fossa carry it down the left side of the mesentery to the root (Monks, "Annals of Surgery," Oct., 1903). The retention of the saline fluid in the belly minimizes shock. It is absorbed with great rapidity after the operation if the patient is placed with his head lower than his feet, because in this position the saline fluid gravitates to the diaphragmatic region, where absorption is very active; in fact, in one hour the peritoneal cavity can absorb from 3 to 8 per cent. of the body weight. If there be widespread infection with stomach contents or feces, eviscerate, wipe out the peritoneum with pads soaked in hot normal salt solution, and wipe the intestines carefully, slowly returning them as they are wiped. Extravasated septic matter is apt to collect in the peritoneal fossæ and between the liver and diaphragm, and these regions must be carefully wiped and irrigated. In cases of septic and purulent peritonitis, flushing, evisceration, and wiping with gauze are not advisable (see page 1162). In some cases it is desirable to drain through a lumbar incision. Rutherford Morison has pointed out that a lumbar opening into the right kidney pouch will drain a fossæ which holds over a pint of fluid, and which, when the patient is recumbent,

is the most dependent portion of the peritoneal cavity. In some cases a drainage-opening is made through the linea alba, through one side or on each side of the belly, or above the pubis or through the vagina. In septic cases it may be advisable to drain with several pieces of iodoform gauze instead of inserting tubes. After most laparotomies drainage is not needed, but it should be used when stomach contents were extravasated, and it must be used if feces or urine have been extravasated, in certain recent septic cases, and when hemorrhage has been severe. We may drain by a rubber tube, strands of gauze, a cigarette drain, or a glass tube. If a glass tube is used, it is introduced at the lower angle of the wound and reaches the bottom of the pouch of Douglas. The tube is repeatedly emptied during the progress of the case by means of a syringe. Before closing the wound arrest hemorrhage and ask for the count of the instruments and pads in order to know that nothing foreign has been left in the belly.

It is highly important that an abdominal incision shall be accurately closed, for any failure of neat approximation will, in all probability, result in the formation of a hernia through the cicatrix. Various methods have been employed. Probably the majority of operators use layer sutures, sewing up the peritoneum with a continuous suture of catgut, and the aponeurotic layers with the same material or with chromicized catgut, and closing the skin with either interrupted sutures of silkworm-gut or a subcuticular stitch of catgut, silkworm-gut, or silver wire. Other operators close the peritoneum with a continuous suture of catgut, then pass silkworm-gut sutures through all the other structures, leaving them for the time untied; put in and tie layer sutures of catgut or of chromicized catgut, and then tie the silkworm-gut sutures. A layer suture makes a beautifully neat approximation, and is frequently quite satisfactory; but I have become persuaded that the dead space, so often left unobliterated when this method of suturing is employed—a space in which blood and inflammatory exudate may gather—is a danger to the future integrity of the wound. The combination of a dead space with catgut, a material that is always somewhat uncertain, is an unfortunate one from the surgical point of view. I have returned in many cases to the use of the through-and-through suture, applied according to the method of the late Dr. Joseph Price. This suture is inserted with the straight needle, is composed of silk or of silkworm-gut, is put in close to the margin of the skin, gathers up a great deal more muscle than skin, and then passes close to the margin of the cut peritoneum and transversalis fascia. When these sutures are adjusted the peritoneal edges are brought into accurate and firm apposition, the peritoneal surface is overlaid with abundant muscle, the skin edges are brought into neat approximation, and the formation of a dead space is rendered impossible. When passing the sutures have a gauze pad under the wound and be very careful not to include bowel or omentum in the stitches. It is necessary to tighten and tie most carefully to prevent omentum being caught in the loop of the stitch. After closing a laparotomy wound, dress with aseptic gauze and apply a flannel binder. In badly infected cases the wound is often kept open.

If a 2-inch incision has been closed without drainage and primary union has taken place, the patient can usually get out of bed in seven or eight days. A large incision offers greater danger of subsequent hernia, and the patient should be kept in bed for two or three weeks. If the wound has been kept open for drainage, a prolonged retention in bed may be necessary. I allow patients up at an earlier period than used to be my custom, but I do not permit them to get up in one to three days as do Kümmel and others (Kümmel, in "Zentralblatt f. Chirurgie," 1908). To get them up reasonably early lessens constipation, favors an early return of appetite and strength, and diminishes the risk of postoperative thrombosis and embolism and of bronchitis. We must bear in mind that, if there be myocardial degeneration, the assumption of the upright posture very soon after abdominal section may prove disastrous or even fatal,

and that in septic diseases there is often myocardial degeneration (E. W. Foote, in "Progressive Medicine," June, 1909). In a case in which an incision of considerable length has been made, an abdominal support should be worn for a variable time. It limits the movements of cough, laughter, etc., and *reminds* the patient of the necessity of caution in lifting, hurrying, etc.

The after-treatment depends somewhat on the case, but certain general rules can be laid down. The late J. Greig Smith said many wise things, and among them this: "A golden rule in the treatment of cases of celiotomy is to let the patient alone. Everything approaching to meddlesomeness is to be condemned. The patient must not be upset by fussy applications of tentative therapeutics; when an emergency arises, it is to be met, promptly and decisively, by a method which has been approved trustworthy" ("Abdominal Surgery"). In many cases immediately after the operation the patient must be treated for shock by methods previously set forth. The treatment of vomiting resulting from the administration of an anesthetic is discussed on page 1343. If vomiting persists during the third or fourth day it may be due to acidosis, but is probably due to the development of inflammation which has caused intestinal paresis; and if it is so produced, medicine is practically useless. In this condition there is usually marked tympanitic distention, and vomiting is, in a sense, a relief. Nothing should be given by the mouth and the patient should be fed entirely by enemata. The insertion of a rectal tube and its retention for a considerable time may afford relief. Lying on the side is more comfortable than recumbency. Washing out the stomach from time to time gives great comfort and is often of real service.

In the average case of celiotomy, in which persistent vomiting does not occur, the question of feeding is of much importance. Usually, for the first twelve or twenty-four hours, nothing is given by the mouth but small quantities of hot water. The day after the operation, if everything is satisfactory, food is given to the patient. In many cases, however, food is not given by the stomach for forty-eight hours and the patient is fed by the rectum during the wait. He should not be given milk because it will not be easily digested, may lead to nausea, and cause flatulence. Peptonized milk, if the patient will take it, does not possess these hurtful qualities. At first albumin-water or liquid beef peptonoids should be given, and later meat-juice, beef-jelly, broth, etc. Food is given every third or fourth hour, and stimulants are administered if required. After the first twenty-four or forty-eight hours considerable quantities of plain water or Poland water should, if possible, be taken, to favor elimination by the kidneys. Hot coffee is not only a stimulant, but is an excellent diuretic. The urine is always scanty after an abdominal operation, and a normal daily amount is not voided for ten days or more. Solid food is not given for seven or eight days. The patient is apt to suffer greatly from thirst, in spite of the hot water given during the first twelve to twenty-four hours. He seldom takes and should never have any great amount of hot water, and iced water and ice are inadmissible and tend to induce nausea and vomiting. Sucking ice or sipping water draws air into the stomach and causes distention. Thirst can be much mitigated by enemata of salt solution. J. Greig Smith recommended an enema composed of from 4 to 20 oz. of tepid water and some brandy. Usually, after the first twenty-four hours, a sufficient amount of liquid can be given to keep the patient free from actual distress.

The bladder must be watched to see that retention does not occur. If retention occurs, a clean catheter must be used at regular intervals. If tympanitic distention occurs after forty-eight hours, a saline purgative should be given and it should be followed by an enema of turpentine. The rectal tube is frequently of signal service in such cases. If obstruction develops, it is treated as directed on page 1123.

In any ordinary case after operation the bowels should be moved after

forty-eight hours as a prophylactic measure against distention, peritonitis, and obstruction. From four to eight 1-dram doses of Epsom salts are given, in hot water, the solution having been filtered through gauze. The saline is followed by the administration of an enema consisting of soap, water, and ½ oz. of castor oil. Should opium be given? Never as a routine, and not to secure sleep; but if the patient be in pain which not only harasses him, but causes him to turn and shift in torturing restlessness, one or possibly two hypodermatic injections each containing ¼ gr. of morphin may be given with confidence that the good will overbalance the harm.

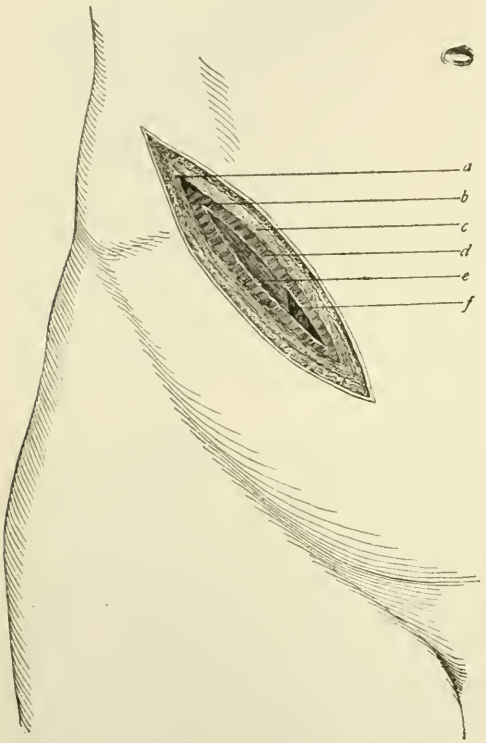

Fig. 709.—Resection of the vermiform appendix, incision through the abdominal wall: *a*, External oblique muscle; *b*, internal oblique muscle; *c*, aponeurosis of external oblique; *d*, aponeurosis of internal oblique; *e*, transversalis fascia and peritoneum; *f*, outer border of rectus abdominis muscle (under it the deep epigastric vessels) (Kocher).

Operation for Appendicitis.—Before operating try to locate the situation of the appendix, and the relation the area of infection bears to the ascending colon. The incision should be over the seat of disease. In the rare left-sided cases and in median cases the incision is median. In some cases in which the appendix is posterior the cut may be in the loin. In 1 case I opened a purulent collection through the rectum. In the vast majority of cases the incision is made in the right iliac region.

In acute appendicitis, when there is not thought to be a distinct abscess, the incision usually made is 2 inches internal to the anterior superior iliac spine and perpendicular to a line drawn from the spine to the umbilicus (Fig. 709). The skin incision is usually 3 inches in length, the upper third of the incision being above the omphalospinous line; the incision in the peritoneum is about 2 inches in length, but if there are many adhesions, it may be necessary to make it much longer. The oblique incision may be carried out as advised by McBurney, the muscles being separated by blunt dissection. By this method very few nerve-fibers are divided, and hence the operation is not followed by marked muscular wasting, a condition which strongly predisposes to hernia. Further, as Van Hook[1] points out, the oblique incision enables the surgeon to reach freely all the ordinary areas of appendix trouble, the wound is parallel with the lines of traction of the abdominal muscles, and does not tend to gape widely. In an acute case I make an oblique incision, but cut the muscles (Fig. 709). In an interval case I separate the muscular fibers. Battle's incision at the outer edge of the rectus muscle is preferred by many surgeons. The anterior layer of the rectus sheath is opened longitudinally, the rectus is drawn

[1] "Jour. Amer. Med. Assoc.," Feb. 20, 1897.

inward, and any existing portion of the posterior rectus sheath with the transversalis, fascia and peritoneum is incised.

I have used *Davis's transverse incision* (Figs. 710 and 711) in many interval cases with entire satisfaction (Gwilym G. Davis, in "Annals of Surgery," Jan., 1906). This incision does not divide arteries, but it divides the deep muscles

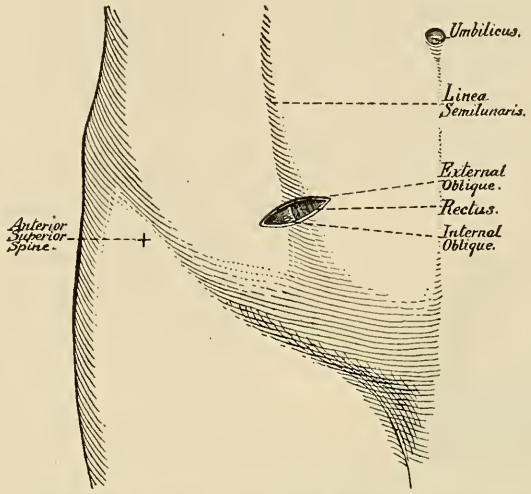

Fig. 710.—Davis's small transverse incision for simple cases.

in the direction of the nerves, hence the nerves are not injured. The center of this incision is almost over the base of the appendix. Davis describes his incision as follows:

"*For easy cases* the incision is made directly transverse, 1½ inches long. Its center is to be on the semilunar line on a level with the anterior superior spine.

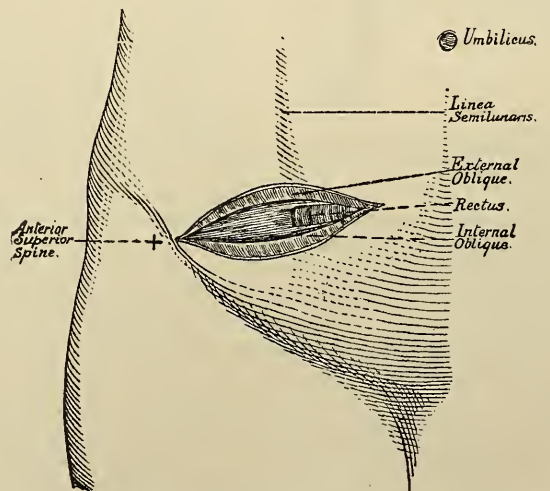

Fig. 711.—Davis's large transverse incision for difficult cases.

The aponeurosis of the external oblique is divided in the line of the skin incision, but obliquely to the direction of its fibers. The fibers of the internal oblique and transversalis muscles are parted—not cut—in the same line as the structures above. The peritoneum is then opened and the incision is carried inward,

first through the anterior layer of the sheath of the rectus. A blunt retractor ¾ inch wide is then inserted and the muscle drawn toward the median line. This exposes the transversalis fascia and peritoneum posteriorly, which are then also divided. Thus is obtained a triangular opening with its base of ¾ inch and two sides of about 1 inch long, which is ample for simple cases.

"*For Difficult Cases.*—If the case is a difficult one, the outer end of the incision is prolonged to the anterior spine or even above and inwardly through the sheath of the rectus to within 1 inch of the median line. This will give an opening 4 to 5 inches long, according to the size of the patient, sufficiently large to insert the hand if necessary and through which the appendix can be extracted under almost all circumstances."

After opening the peritoneum examine very gently to detect the situation of the appendix, and if there are or are not adhesions. In a very recent case and in a very acute case there will probably be no adhesions unless there have been previous attacks. If there be infection, surround the region involved with packs of plain gauze, each strip being 2½ inches wide, 15 inches long, and four layers in thickness. The edges of the wound should be lifted up by retractors and the strips inserted around the cut, between the parietal peritoneum and intestines and to a distance of 3 inches from the wound. Strips of gauze are passed, when possible, below the appendix to prevent entrance of infected material into the pelvis, and a piece is pushed upward toward the liver (Van Hook). Over the packing gauze, which it may be necessary to leave in place after the operation, other pads are packed. The appendix is sought for by finding the colon. The colon is found by following the parietal peritoneum with the finger. The course of the finger is first outward, next backward, and finally inward; the first obstruction it encounters is the colon. The fact that it is the colon can be confirmed by finding the longitudinal bands. The anterior longitudinal band leads directly to the appendix. Pass the finger down to the head of the colon, find the appendix, usually posterior and internal, and lift it and the head of the colon into the wound. In many cases it will be advisable to deliver the head of the colon from the belly (Fig. 712); in other cases this will not be necessary, in some it will not be possible. Do not permit the appendix to touch the skin of the abdomen as in Fig. 712. If adhesions exist, they must be gently and carefully separated. Barker's method (Fig. 713) is a very satisfactory mode of removing the appendix. It is done as follows: Turn up a cuff of peritoneum, pull down the other coats, ligate at the base, cut through the tube, let the musculomucous stump retract, and tie or suture the peritoneal cuff over the stump. Another method, which is the one I usually employ, is as follows: Pass a ligature through the meso-appendix, as shown in Fig. 714, *A*, tie the ligature, and cut off the meso-appendix on the appendiceal side of the threads. Crush the stump of the appendix with strong straight hemostatic forceps. This divides the mucous membrane, submucous tissue and muscular coat, and leaves the peritoneal coat

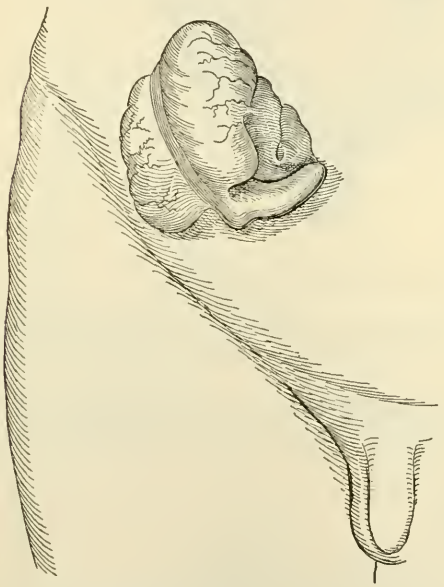

FIG. 712.—Radical operation for appendicitis (Kocher).

undivided. Remove the forceps. Surround the appendix with a catgut ligature and tie the ligature in the groove produced by the crushing. When the ligature is tied, peritoneum is brought against peritoneum. Cut off the appendix between the ligature and a clamp by the cautery, a knife, or scissors. Disinfect the stump of the appendix by pure carbolic acid, being careful to allow no excess of the acid to run over the adjacent peritoneum. Such excess should be touched quickly with an alcohol sponge. The stump beyond the ligature contains mucous membrane and muscle, which are lifted out with forceps and scissors. Suture the fringe of the meso-appendix, invert the stump into the wall of the colon, and suture a portion of the wall over it by inversion stitches. Figure 714 shows an older method still used by many. The meso-appendix is tied off by one ligature, the appendix is not crushed, but is tied off by another ligature, and both structures are cut off below their respective ligatures. The stump is disinfected with pure carbolic acid or the cautery, inverted, and the fringe of the meso-appendix is sutured. This method does not entirely remove the appendix, but inverts glandular tissue into the wall of the bowel. The stump may not be completely asepticized by the carbolic acid and hence may lead to postoperative abscess, dense adhesions or fecal fistula, or the

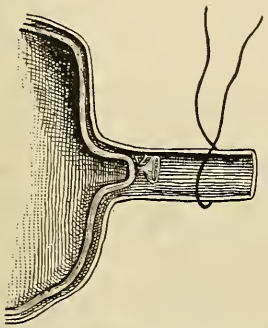

Fig. 713.—Barker's technic of operation for removal of the appendix.

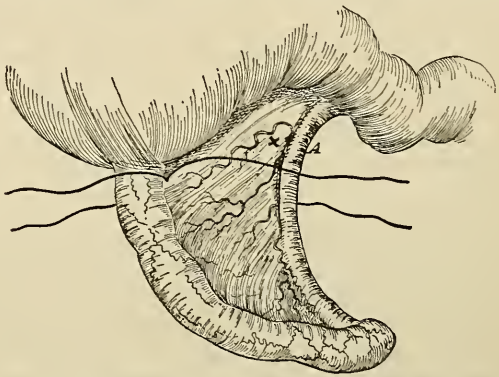

Fig. 714.—Ligation of appendix and meso-appendix.

undestroyed lymphoid structure may cause further trouble, even persistent ill health (Joseph Price). Some remove the appendix by an elliptical incision around its base, and close the colon wound by Lembert sutures. This method, of course, removes the appendix completely. Dawbarn surrounds the appendix with a continuous Lembert purse-string suture of silk. This is inserted in the superficial layers of the cecum, ½ inch from the appendix. The appendix is divided so as to leave a stump never shorter than ½ inch. The lumen of the stump is gently stretched by inserting a pair of mouse-toothed forceps and opening the blades. The stump is then invaginated into the cecum, that is, it is turned "outside in." The sutures are tightened, and while this is being done, the mouse-tooth forceps used in effecting inversion are withdrawn. Finally, the sutures are tied (Robt. H. M. Dawbarn, in "Internat. Jour. of Surg.," May, 1895). In this method the stump is not ligated and hemorrhage is liable to take place into the gut. Deaths from such hemorrhage are on record. The retained bit of appendix drains into the colon. I believe it is a mistake to trust to simple ligation and to fail to bury the stump left after appendectomy. If a surgeon follows this plan in any large number of cases he will now and then have a case in which the ligature slips and feces pass into the peritoneal cavity, or cases of temporary fecal fistula, or cases of intestinal obstruction from adhesion of some portion of the bowel to the exposed stump (Murat Willis, in "Annals of Surgery," July, 1908). I do not believe that a buried stump increases postoperative pain.

If there is no pus and no extravasated feces, if the peritoneum is not seriously affected, if the appendix is not gangrenous or perforated, and if there is no pus within the appendix, remove the pads which were inserted last, irrigate with hot salt solution, remove the strips of gauze which were inserted first, and close the wound. If any of the above conditions have been found, remove the infected pads, but leave in place the strips which were first inserted in order to limit infection and secure drainage. Pass sutures through wound edges, tie some of them and leave some untied until gauze is removed at a later period (Van Hook).

If an operation is performed in a distinct interval, pus is absent and the surgeon can proceed without apprehension. If there is any question of the presence of pus, surround the region with gauze, as suggested above, before breaking down adhesions and liberating the appendix. An interval operation should not be performed until three weeks after an attack. In an interval case McBurney proceeds as follows: He makes the skin incision in the direction of the fibers of the external oblique muscle, separates the fibers of this muscle by blunt dissection, retracts them, separates the fibers of the internal oblique and the transversalis muscles in the same way and retracts them, and opens the transversalis fascia and peritoneum. No muscle-fibers are cut and hernia is not apt to follow. Such a wound is closed as follows: a continuous catgut suture for the peritoneum, sutures of chromic gut for the transversalis fascia, the muscles are restored to place, the aponeurosis of the external oblique is sutured with chromic gut, and the skin is closed by interrupted sutures of fine silk or silk-worm gut or by a subcuticular stitch.

If an *abscess* is believed to exist, make an incision parallel with Poupart's ligament and over the area of dulness on percussion (Willard Parker's oblique incision). If the abscess is adherent to the anterior abdominal wall such an incision will not enter the free peritoneal cavity. If, after opening the abdomen, an abscess is thought to exist, although it is not adherent to the anterior abdominal wall, surround the abscess with gauze before opening it, as directed under acute appendicitis. The gauze is placed under the margins of the incision in the peritoneum all around the appendix area; a piece is carried toward the pelvis and another piece toward the liver. Overlay this gauze with gauze pads (Van Hook). Adhesions are broken through with the finger, and when pus appears it is at once wiped away. Remove the appendix in most cases, but not in all. If the appendix lies loose in the abscess cavity, if it is sloughed off or but loosely attached to the abscess wall, remove it. If the appendix is firmly fixed in the abscess wall and must be dug out of a mass of inflammatory material do not remove it. To remove it under these circumstances may rupture the wall and disseminate the pus into regions not protected by pads and gauze. Deaver and others tell us always to remove the appendix. I do not believe this to be a safe rule to follow. To insist on removing the appendix may cause death. When the appendix is left, it usually sloughs away. It is true, a fecal fistula may result, but this is in the large bowel and usually heals spontaneously. Even if a fecal fistula forms and does not heal, the surgeon has acted properly in not removing the appendix, because a fecal fistula may be remedied by another operation. It is rarely that secondary abscess forms, and there are not a great many cases recorded in which an appendix has subsequently given serious trouble when left after operation. In fact, in many cases the appendix is destroyed or obliterated by inflammation. In some cases, however, a secondary operation will be required because of a fecal fistula, a persistent sinus, or an acute inflammatory attack. When Deaver decides to remove such an appendix, he makes an incision in the median line of the abdomen, packs around the periphery of the abscess with gauze, opens the abdomen by another incision, removes the appendix, disinfects, inserts drainage, and then removes the surrounding gauze and closes the median incision. In every abscess case search for fecal concre-

tions and remove them if found. Irrigation should not be employed in appendicular abscess. The force of the stream may break down barriers of lymph and spread infection. After the evacuation of the pus, whether the appendix has been removed or not, take out the pads, but leave the long strands of gauze first placed to keep the wound open. Introduce iodoform gauze into the abscess cavity and insert a rubber tube, partially suture the wound, and dress with dry gauze. In forty-eight hours all the strands of gauze are removed and fresh pieces are inserted for drainage. After this period the gauze drain is changed daily. Morris maintains and proves that large pieces of gauze sometimes cause intestinal obstruction and iodoform gauze sometimes causes iodoform-poisoning, but the risk, it seems to me, should be taken. An interval case should be up and about in from ten days to two weeks after operation. An abscess case may require a much longer time for complete recovery. A fecal fistula sometimes results in cases in which the appendix was not removed, and occasionally forms when it was removed.

If on opening the abdomen pus is found, unlimited by adhesions but widespread in the peritoneal cavity, remove the appendix, and then bear in mind Murphy's wise counsel as to how to treat general peritonitis (see page 1162). Put a drainage-tube into the pelvis and one in the appendix region, place the patient in Fowler's position, and administer salt solution by continuous proctoclysis at a low pressure. The after-treatment of an ordinary appendix operation is that advised after celiotomy (see page 1209).

Mortality after Operations for Appendicitis.—The interval operation is practically without mortality. In over 1000 cases Treves had 2 deaths. In 446 cases of chronic appendicitis the Mayos had 1 death ("Report of St. Mary's Hospital for 1912"). In grave acute cases the mortality is large. In 100 consecutive cases of this character collected by Hearn and operated upon in the Jefferson Hospital by Keen, Hearn, and DaCosta, there were 8 deaths. As previously stated, Maurice H. Richardson reported a death-rate in such cases of 18 per cent. in 750 cases. Deaver reports from the German Hospital 144 cases, with a mortality of 17.8 per cent. He eliminates 1 death from diabetes, 1 from pneumonia, and 1 from phthisis, and estimates his personal mortality at 15.9 per cent. (Deaver and Ross, in "Jour. Am. Med. Assoc.," Oct. 5, 1901). In 124 cases (including all chronic cases and those acute cases in which the inflammation had not extended beyond the peritoneal coat) there was 1 death. In 347 cases of acute and suppurative appendicitis operated upon in the Mayo clinic in 1912 there were but 2 deaths ("Report of St. Mary's Hospital for 1912"). In the Mayo clinic from Jan. 1, 1907 to Jan. 1, 1918 there were 12,329 operations for appendicitis with a mortality of 0.6 per cent. (Personal Communication to the author). I fancy most of these cases came from a distance and hence the proportion of violent and rapid cases must have been less than is usually the rule in a great city. In Burgess's 500 consecutive operations there were 40 deaths ("Brit. Med. Jour.," Feb. 24, 1912). When infection was limited to the appendix the mortality was 0.74 per cent. (135 cases); when there was circumscribed abscess it was 4.64 per cent. (213 cases); when there was diffuse spreading peritonitis it was 19.07 per cent. (152 cases). The usual causes of death are intestinal obstruction, septic peritonitis, septic endocarditis, pylophlebitis, hepatic suppuration, metastatic abscesses, endocarditis, and gangrene of the bowel. In a further report from September 1, 1902, to September 1, 1903, Deaver reports 566 cases in the Lankenau Hospital, with an aggregate mortality of 5 per cent. In cases with diffuse peritonitis the mortality was 31 per cent. In abscess about a necrotic and perforated appendix it was 12 per cent. In early appendicitis or when disease was confined to the appendix it was 0.8 per cent. In 107 cases of circumscribed abscess in which Burgess removed the appendix the mortality was 1.86 per cent. In 106 cases in which he did not remove the appendix it was 7.54 per cent. ("Brit. Med. Jour.," Feb. 24, 1912).

Appendicostomy (Weir's Operation).—This operation was devised by Weir, of New York, in 1902. It consists in opening the abdomen, finding the appendix, fastening this structure to the skin, closing the rest of the wound, opening the appendix to see that it is patent, and applying a temporary ligature to prevent leaking. The temporary ligature is removed in a day or two, and a few days later the adherent and open appendix is used as a route for the introduction of irrigating fluids. The operation is of the greatest value in chronic ulcerative colitis, as it enables us to irrigate thoroughly the large bowel. Daily a large tube is passed into the rectum and a small tube into the appendix. The fecal matter is washed out of the bowel through the rectal tube by salt solution, and then a 1 : 5000 solution of silver nitrate or bismuth and starch water (1 dram to 1 oz.) is used to irrigate the colon. It is injected by way of the appendix and it runs out of the rectal tube. It is used for the same purpose in some cases of tuberculous rectal or anal fistulæ. A most extraordinary suggestion is that appendicostomy be performed in epileptics,

Fig. 715.—Eye of the calyx-eyed needle.

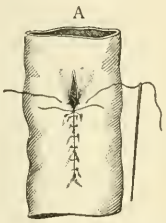

Fig. 716.—Enterrorhaphy: A, Lembert suture; B Dupuytren's suture.

so that the opening may be used to flush the bowel, a suggestion which I will not act upon. When the fistula exists, it does not leak to any appreciable degree. When we wish to close it we insert within the lumen of the tube the Paquelin cautery at a red heat. This destroys the mucous membrane and the fistula closes (Robt. Weir, in "Med. Record," August 9, 1902).

Enterorrhaphy, or Suture of the Intestine.—Surgical opinion has greatly altered in regard to this operation since the day when John Bell wrote his famous attack on Benjamin Bell. John Bell said: "If in all surgery there is a work of supererogation, it is this operation of sewing up a wounded gut." To-day we know that if in all surgery there is a proceeding of imperative necessity, it is the sewing up of a wound in the intestine. To perform this operation take fine sterile silk and thread a thin, round, straight, calyx-eyed needle with it (Fig. 715). The needle is very useful, as it can be threaded rapidly by pushing the calyx eye down upon the silk thread while the latter is kept taut. *Lembert's suture* (Figs. 716, A, 717, and 718) was devised in 1823. Lembert used it on animals, but never on man. It is inserted at right angles to the wound. It goes down to, but not through, the mucous membrane. It is formed by picking up a fold of the intestine ($\frac{1}{12}$ to $\frac{1}{8}$ inch wide) $\frac{1}{8}$ inch from the edge on one side of the wound, passing the needle through, picking up a fold on the opposite side of the wound, and passing the needle through. On tying the threads the serous membrane is inverted and peritoneum is brought into contact with peritoneum. For many years it was taught that this suture should include only the serous coat, but Halsted, in 1887, showed that it must include the tough submucous coat. The submucous coat is strong and will hold a suture. The other coats are thin, tear easily, and will not hold a suture. So thin are the coats that a surgeon could not suture the serous coat alone were he to try. Sutures which include only the muscular and serous coats tear out easily. *Dupuytren's suture* (Fig. 716, B) is simply a continuous Lembert

suture running obliquely across the wound. *Cushing's right-angled suture* (Fig. 719) is a continuous suture catching up the submucous coat and serving to invert the serous layer. Ford, of San Francisco, employs a continuous inversion suture, which is tied in a single knot each time it is drawn through (Fig. 720).

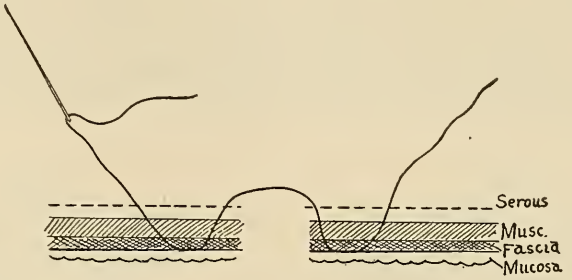

Fig. 717.—Lembert's suture.

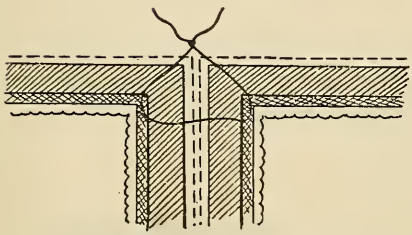

Fig. 718.—Lembert's suture closed.

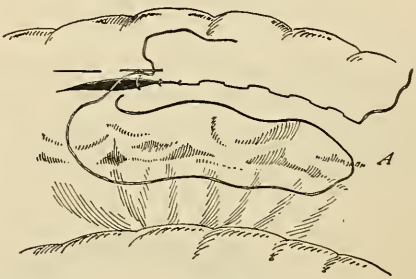

Fig. 719.—Cushing's right-angled suture (Senn).

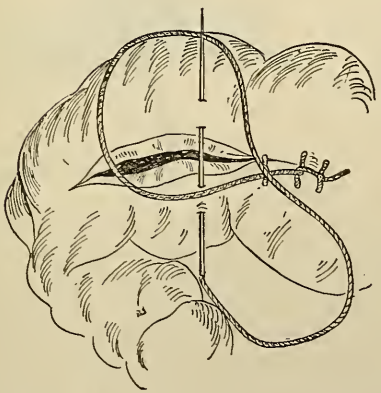

Fig. 720.—Ford's stitch, showing a Lembert insertion and the needle passed so as to tie a single knot by drawing it on through.

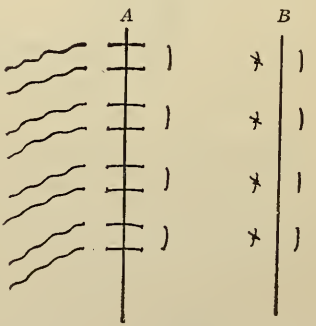

Fig 721.—*A*, Halsted sutures untied; *B*, Halsted sutures tied and serous surface inverted.

Halsted's mattress or *quilt suture* is shown in Fig. 721. Each stitch picks up the submucous coat. Mattress sutures do not tear out easily, they appose evenly considerable surfaces, and do not constrict the tissue as much as Lembert stitches. The *Czerny-Lembert suture* is a suture passed through the serous membrane on one side of the wound, made to perforate the mucous membrane, and to emerge at a corresponding point of the serous membrane. A Lembert

suture is added (Fig. 722). As at present used, the Czerny suture is carried to, but not through, the mucous membrane (Fig. 723). *Gussenbauer's suture* is similar to the Czerny-Lembert suture, except that it applies the Czerny and the Lembert with one suture, and this suture does not pass through the mucous membrane (Fig. 724). In *Connell's suture* (F. Gregory Connell, in "Phila. Med. Jour.," Jan., 1899) the knots are placed within the lumen of the bowel (Plate 11). Connell's very useful and ingenious stitch seems to be a modification of a stitch described by Frederick Holme Wiggin ("Med. Record," Nov. 19, 1898). *Wölfler's suture* unites broad layers of the serous coat, the knots

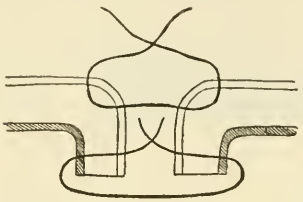

Fig. 722.—Czerny-Lembert suture.

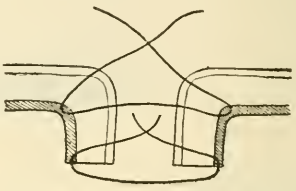

Fig. 723.—Czerny-Lembert suture as at present used.

being tied internally (Fig. 725). Senn says that after suturing a large wound of the stomach or of the intestine a strip of omentum ought to be laid over the wound and fastened by catgut sutures (*omental graft*). These grafts adhere and are a safeguard against leakage. (For other methods of enterorrhaphy see Intestinal Resection and Anastomosis.)

Operations upon the Stomach.—In some serious operations, for instance pylorectomy, it may be found desirable to do a two-stage operation—first gastro-enterostomy and two or three weeks later the major operation. The patient is thus nourished and strengthened before the great trial. After gastro-enterostomy the disappearance of fibromatosis makes the outline of the cancer evident. A patient must be carefully prepared for an operation upon the stomach. The Johns Hopkins method, founded on the researches of Harvey Cushing regarding sterilization of the stomach, is to be used. During the two or three days immediately preceding operation clean the mouth and teeth several times during the day with a carbolic solution. Give only sterile water and sterile liquid food by the mouth, and for twelve hours before operation give no food whatever. During the two or three days before operation wash out the stomach with boiled water night and morning. I do not wash immediately before operation, as it sometimes leads to annoying vomiting and thus may interfere with anesthetization. If the tissues of the patient are seriously dehydrated give salt solution by hypodermoclysis for the two or three days preceding operation. After operation give no food whatever for thirty-six hours.

EXPLANATION OF PLATE 11.

Intestinal suture, all knots inside (Connell).

a, Suspending loops 2, 3, and 4 are made with one thread inserted at a point two thirds of the distance from mesenteric to convex border. The needle with suture is passed through the four walls of the cut ends, and that portion of suture within each lumen is drawn up to a sufficient length, then cut, and the contiguous threads tied at the points indicated by the arrows; thus having as a result four suspending loops dividing the circumference of each cut end into thirds. Instead of employing four suspending loops which divide the circumference of the bowel into thirds, we may use but two loops, and thus divide the circumference into halves; or, if available, the "holder" devised by Dr. E. H. Lee can be recommended highly, and will be found a most efficient aid in maintaining the cut edges in apposition. (The description of the instrument will be found in the "Annals of Surgery," January, 1901.)

b, Loop 2 has been cut away, and loop 1 takes its place in one hand of the assistant, with loops 3 and 4 held in the other hand, thereby bringing into apposition that portion of the walls to be included in the second third of the suture. The operator continues the suture to the points of insertion of loops 3 and 4, where again a back stitch is taken, to fix the suture and prevent a purse-string contraction of the same. The white elevation in the center of illustration, representing mesentery, shows that that portion of the intestinal wall not covered by peritoneum, at the mesenteric border, has been secured in the suture.

c, The needle, after having entered the lumen, is passed out again on the same side ⅛ inch distant; then over to the opposite cut end, where it is inserted from without in, and again emerges from within out, on the same side. This step—the taking of a bite—is repeated alternately on opposing margins until the necessary number of stitches have been inserted. It will be observed that when the needle enters the lumen the last time, it makes what might be termed a half-stitch, as it does not return again *through* the wall; but having reached the point where the suture was commenced, the free end and the needle end will complete the last stitch, when tied, on the mucosa. The needle at this point is then brought out of the lumen at the angle of wound alongside of the free end of the suture. The cross-over stitches are next carefully drawn up, thus bringing into contact the opposing serous surfaces at every point except where the suture ends still protrude.

d, The eye-end of threaded needle is made to emerge alongside of the suture ends, and is then withdrawn a little, which causes its thread to form a loop, through which the assistant passes the ends of the suture. The operator next withdraws the threaded needle, at the same time bringing with it the suture ends, and they present externally at the point of withdrawal of the needle. The serous coats throughout the entire circumference are now in apposition, and the suture ends can be tied.

e, By slight traction on the suture ends the opposing mucous surfaces are brought in close contact; the suture ends are then tied firmly, and deep between the serous coats, thus tying the knot upon the mucous coat, and the ends then cut off short.

Small quantities of hot water are allowed as soon as the patient recovers from ether. During the first twenty-four hours give an enema of hot salt solution and coffee every five hours and then alternate nutritive enemata with salt enemata. After thirty-six or forty-eight hours usually begin to give food by the mouth—at first small doses of albumin-water, and, if this be tolerated, broth and milk. Solid food should not be given for two weeks.

If the patient is advanced in emaciation and much exhausted we should not wait for thirty-six hours to feed him, but should give milk and broth as soon as the patient recovers from ether. The bowels should be moved by enema the day after operation. If the enema fails, calomel is given (3 or 4 gr.).

Digital Dilatation of Pylorus for Cicatricial Stenosis (Loreta's Operation of Pylorodiosis).—Place the patient recumbent and administer ether. Make a vertical incision in the linea alba or through the right rectus muscle. The median incision begins 1 inch below the ensiform cartilage. The cut in either case should be 5 inches in length. When the peritoneum has been opened the stomach is drawn out of the wound, any adherent omentum is separated, and the pylorus is carefully examined. The stomach, after being surrounded with gauze pads, is opened near the center of its anterior surface, "but rather nearer to its pyloric end" (Jacobson).

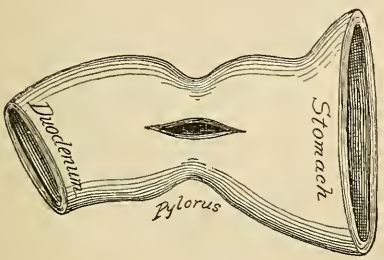

FIG. 726.—Heineke-Mikulicz's pyloroplasty: The incision.

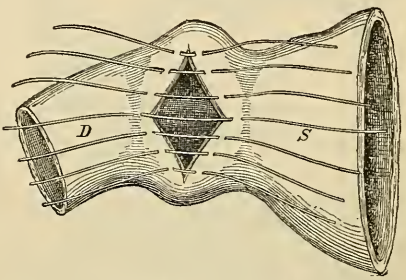

FIG. 727.—Heineke-Mikulicz's pyloroplasty: The axis of the incision is changed by traction from horizontal to vertical; sutures in position; only one of the two rows of sutures is shown.

Insert the index-finger through the stomach wound and into the pylorus, and follow that with the middle finger. The pylorus can be well dilated by separating the fingers. If the stenosis is so tight as to prevent the entry of a finger, introduce a pair of closed hemostatic forceps and open the blades a little when they are within the lumen of the constricted area. The wound in the stomach is closed by a continuous silk suture of the mucous membrane and two layers of Halsted sutures, to invert and approximate the peritoneal surfaces. After closure of the stomach wound the abdominal wound is sutured.

Divulsion by the fingers or by an instrument is no longer practised, because experience has shown that the constriction is sure to return.

Pyloroplasty (Heineke-Mikulicz Operation).—The first operation was performed by Heineke in 1886. Early in 1887 Mikulicz, not knowing of Heineke's antecedent operation, did the same thing. Open the abdomen in the middle line or, better, through the right rectus muscle. Draw up as much of the pylorus as possible, and pack warm moist gauze pads around it; make an incision through the stricture and in a direction corresponding to the long axis of the stomach and bowel (Fig. 726). Catch an aneurysm-needle under the upper margin of the incision and draw it up, and an aneurysm-needle under the lower margin and draw it down. The effect of traction is to convert the longitudinal wound into a transverse wound. The sutures are applied so as to maintain the wound in a vertical line (Fig. 727). The mucous membrane is sutured with a continuous suture of silk, and interrupted Lembert or Halsted

sutures of silk close the peritoneal and muscular coats (Figs. 727 and 728). Do not drain. A. W. Mayo Robson inserts a bone bobbin and then applies the sutures. The operation of pyloroplasty shows a mortality about the same as or slightly less than gastro-enterostomy. In some cases it is a very satisfactory procedure, but there are objections to it, and in 30 per cent. of cases it fails to give relief (Wm. J. Mayo). The outlet is not at the most dependent part of the stomach, hence the stomach may not empty itself. Further, as Finney points out, it cannot be performed if there are firm adhesions or active ulceration, and the scar may contract and give rise to stenosis. Again, it is difficult to suture the wound so as certainly to provide against leakage. The Mayos reported 21 pyloroplasties without a death, but 7 cases required secondary operations ("Annals of Surgery," Nov., 1905). Pyloroplasty has been abandoned by many surgeons; J. Rutherford Morison still advocates it. Finney has devised an operation to correct the objections to pyloroplasty.

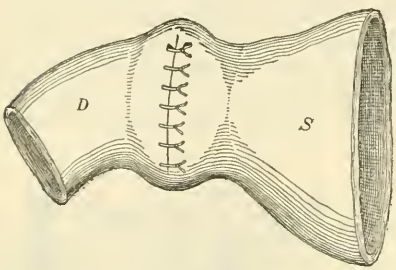

FIG. 728.—Heineke-Mikulicz's pyloroplasty: After tying the sutures.

Gastroduodenostomy by Finney's Method.—This operation is usually called a method of pyloroplasty, but it is rather a gastroduodenostomy. The operation was described in the "Johns Hopkins Hospital Bulletin," July, 1902, and was then called pyloroplasty. It is performed as follows: Thoroughly free the first portion of the duodenum and the pyloric end of the stomach by dividing the posterior layer of peritoneum 1 inch to the right side of the duodenum. This step is known as mobilization. Insert three retractor sutures (Fig. 729) and draw upon them. Suture together, as far posterior as possible, the peritoneal surface of the duodenum and the peritoneal surface of the stomach along its greater curvature (Fig. 730). Then insert an anterior row of mattress sutures, but do not tie them as yet (Fig. 731). Make a horseshoe-shaped incision (Fig. 732); arrest bleeding; excise as much scar-tissue as possible on either side of the incision, and trim off the redundant mucous membrane. Insert a continuous catgut suture on the posterior side of the incision and carry it through all the coats (Fig. 733). Straighten out the anterior sutures and tie them (Fig. 734). The Mayos reported 58 Finney operations, with 4 deaths and 2 secondary operations (Wm. J. Mayo, in "Annals of Surgery," Nov., 1905).

The mortality is greater than after gastro-enterostomy, due probably to the necessity of separating adhesions and setting the duodenum free. The operation should be restricted to cases in which adhesions are not widespread and firm and in which the gastrohepatic omentum is of fair length. In properly selected cases it is a very valuable operation.

Pylorectomy (Excision of the Pylorus).—The removal of a portion of the stomach is a partial gastrectomy, and pylorectomy is a partial gastrectomy in which the pylorus and also a portion of duodenum are removed.

The experiments of Gussenbauer and von Winiwarter on dogs in 1876 led them to suggest the operation. It was first performed by Péan in 1879. It was next performed by Rydygier in 1880. Billroth did the first successful pylorectomy in 1881. The operation is seldom performed for anything but cancer, but sometimes is done for plyoric ulcer and its results. In many cases of pyloric cancer the abdomen is opened only after a palpable tumor is detected, and when a palpable tumor is detectable it is usually too late to perform pylorectomy.[1] The lesson is to explore suspected cases earlier than has been our custom.

I agree with Hemmeter that stenotic symptoms, even when no tumor is palpable, call for exploratory laparotomy. If the stomach is dilated, if there is cachexia, if there is no free hydrochloric acid in the gastric juice, if there is an excess of lactic acid in the gastric juice, if the patient is forty or beyond, when there is vomiting of blood, when the Oppler bacillus is present, when blood examination shows a diminution in red corpuscles and hemoglobin, and also shows that there is no increase in white corpuscles after a full meal—explore. After the abdomen has been opened the stomach is examined, and if a tumor exists, the surgeon must decide between the performance of pylorectomy and gastro-enterostomy. If the tumor is not very extensive, if there is no glandular involvement or only involvement which can be removed, and if adhesions are not extensive, pylorectomy is chosen; otherwise gastro-enterostomy is selected.

Until lately the mortality from pylorectomy was usually estimated to be at least 25 per cent., even in favorable cases. During recent years the mortality has been much reduced. The operative mortality in the Mayo clinic has been from 13.2 to 14.4 per cent. In 38 recent cases operated upon by Balfour's method of partial gastrectomy followed by anticolic gastrojejunostomy the mortality was 5.2 per cent. (D. C. Balfour, in "Surgery, Gynecology, and Obstetrics," 1917, xxv). During twenty years there were in the Mayo clinic

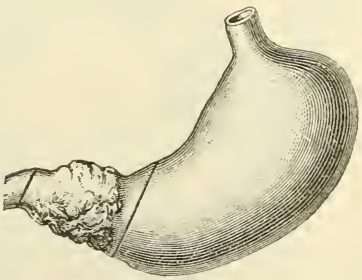

Fig. 735.—Billroth's method of pylorectomy.

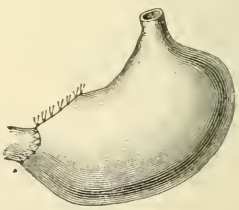

Fig. 736.—Pylorectomy.

651 resections of the stomach for cancer. Of 427 patients operated upon more than three years ago who recovered from the operation 311 have been traced and of these 120 (38.6 per cent.) were alive three years or more after operation. Of 313 patients who were operated upon more than five years ago, 239 who recovered were traced and 62 (26 per cent.) were alive five years or more after operation. Such results compare favorably with operations for cancer in other regions (Collected Papers of the Mayo Clinic, 1917) (see page 1223). Prepare the patient for pylorectomy as for any stomach operation. The best incision through the abdominal wall is a vertical one in or near the median line. A small incision is first made to permit of exploration, and if the growth is found to be removable, the incision is enlarged. In some cases it will be found necessary to divide the rectus muscle by a transverse cut.

Method of the Mayos.—This is the best operation. The Billroth method, which was long employed, does not remove enough of the stomach if there is malignant disease, the opening left in the stomach is much larger than the duodenal opening, and in suturing so as to make the two openings of equal size an angle is left which is apt to leak. Billroth's operation is shown in Figs. 735 and 736. In the Mayo method, after the stomach has been exposed the gastric artery is ligated close to the stomach, the lesser omentum is tied in several segments close to the liver and then divided, and the pyloric artery is tied. Two clamps are applied to the duodenum 1 inch apart, and the duodenum is divided by means of the cautery (Fig. 737).

The right end of the duodenum is closed by means of a continuous catgut

suture, the clamp is removed, and the closed end of the duodenum is inverted by a purse-string suture (Fig. 738). A hand is passed from above back of the stomach and lifts the great omentum forward. The right gastro-epiploic artery is tied close to the stomach. The left gastro-epiploic artery is tied distinctly to the left of any enlarged glands in the great omentum. The great omentum is tied in several segments. The great omentum is divided, leaving any enlarged glands attached to the portion of the stomach it is the intention to remove. The stomach is to be divided to the left of all lymphatic glands into which the cancerous region drains. The clamps are applied as shown in Fig. 737. The stomach is divided between the clamps by a cautery, and as the division is being carried out the stump is caught here and there by hemostatic forceps to prevent it slipping through the clamps. Slipping is disastrous and will cause leaking and entrance of air into the stomach, and entrance of air is apt to be followed by pulmonary difficulty. A row of locking stitches is passed through all the coats of the stump. The stitches are tied and a second row is passed and tied (Fig. 738). The clamp is removed and the stump is buried by Cushing's right-angled suture or Dupuytren's suture. A gastrojejunostomy is then performed to the posterior wall of the portion of stomach which remains.

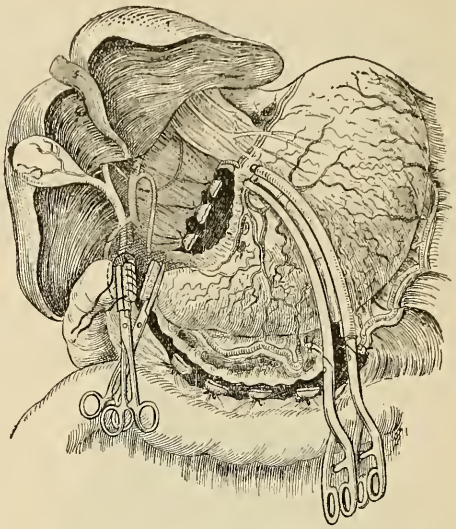

Fig. 737.—Pylorectomy by the Mayo method: Clamps applied, duodenum divided, and continuous catgut stitch introduced (Mayo).

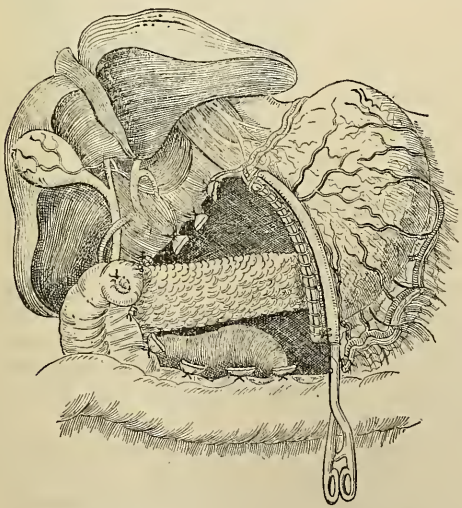

Fig. 738.—Pylorectomy by the Mayo method: End of divided duodenum buried by a purse-string suture. Row of lock stitches inserted in stomach stump (Mayo).

Such a patient is usually much dehydrated, and if he is, salt solution should be given intravenously during the operation, and an enema of warm salt solution should be administered every six hours for several days after the operation. Active stimulation is usually necessary and 8 oz. of coffee should be given by rectum at the completion of the operation. The patient must be placed erect or semi-erect in bed as soon as the effects of the ether pass away. Twelve hours after operation begin to give small amounts of hot water by the mouth. Nourish by the rectum from four to six days, when fluid food may be given by the mouth, starting with small doses of albumin-water, and, if this is tolerated, giving dessertspoonful doses of peptonized milk every hour. From Jan. 1, 1906, until Jan. 1, 1918, there were 589 resections in the Mayo clinic with a

mortality of 12.9 per cent. Their mortality after resection for ulcers and benign tumors is very small. If during the operation the pancreas be wounded the closed end of the duodenum is applied directly to the pancreatic wound, as Willy Meyer suggested ("Trans. of Am. Surg. Assoc.," 1910). "The anterior peritoneum and adventitious sheath of the pancreas are then sutured to the anterior surface of the duodenum." This plan prevents leakage from the duodenum and pancreas (Wm. J. Mayo, in "Annals of Surgery," August, 1913).

Total Gastrectomy.—The entire stomach was first removed by Conner, of Cincinnati, in 1883. The first successful operation was performed by Schlatter, of Zürich, in 1897. Total gastrectomy will rarely be required, but in certain unusual cases it will be proper to perform it. In some cases the duodenal end can be sutured to the divided esophagus; in others it will be necessary to close the end of the divided first portion of the duodenum, and anastomose the esophagus to the jejunum.

The cases suitable for total gastrectomy are those in which the entire viscus, or almost the entire viscus, is cancerous, the stomach being still freely movable, and the glands not so much implicated as to forbid attempts at removal. It is a remarkable fact, first demonstrated in Schlatter's case, that an individual can digest food very well without a stomach. This statement is true only if the stomach function has been gradually abolished by disease. During this period the functions of the stomach have been assumed to a greater or less degree by other parts. In a recent injury of the stomach complete removal would almost certainly be followed by death, as in such a case other parts would have had no chance to learn how to assume gastric duties. The reported cases of total gastrectomy show 10 deaths out of 27 cases, but, as Robson truly says, if all cases were reported, the mortality would probably be found to be 50 per cent. Trinkler ("Archiv. für klin. Chir.," Berlin, xcvi, No. 2) reports 1 case (which died on the eighth day) and gathers 25 from literature; 13 recovered. When the duodenum was stitched to the esophagus the mortality was 57.1 per cent. When the jejunum was stitched to the esophagus the mortality was 28.5 per cent.

I have done the operation once. The patient died on the third day.

Gastrotomy.—This term is used to designate the operation of opening the stomach for the accomplishment of some purpose, and immediately closing the incision in the gastric wall when that purpose has been accomplished. Gastrotomy may be performed to permit of the removal of foreign bodies, of exploration of the stomach and its extremities, of divulsion of the pyloric orifice, of the treatment of bleeding of an esophageal stricture or a stricture of the cardiac orifice of the stomach, or of the removal of a foreign body lodged in the esophagus. The first case on record was in 1602, when Florian Mathias, of Brandenburg, removed from the stomach of a juggler a knife which had been accidentally swallowed. When Evelyn was in Leyden in 1641 he saw a knife which had been removed by gastrotomy. He says (Evelyn's Diary): "I was showed the knife newly taken out of a drunken Dutchman's guts by an incision in his side, after it had slipped from his fingers into his stomach. The picture of the surgeon and his patient, both living, were there."

The patient is prepared as for pylorectomy. The incision may be vertical in the middle line or identical with the incision for pylorectomy. If a large foreign body can be felt, the incision is made directly over it. When the peritoneal cavity is opened, the surgeon decides as to the point where the stomach is to be incised, and draws this portion out through the wound, packing gauze pads under and around it. The stomach is opened by means of scissors, the cut being at a right angle to the long axis of the viscus (Jacobson). Bleeding vessels are ligated with catgut. The purpose for which the stomach has been opened is now carried out, the interior of the stomach and the surface of the extruded portion are irrigated with hot salt solution, the

mucous membrane is sutured with a continuous suture of silk, and two rows of Halsted sutures are inserted. The abdominal wound is closed, drainage being employed for twenty-four hours.

Gastrostomy is the making of a permanent gastric fistula, through which the patient can be fed. Gastrostomy was first proposed by Egebert in 1837 and was first performed by Sédillot in 1849. In 1875 Sydney Jones operated upon the twenty-ninth case and obtained the first recovery (Keen). Up to 1884 the estimated mortality was 80 per cent. At present the mortality in malignant cases is from 20 to 25 per cent., and in non-malignant cases from 8 to 10 per cent. Gastrostomy is employed in cases of esophageal obstruction or obstruction of the cardiac end of the stomach. In many cases of malignant

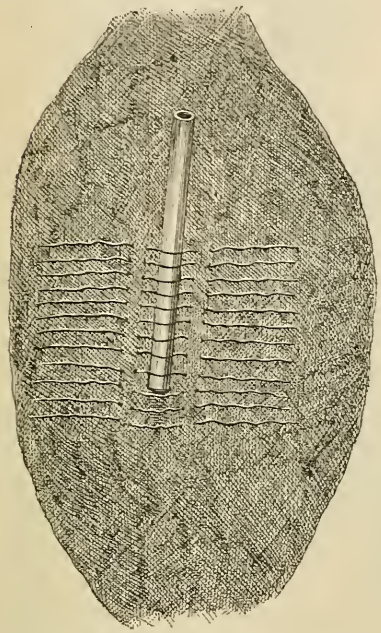

FIG. 739.—Witzel's method of gastrostomy, showing application of sutures in wall of stomach, embedding tube obliquely therein.

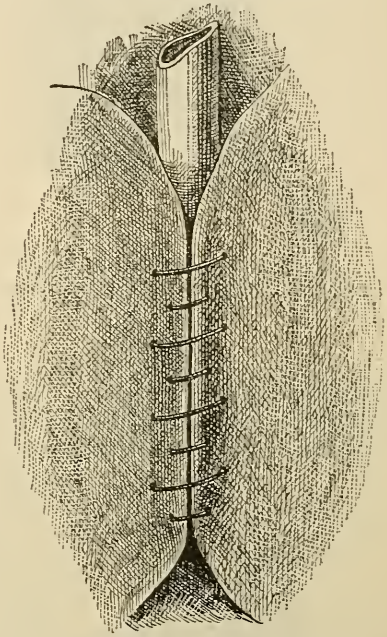

FIG. 740.—Sutures tied, completely embedding tube obliquely therein.

disease the operation is performed too late, and if performed when the patient is greatly emaciated and exhausted the operation has, of course, a high mortality. An early operation is far safer and confers the maximum of relief. The operation should be performed, as Mikulicz advises, when the patient is steadily losing weight and there is beginning to be difficulty in swallowing semisolids or liquids. The surgeon must endeavor to perform an operation which will not permit of leakage. Prepare the patient as for any stomach operation. It will usually be impossible to wash out the stomach.

Witzel's Method.—This operation was first practised in 1891. Make an incision 4 inches in length, to the left of the middle line, just below the border of the ribs. After opening the peritoneal cavity seize the stomach, bring it out of the wound, and pack gauze around it. Introduce a rubber tube into the stomach and enfold it by a double row of Lembert sutures (Figs. 739, 740). This tube should be 5 inches long and of the same diameter as a No. 25 French bougie. The opening is made in the stomach toward the cardiac extremity, the tube is placed parallel with the belly wound, and the

outer end of the tube emerges in the median line. The tube is retained in place by a catgut stitch carried through the tube and the stomach wall. The stomach is returned and is stitched by three sutures to the abdominal wall. The abdominal incision is sutured and a clamp is placed on the tube. When the patient is fed, a funnel is slipped into the tube, the clamp is removed, and liquid

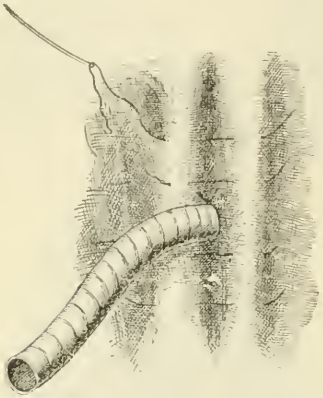

FIG. 741.—Kader's method of gastrostomy: Tube in place and first row of sutures inserted.

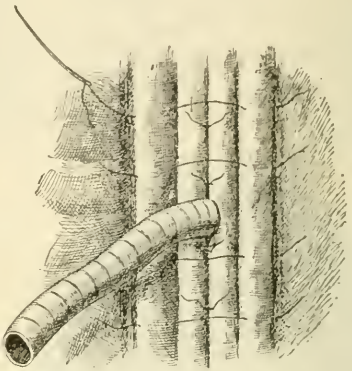

FIG. 742.—Kader's method of gastrostomy: First row of sutures tied and second row inserted.

food is poured into the funnel. After the wound heals it is not necessary to retain the tube permanently. It is passed when the patient desires food.

Kader's Method.—This operation was devised in 1896. It is a modification of Witzel's method. A small incision is made in the stomach and a tube is introduced and fastened to the stomach by one catgut stitch. Four Lembert sutures are passed so as to form a fold on each side of the tube and turn the stomach wall inward around the tube (Fig. 741). Lembert sutures are inserted in the furrow on each side of the tube. Two more folds are formed over the first two (Figs. 742 and 743). The stomach wall is stitched to the parietal peritoneum and sheath of the rectus muscle (Willy Meyer). I prefer Kader's method. It can be performed easily and rapidly, even upon a shrunken stomach and the wound does not leak. The fistula can be kept open by regular passing of a tube and closes rapidly if the passage of a tube be abandoned.

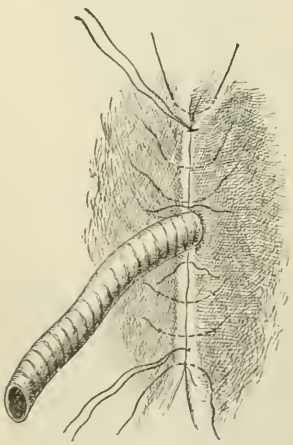

FIG. 743.—Kader's method of gastrostomy: Second row of sutures tied.

The Ssabanajew-Frank Method.—This operation is preferred by many surgeons. I used to employ it but only if the stomach was not so shrunken as to render the pulling out of a sufficient cone difficult. It was first performed by Ssabanajew in 1890 and was performed independently by Frank in 1893. Fenger's incision is made (a curved incision at the margin of the costal cartilages of the left side). A cone of the stomach is pulled out of the wound and is passed under a bridge of skin which has been prepared for it. The stomach is fixed above the margin of the ribs and opened (Figs. 744, 745). Von Hacker makes the gastric fistula through the left rectus muscles, and Hahn between two of the rib cartilages (Willy Meyer).

The Younger Senn's Method.—Emanuel Senn devised the following method: A cone of the stomach is pulled out of the abdominal wound, and this cone is puckered by the insertion of two drawing-string sutures of chromicized catgut. A cuff of gastrocolic omentum is sutured by silk around the neck of the puckered cone. The stomach is sutured to the belly wall with silk, the sutures including the omental cuff, the serous and muscular coats of the stomach, and the structures of the belly wall, except the skin. The skin is partly sutured. The stomach may be opened at any time.

Gastro-enterostomy or **gastrojejunostomy** is the establishment of a permanent opening between the stomach and the small intestine, in order to side-track the pylorus. The operation is performed for cancer of the pylorus, for non-cancerous stenosis of the pylorus, in some cases of ulcer of the stomach, and for tetany. Anterior gastro-enterostomy was proposed in 1881 by Wölfler's assistant, Nicoladoni and was first performed by Wölfler the same year. In Wölfler's early operations the jejunum was so placed that the proximal end was to the right of the anastomosis opening. Hence peristalsis in the stomach was from left to right and in the jejunum from right to left, and this was supposed to be responsible for the common occurrence of regurgitant vomiting. It was sought to prevent this by altering the direction of the loop (Lücke), then by entero-anastomosis (Braun), and finally by posterior anastomosis. Posterior gastro-enterostomy was first proposed by Courvoisier in 1883. His suggestion was that the posterior surface of the stomach be reached through the transverse mesocolon. His plan necessitated a transverse division of the mesocolon, but it was found that this impaired the blood-supply of a part of the colon and might lead to gangrene. Von Hacker, in 1885, devised an improved posterior operation. As a matter of fact, the transverse mesocolon has a marginal artery, unlike other parts of the colon, and the danger of gangrene from a transverse incision is probably not very great. In the earlier operations by the posterior method a long loop was used and results were not notably better than after the anterior operation. In 1890 Czerny and his assistant Peterson advised the making of the jejunal opening close to the duodenojejunal flexure. The results from this operation are vastly better than from the anterior operation. Posterior gastro-enterostomy has been signally im-

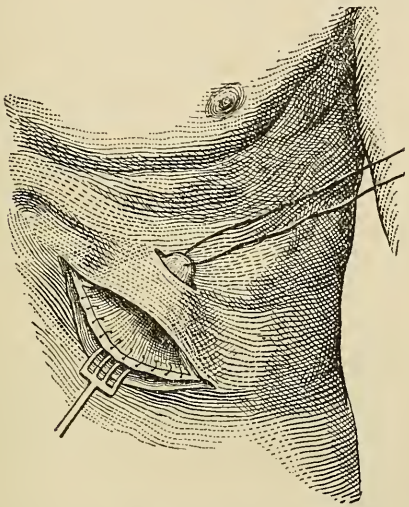

Fig. 744.

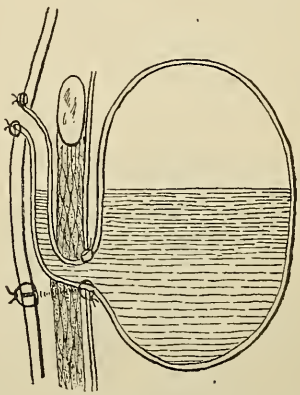

Fig. 745.

Figs. 744, 745.—The Ssabanajew-Frank method of gastrostomy in carcinoma of the esophagus.

proved in technic by the Mayos, Moynihan, and others. In the earlier operations of anterior gastro-enterostomy the mortality was 40 per cent. In non-malignant conditions the mortality after gastro-enterostomy is now very low (under 3 per cent.), the hyperacidity of the gastric juice disappears, and the functions of the stomach are restored. In malignant cases the mortality is about 20 per cent., but even in such cases, if operation be done early, life may be prolonged and made comfortable for months. Wm. J. Mayo makes the following report upon 421 cases of gastrojejunostomy: "Benign, 307 cases, 19 deaths (6.18 per cent.). In the last 140 there were 4 deaths, a mortality of 2.85 per cent.; the last 80 gave but 1 death. Malignant, 114 cases, with 21 deaths (18.5 per cent.). Of these 114 cases, 63 were in connection with pylorectomy and partial gastrectomy, with 8 deaths (12.6 per cent.). The very unfavorable cases of cancer obstruction were subjected to gastro-enterostomy, so that this operation gives a higher mortality than radical excision. In the last 40 gastrojejunostomies for malignant disease the mortality was 8 per cent. In the 421 gastrojejunostomies there were 21 reoperated cases (5 per cent.)" ("Annals of Surgery," Nov., 1905). In the Mayo clinic from Jan. 1, 1907 to Jan. 1, 1918 there were 302 gastro-enterostomies for ulcer of the stomach with a mortality of 1.6 per cent.—2593 for duodenal ulcer with a mortality of 1.3 per cent.—351 for pyloric cancer with a mortality of 8 per cent. (Personal communication to the author). In about 5 per cent. of cases of gastro-enterostomy for benign disease secondary operation has been required. In Krönlein's clinic, 51 cases of malignant disease subjected to gastro-enterostomy showed an average duration of life of 192 days; 470 days after operation 17 cases were living. The causes of death, according to Wm. J. Mayo, are: exhaustion, exhaustion with vomiting, pneumonia, and detachment of the anastomosed intestine.

Treatment after Gastro-enterostomy.—On returning the patient to bed at once establish continuous proctoclysis with deci-normal salt solution, the reservoir being only 6 inches above the level of the bed. As soon as the patient is out of ether place him semi-erect. Mayo begins in from sixteen to twenty hours to administer by the mouth 1 oz. of hot water every hour, and if it be well tolerated the amount is quickly increased, and in thirty-six hours liquid food is given, and if tolerated, is continued.

Complications Following Gastro-enterostomy.—Among them are *lung complications*. These are not due to the anesthetic, for they tend to occur even when local anesthesia has been employed. They are not due to the epigastric incision interfering with cough and expectoration, for they are not nearly so common after operations upon the gall-bladder (Wm. J. Mayo). Mayo says that the latest theory is that some of the venous blood returning from the stomach does not pass through the liver, and infected emboli are deposited in the lungs. The *suture line* may *leak* after gastro-enterostomy because of imperfect suturing, or the anastomosed intestine may become *detached;* 20 per cent. of the deaths among Mayo's cases resulted from this cause. *Contraction* of the *anastomosis opening* may gradually take place. This has been held by some to be particularly common in cases of dilated stomach, shrinking of the stomach being the efficient cause, but evidence upon this point is not conclusive. In cases in which the pylorus is not obstructed shrinking often occurs, but it rarely takes place when the pylorus is obstructed. In some cases after operation a *spur* forms in the jejunum because of angulation; in other cases adhesions produce obstruction; and in rare instances ulceration takes place in the jejunum. The most common complication after gastro-enterostomy is *persistent vomiting*, which may or may not be expressive of the formation of a vicious circle.

Peptic Ulcer of the Jejunum.—The first case was reported by Braun in 1899. The first English case was reported by Mayo Robson in 1903. Herbert J. Pat-

erson reported a case and collected reports of 61 other cases (A. W. Mayo Robson, "Brit. Med. Jour.," Jan. 6, 1912). F. Gregory Connell has collected 38 cases and reported 1 of his own, 39 in all ("Surg., Gynec., and Obstet.," Jan., 1908). He points out that in many of the reported cases acute perforation occurred. Most of the reported cases suffered from non-malignant trouble and had hyperacid gastric juice. It very seldom occurs after operations for cancer. Most of the reported cases happened after the anterior operation and when the anastomosis was very near to the pylorus. It has happened, however, in cases after the posterior operation, and cases have been reported following both the anterior and posterior methods associated with entero-anastomosis. It is probable that more cases seem to follow the anterior method because until late years it has been the operation commonly performed. In most of the reported cases the ulcer was single; in 3 out of 24 cases it was multiple. It is usually in the distal loop, but may be in the proximal loop. It may be situated at the anastomosis level, a little way below it, or even 5 or 6 inches below it. The ulcer may appear a few days after the operation, weeks after, months after, or even years after. The condition results from hyperacid gastric juice passing directly into the jejunum before it has been neutralized by admixture with bile and pancreatic juice. It is possible that the condition is predisposed to by a twist in the jejunum and by an anastomosis opening too small to correct hyperacidity. Wm. J. Mayo blames for the development of an ulcer at the suture line, silk or linen sutures which cut and hang in the lumen. He says they may hang for months. In one of his cases they hung for twenty-two months ("Brit. Med. and Surg. Jour.," Jan. 29, 1914).

There may be no symptoms at all until there is a severe hemorrhage or perforation, or symptoms similar to those which called for the gastro-enterostomy may return. Connell's table shows that acute perforation took place in 14 of the 39 reported cases. Pain is to the left of the umbilicus, comes on two or three hours after eating, and is relieved by food. There may be tenderness and there may be rigidity of the left rectus muscle (Robson, Loc. cit.). In some cases an ulcer at the suture line penetrates the transverse colon. In such a condition colonic matter enters the stomach and may be recognized in washings from the stomach. In chronic cases treatment is first medical; if this fails, operation is indicated. If on opening the abdomen it is found that the original pyloric or duodenal ulcer has healed, but there is an ulcer in the jejunum, separate the bowel from the stomach, close the stomach opening, excise the jejunal ulcer, and close the wound in the bowel. If there is stenosis of the pylorus or duodenum we must have a gastro-enterostomy, so we make another after closing the original opening (Robson). Very extensive ulceration may call for resection. If the patient is greatly weakened or if the ulceration is extensive, jejunostomy (see page 1244) may be done (Robson). In perforation, operation must be immediate.

The Vicious Circle and Regurgitation.—Vomiting may occur after the performance of gastro-enterostomy. It may soon cease, may be productive of disastrous consequences, and may be expressive of an existing complication of great gravity. In some cases of gastro-enterostomy vomiting arises because the anastomosis has been made high up on the anterior gastric wall and the stomach is not drained. In other cases ether induces vomiting, and the mechanical efforts force the contents of the duodenum and even of the jejunum into the stomach. The true "vicious circle" is a condition in which the contents of the stomach pass through the anastomosis opening into the duodenal side of the loop of intestine, mix with the duodenal secretions, and return to the stomach (Fowler, in "Annals of Surgery," Nov., 1902). The following conditions are often classified under the same head, but each is called by Fowler a regurgitation or reflux: (1) When the duodenal secretions pass back into the stomach through a permeable pylorus (as in cases of gastroptosis, noncancerous pyloric stenosis, and gastric dilatation); (2) when the duodenal

secretions enter the stomach through the anastomosis opening; (3) when the contents of the jejunum pass into the stomach, because of efforts at vomiting or as a result of reversed peristalsis. In some cases the contents of the jejunum may pass into the afferent loop of intestine and distend it. It was long thought that the vicious circle was due purely to bile passing into the stomach from the proximal (afferent) loop of the jejunum. Dastre's experiments on dogs show that bile in the stomach does not impair either digestive power or the general health, and Moynihan has confirmed these experiments by clinical observation. It has been held that the cause of this condition is the making of an anastomosis with a long loop between the duodenojejunal flexure and the anastomotic opening into the jejunum, the loop being unable to propel its contents downward and tending by its weight to produce a bend or kink at the seat of anastomosis. This is a very doubtful theory.

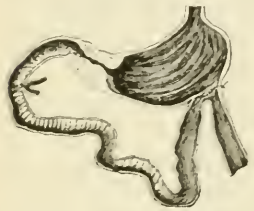

FIG. 746.—Billroth's method of gastro-enterostomy.

Persistent vomiting may be due to spur formation, which deviates stomach contents into the duodenal side of the loop. It is in some cases due to kinking or twisting of the distal loop; in others, to failure of peristalsis in the proximal loop; in still others, to contraction of the opening in the stomach wall (Chlumsky on "Gastro-enterostomy" in the Breslau Clinic; article by Charles L. Gibson, in "Annals of Surgery," Aug., 1908). I cordially agree with the statement of Herbert J. Paterson, viz.: "Most, if not all, fatal cases of regurgitant vomiting are due to mechanical obstruction at the afferent opening" ("The Hunterian Lectures," delivered before the Royal College of Surgeons of England, Feb. 19, 21, and 23, 1906). In order to lessen the danger of vomiting after gastro-enterostomy, do the operation under a local anesthetic whenever possible; and in order to prevent regurgitant vomiting take every care in the operation to prevent the formation of a spur on the mesenteric border of the jejunum (Herbert J. Paterson, Ibid).

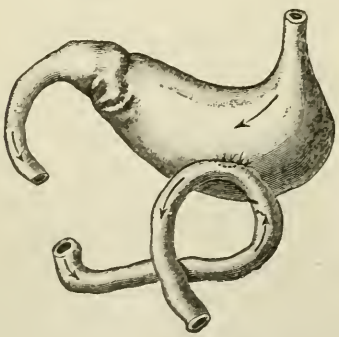

FIG. 747.—Gastro-enterostomy (after Lücke).

FIG. 748.—Wölfler-Lücke method of gastro-enterostomy.

After Billroth's operation (Fig. 746) and in all the earlier methods the contents of the duodenum certainly pass into the stomach, mix with the stomach contents, and usually, but not always, pass into the efferent loop. In all these operations there is great danger of the development of a vicious circle.

Lücke devised an operation with the idea of preventing such a complication. In the Lücke operation the direction of peristalsis in the efferent loop is the same as in the stomach (Fig. 748). McGraw points out that the crossing of the loop which is effected is dangerous. The Wölfler-Lücke operation is

shown in Fig. 748. Wölfler also devised the operation pictured in Fig. 749. Von Hacker's posterior operation is thought by some to be less apt than the anterior method to be followed by the vicious circle (Fig. 750). Kocher devised an operation in which a valve is formed, but, as Fowler points out, this valve does not prevent filling of the duodenum and imbibition of the material by the stomach; and, further, that the valve does not work when the parts become cicatricial (see Fig. 754).

The combination of gastro-enterostomy with entero-anastomosis does tend to prevent the vicious circle. This operation is shown in Figs. 751 and 752.

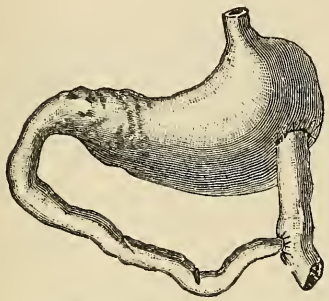

Fig. 749.—Implantation of duodenum into jejunum and jejunum into stomach (after Wölfler).

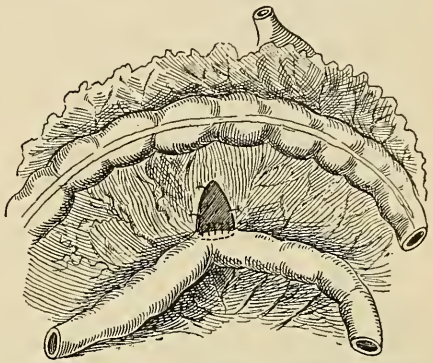

Fig. 750.—Von Hacker's posterior gastro-enterostomy.

I do not believe it should ever be a primary operation. It permits acid gastric juice to flow directly into the jejunum and keeps away the bile which would normally protect mucous membrane. Hence such an operation exposes the patient to the danger of jejunal ulceration. Another defect in such an operation is that there is still a communication between the stomach and the efferent loop. Fowler's operation (see Fig. 758) closes the jejunum and corrects the de-

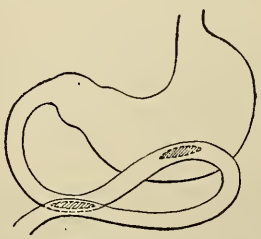

Fig. 751.—Jaboulay's method of gastro-enterostomy.

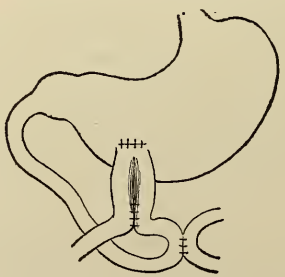

Fig. 752.—Braun's method of gastro-enterostomy.

fect inherent in Braun's and in Jaboulay's operation. Other operators close the pylorus. McGraw's operation (see Figs. 755 and 756, which show entero-anastomosis) tends to prevent the formation of a vicious circle. It seems certain that the danger of the formation of a vicious circle is greatest after a long-loop anterior operation and least after a short-loop posterior operation. The shorter the loop, the less the danger, hence the latter is the operation of choice. The safest operations and the operations of choice are the short-loop operation of Moynihan or Scudder (see page 1237) and the "no-loop" operation of the Mayos (see page 1240).

The Question of Closing the Pylorus.—This was suggested by Doyen in 1893 and in 1895 by von Eiselsberg. The indications are absence of narrowing of the pylorus in chronic ulcers and active ulceration of the pylorus or duodenum (Gibson and Beekman, in "Annals of Surgery," April, 1915). If the pylorus is closed all gastric material passes through the artificial opening. Wilms takes a band of fascia from the fascia lata or the anterior sheath of the rectus abdominis, the band being ½ an inch in width and 4 inches in length. A clamp is carried back of the pylorus through the gastrocolic omentum and out through the gastrohepatic omentum, this clamp grasps the fascia and draws it around back of the pylorus, the muscle surface of the fascia being in contact with the serous coat of the stomach. The fascia is pulled sufficiently tight to occlude the pylorus and the fascial ends are sutured with chromic catgut. The fascia is also sutured to the stomach. The closure by this method is not apt to be permanent. Instead of a band of fascia it has been suggested that the round ligament of the liver could be used.

Many surgeons have used silk or linen to constrict but not to strangulate the pylorus. An occlusion effected thus is only temporary and the ligatures finally cut into the pylorus and are passed through the bowel. Hoffman divides the serous and muscular coats, sutures the fascial strip around the mucous membrane and closes the muscular and serous coats. This is very difficult of accomplishment without opening through the mucous membrane.

Von Eiselsberg divides the stomach proximal to the pylorus and inverts each end. Other surgeons have divided the pylorus, closed the duodenal end and anastomosed the stomach end to the side of a loop of jejunum, or to the duodenum distal to the area of ulceration.

Biondi incises the pyloric portion of the stomach the incision going to but not through the mucous coat. The mucous tube is dissected free, doubly ligated, divided between the ligatures, and the cuts in the muscular and serous coats are sutured. Bartlett makes a partial exclusion by dividing the prepyloric portion of the stomach from the greater curvature to within an inch of the lesser curvature and suturing the cut edges.

Brewer suggests obtaining occlusion by the use of an aluminum band (see Charles L. Gibson and Fenwicke Beekman, in "Annals of Surgery," April, 1915).

Treatment of Persistent Vomiting after Gastro-enterostomy.—If vomiting persists in spite of gastric lavage and rectal feeding following the operation of gastro-enterostomy with a long loop without entero-anastomosis, open the abdomen again and perform anastomosis between the afferent and efferent loops of intestine. This was suggested by Braun in 1892, and both he and Jaboulay performed it in the same year. The operation has saved lives. In a short-loop operation we should assume that the jejunum has been twisted, should open the abdomen, and endeavor to correct the condition. Herbert L. Paterson ("Hunterian Lectures," before the Royal College of Surgeons of England, Feb. 19, 21, 22, 1906) points out that slight cases of regurgitant vomiting not immediately following an operation may be due purely to constipation, and may be recovered from if care be taken to secure daily a free bowel movement. In Paterson's opinion constipation causes reversed peristalsis, and as both the duodenal "siphon-trap and the pyloric sphincter are put out of service," regurgitation takes place from the efferent loop into the stomach.

Anterior Gastro-enterostomy. *Senn's Method.*—A median incision is made through the abdominal wall, from below the xiphoid cartilage to the umbilicus. An opening is made in the lower part of the anterior wall of the stomach in the direction of the long axis of the viscus, and its edges are stitched by a continuous catgut suture. The contents of the jejunum are forced along to below the point where an incision is to be made. The loop of jejunum should be from 12 to 14 inches in length. A rubber tube is fastened around the bowel

above this point, and another below it; an incision is made in the long axis of the bowel, and the margins of the wound are sutured in the same manner as the stomach wound. Bone plates are introduced into the stomach and intestine, and the ligatures are tied as in intestinal anastomosis. Catgut rings or rubber rings may be used.

Mayo's Anterior Method (Fig. 753).—Open the abdomen, and pick up the small intestine and find a point of jejunum about 14 inches from the point at which it emerges from under the mesocolon. Effect the union to the inferior border of the stomach close to the greater curvature and at the lowest portion of the stomach pouch. When the anastomosis is completed the stomach pouch is funnel shaped. The usual custom has been to place the opening higher on the anterior wall. It sometimes led to the formation of a pouch on the anterior wall, did not drain the stomach, and caused vomiting. After the performance of gastro-enterostomy the edges of the omentum are caught

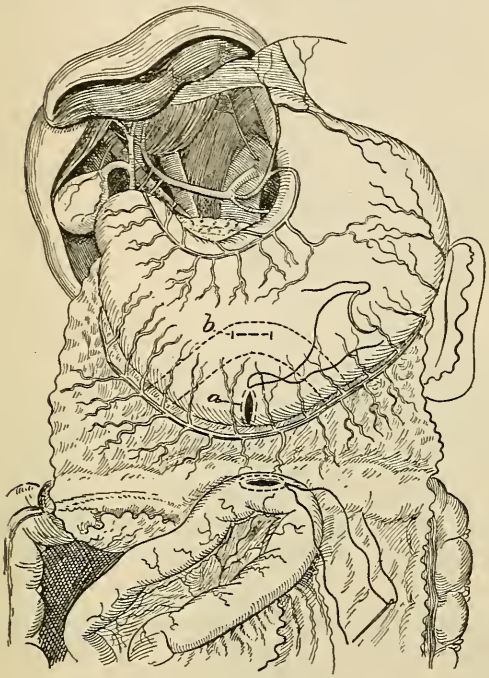

Fig. 753.—Mayo's method of anterior gastro-enterostomy showing proper and improper locations of openings: *a*, Proper position, leaving no pouch; *b*, usual position forming intragastric pouch ("Annals of Surgery").

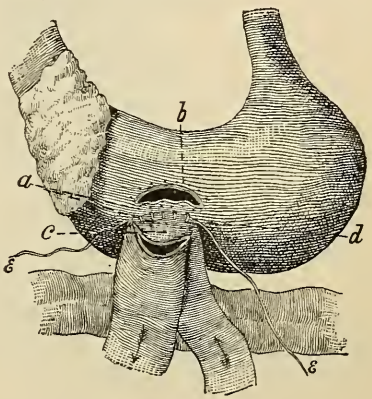

Fig. 754.—Kocher's method of gastro-enterostomy: *a*, Places of posterior annular suture through entire wall of stomach and intestine; *b*, places of anterior annular suture through the entire wall; *c*, valve at the jejunum by arch-formed incision; *d*, posterior annular suture of the serosa; *e*, thread ends for continuing anterior suture of the serosa.

upon each side of the anastomosis and are sutured to each other and to the stomach wall 1 inch above the opening. The edges are then united to each other in a downward direction for about 3 inches so as to form an apron over the anastomosis, yet not connected with it. Catgut is used for suturing. If leakage occurs, the omentum is adjacent and "available." If it does not occur, the omentum soon returns to its normal position (Wm. J. Mayo, "Annals of Surg.," Aug., 1902).

Kocher's Method (Fig. 754).—After opening the abdomen lift up the omentum, pull up a loop of intestine, and find the point where the jejunum appears from under the mesocolon. Select a loop 16 inches from the origin of the jejunum and prepare to attach it to the stomach. Wölfler believed that the intestine should be applied to the stomach in such a manner that the direction of peristalsis in the bowel would correspond to the direction of the stomach-

tide. This can be accomplished by having the proximal portion of gut to the left, and the distal portion to the right. The operation is to be so performed that after its completion the stomach contents pass into the distal portion of the gut, and intestinal contents do not tend to enter the stomach (see Fig. 748). In order to accomplish this Kocher hangs the intestine to the stomach wall in such a manner that the proximal portion of the loop is posterior and ascending, and the distal portion is anterior and descending. The bowel is hung to the stomach by a continuous serous suture of silk, the ends of which are left long. The intestine is opened by a curved incision, the convexity of which is downward. The stomach is opened so that the convexity of the cut is upward. The valve-like portion of the bowel wall is sutured to the stomach below the incision in that viscus. The two openings are well approximated by sutures.

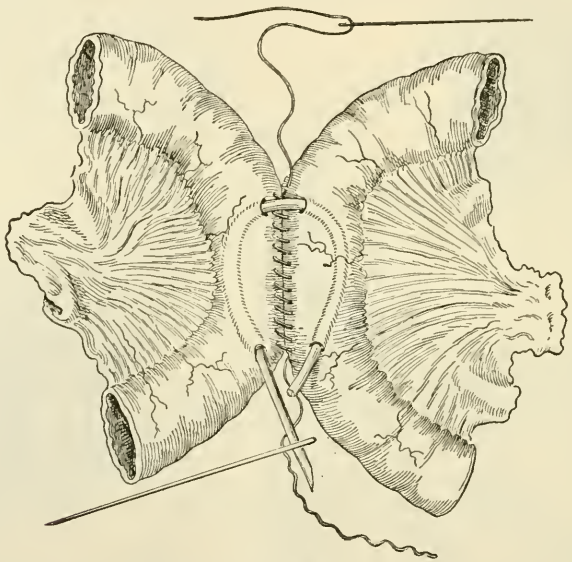

FIG. 755.—McGraw's method of lateral anastomosis: The elastic ligature is introduced (Walker). Gastro-enterostomy is done by the same plan.

Operation by McGraw's Elastic Ligature (Figs. 755–757).—The elastic ligature was introduced by Silvestri in 1862, and was first used in intestinal anastomosis by the same surgeon. McGraw perfected the operation in 1891. (See Dudley Tait, in "Annals of Surgery," Feb., 1906.) The operation may be anterior or posterior. The intestine and stomach are sutured together by Lembert stitches. The elastic cord, which is 3 to 5 mm. in diameter, is passed through the stomach and then the bowel, in the long axis of each, and is tightly tied, and the knot is fastened with a silk thread. Another row of Lembert sutures buries the elastic cord from sight. The cord cuts through in from forty-eight to seventy-two hours and makes the anastomosis. Thus the danger of infection is greatly lessened, for when the anastomosis opening is formed it is completely encompassed by firm adhesions. Further, the danger of the formation of a vicious circle is greatly lessened, because there is no communication between the stomach and bowel for between forty-eight and seventy-two hours, the period in which vomiting of the type previously described is most apt to occur. The method is not suitable for absolute pyloric occlusion. In this condition it is imperative to give nourishment early, and, again, an ordinary gastro-enterostomy allays auto-intoxication and this operation cannot until the ligature cuts through. It is particularly valuable in the performance of lateral

intestinal anastomosis. The cuts show the operation of lateral anastomosis of intestine, but gastro-enterostomy is performed in the same manner.

Jaboulay's Gastroduodenostomy.—This operation was devised by Jaboulay in 1892. It aims to obviate some of the objections to pyloroplasty and at

FIG. 756.—McGraw's method of lateral anastomosis: One tie of the elastic ligature with a strong silk ligature underneath ready to fasten the elastic ligature where it is drawn taut (Walker).

the same time to retain the advantages this operation possesses over gastro-jejunostomy. Jaboulay's gastroduodenostomy has never become popular with surgeons, and Finney's method is much more satisfactory (see page 1220).

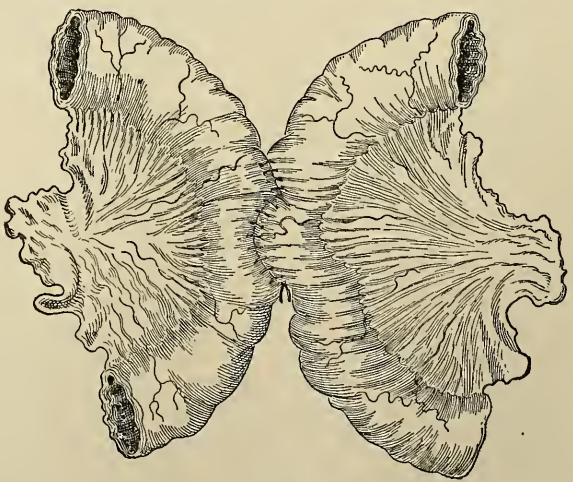

FIG. 757.—McGraw's method of lateral anastomosis: The operation completed (Walker).

Posterior Gastro-enterostomy (see pages 1237–1242).—In a thin subject with a long mesocolon posterior gastro-enterostomy is to be chosen, but if the mesentery be short or contain much fat, or if the vascular loop, coming from

the superior mesenteric artery to supply the transverse colon, be small—so that an opening in the posterior layer of the gastrocolic omentum would be close to the artery—the anterior operation is employed (Wm. J. Mayo, in "Annals of Surgery," Aug., 1902). If a Murphy button is used, the posterior operation is selected. Posterior gastro-enterostomy is commonly performed as follows: After the abdomen has been opened the stomach and omentum are raised; a portion of the upper jejunum is seized, emptied, and a site selected for the clamp. This site must be within 5 inches of the flexure. If there be a broad mesocolic band preventing a near approach to the flexure the band must be divided. A clamp is applied on the side opposite the mesenteric attachment. A spot is selected on the transverse mesocolon where there are no vessels, and an opening is made through the mesocolon with a blunt instrument. The posterior wall of the stomach is pulled into the opening and sutured to its edges. This prevents downward displacement of the stomach and obstruction of the loop of gut. A portion of the posterior wall of the stomach is pulled out into a cone and clamped. Openings are made and the sutures applied as directed on pages 1237–1242. Regurgitation is less common after posterior than after anterior gastro-enterostomy. In 250 posterior operations in Czerny's clinic there was not one case of regurgitant vomiting; 170 cases were button operations and 45 were by sutures alone (Peterson). Von Hacker had one instance of regurgitation in 60 posterior operations.

Operation by the Murphy Button.—Gastro-enterostomy may be quickly performed by the use of a large-sized Murphy button. Murphy said that in some reported cases the button has slipped back into the stomach, but this accident can be prevented by the use of an oblong button and by making the anastomosis on the posterior stomach wall. The same surgeon advised us to scarify the peritoneum in order to hasten union, and said supporting sutures about the button are not required, except when considerable tension exists. There is no question that an anastomosis on the anterior wall, accomplished by a Murphy button, can be speedily performed. Anastomosis on the posterior wall cannot be performed so speedily, and it sacrifices to some extent the great advantage of the button operation—that is, speed. In spite of the reported cases we can positively assert that the danger of the button producing grave trouble is slight. In some cases it drops into the stomach and remains there, but seems to do no harm. In other cases it takes a long time to pass. In 1 of the author's cases it did not pass until the eighty-sixth day. In one of Keen's cases it has been retained for years. If it does not pass in four weeks, the rectum should be explored by the finger from time to time to see if it is lodged in that region. The *x*-rays will determine whether the button is in transit. If the wall of the stomach is thick, the incision should be made in the stomach wall before the suture is passed, and this suture should pick up only a small portion of the stomach wall, otherwise the button may be retained in place for a very long time (Wm. J. Mayo). "In many cases in which the button passes, vomiting with symptoms of obstruction may appear during the second or third week while it is in transit. Gastric lavage and rectal feeding for a day or two cause these symptoms to subside" (Wm. J. Mayo, in "Annals of Surgery," Aug., 1902). Mayo long ago maintained that the suture operation is as good as the button operation, and that the results are about the same. Mikulicz says that in the suture operation entero-anastomosis is necessary, but not in the button operation, because the button, while in place, prevents angulation. The last-named surgeon uses the button in malignant cases and the suture in benign cases. Czerny is an advocate of the button. Every button should be tested before it is used. Mayo finds nearly 20 per cent. of buttons imperfect and dangerous.

Fowler's Method (Fig. 758).—Anastomose the posterior wall of the stomach to the jejunum and do an entero-anastomosis between the afferent and efferent

loops of jejunum. Pass a No. 20 silver wire two or three times around the afferent loop of jejunum and draw it sufficiently tight to occlude the lumen without strangulating the wall of the gut. The ends are twisted, cut short, rolled into a flat coil, the cut ends being in the coil. (See Geo. Ryerson Fowler, on the "Circulus Vitiosus" following gastro-enterostomy, "Annals of Surgery," Nov., 1902). This operation positively prevents the entrance of material from the duodenal loop into the stomach and also drains that loop.

Moynihan's Method.—This plan I have employed repeatedly. It is easy, rapid, and clean: Make a 4-inch incision 1 inch to the right of the middle line and above the umbilicus. Open the anterior sheath of the rectus and separate it from the front of the muscle as far as the middle line. Draw the entire muscle outward, open the posterior portion of the sheath, and then open the belly. Inspect and feel the entire stomach. Lift the omentum and transverse colon out of the abdomen and make the mesocolon taut by raising the stomach and colon with the left hand. Find "a bloodless spot in the arch of the middle colic artery," pick up a bit of the under surface of the mesocolon by a pair of hemostatic forceps, lift it from the posterior stomach wall, and open the lesser sac of peritoneum by the scissors. Enlarge the opening by dilatation or tearing until it admits three fingers. Inspect and feel the posterior stomach wall. Place the stomach in its natural position, mark with the thumb the lowest part of the posterior stomach wall, and again turn the viscus over. From the spot marked by the thumb a fold is raised. The fold is oblique and its upper end is to approach the cardia and lesser curvature. A stomach clamp (Fig. 759) having a rubber tube stretched over each blade is applied obliquely so as to grasp the base of this fold. In applying the clamp

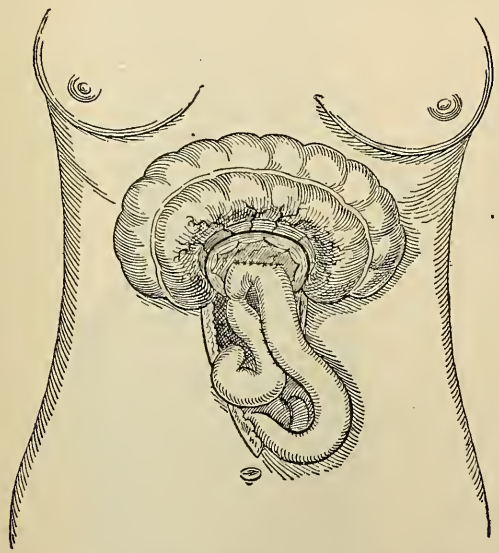

Fig. 758.—Fowler's method of gastro-enterostomy.

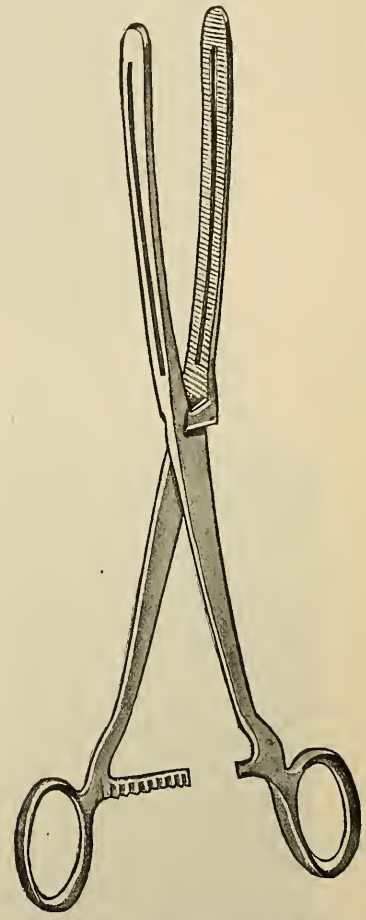

Fig. 759.—Moynihan's clamp for gastric and intestinal operations (made by Down Brothers, London).

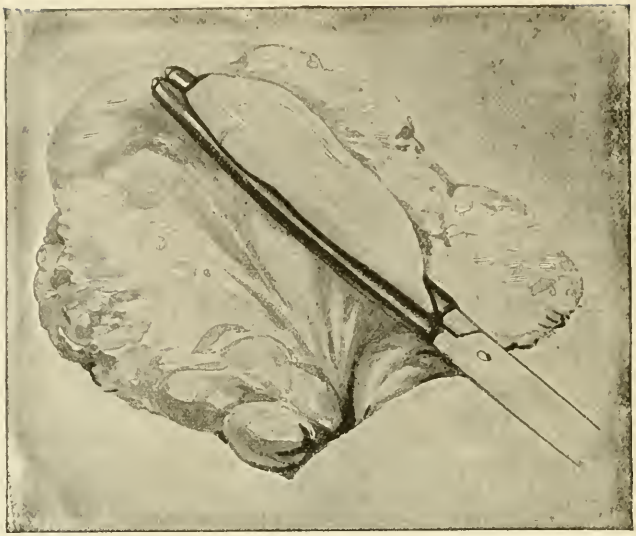

Fig. 760.—Moynihan's method of gastro-enterostomy: The oblique application of the clamp to the stomach (Moynihan).

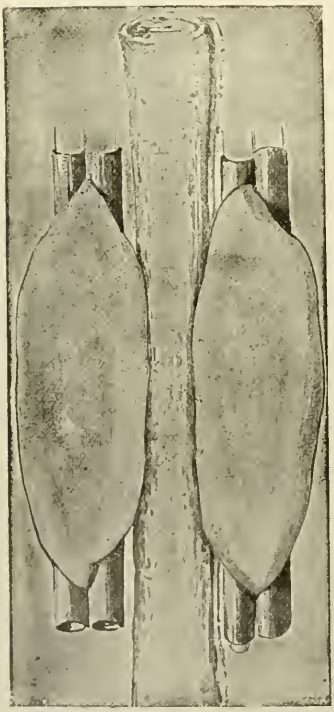

Fig. 761.—Moynihan's method of gastro-enterostomy: The strip of gauze between the clamps (Moynihan).

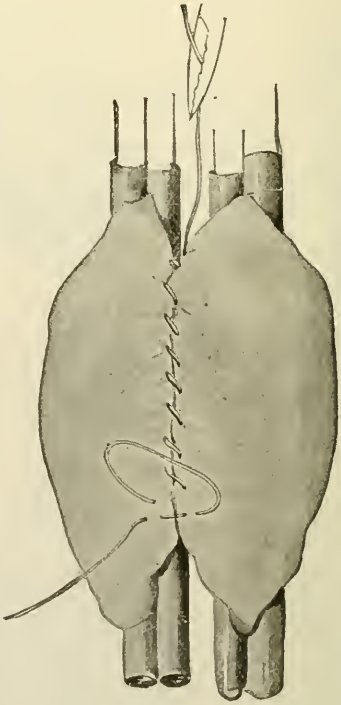

Fig. 762.—Moynihan's method of gastro-enterostomy: The first layer of serous suture (Moynihan).

the tip should point to the right shoulder and the handle to the outer side of the left hip, and the lowest portion of the stomach is grasped in the tip of the blade of the clamp (Fig. 760). The clamp is now put in a horizontal position. The duodenojejunal flexure is found by the finger, the jejunum is identified and its natural position is noted. The jejunum is picked up and "drawn tight" and a spot is noted which reaches the greater curvature of the stomach when the jejunum is in its natural position. The point noted is 5 inches from the flexure and the anastomosis is made to the jejunum above the spot. The clamp is applied in the side of the gut opposite the mesentery. The surgeon must be sure that the jejunum is not twisted around its longitudinal axis. If it is, the clamps are not rightly applied, and they must be placed so that after the anastomosis the jejunum lies in its natural position without a twist. The clamped

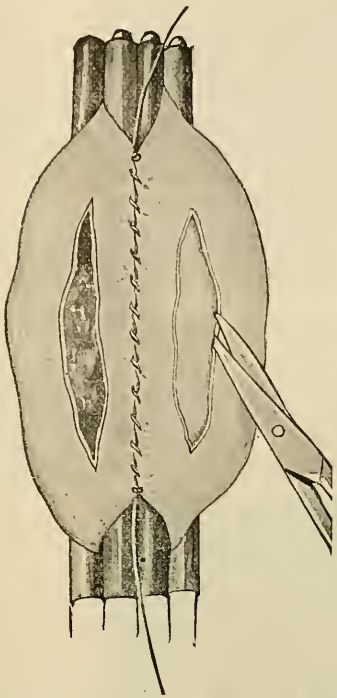

Fig. 763.—Moynihan's method of gastro-enterostomy: Removal of the ellipse of mucous membrane (Moynihan).

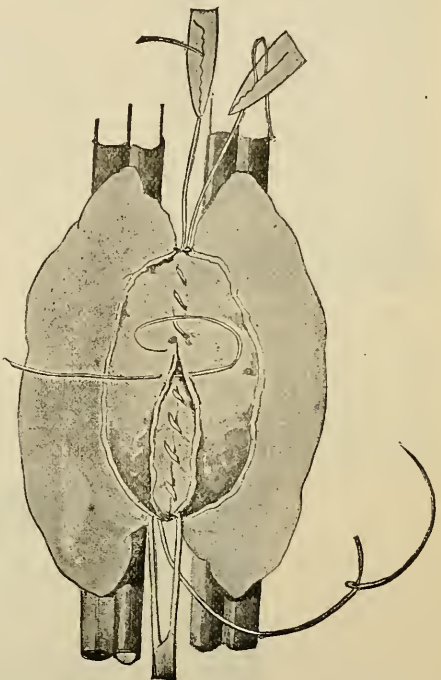

Fig. 764.—Moynihan's method of gastro-enterostomy: The inner suture continued (Moynihan).

gut is placed by the side of the clamped stomach, a bit of gauze being put between them (Fig. 761). The stomach (except the clamped portion), the omentum, and transverse colon are returned to the abdomen and the clamps are surrounded by gauze. Each clamp holds a fold 3½ to 4 inches in length. Pagenstecher's celluloid thread is used for suturing. The first line of sutures is passed as shown in Fig. 762. In front of these sutures an incision is made into the stomach and another into the jejunum, the serous and muscular coats being first divided, and an ellipse of mucous membrane being removed (Fig. 763). The next row of sutures is inserted as shown in Fig. 764. When this row is completed the clamps are removed and the long suture of the first row is picked up again and the operation is completed (Fig. 765). Finally the edges of the mesocolic opening are sutured to the jejunum. The parts are cleansed with salt solution, the sulture line is inspected, the parts are returned to the belly, and the abdomen is closed. (See Moynihan's "Abdominal Operations.")

The No-loop Operation of the Mayos (Figs. 766–768).—It is this operation, I usually perform. By it the gastric opening, which is placed in the line advised by Moynihan, extends ¼ or ½ inch into the anterior wall of the stomach, and thus the lowest part of the opening will be the lowest part of the stomach (Fig. 766). The incision in the intestine begins from 1 to 3 inches from the origin of the jejunum, the measure being made on the anterior surface (Fig. 766).

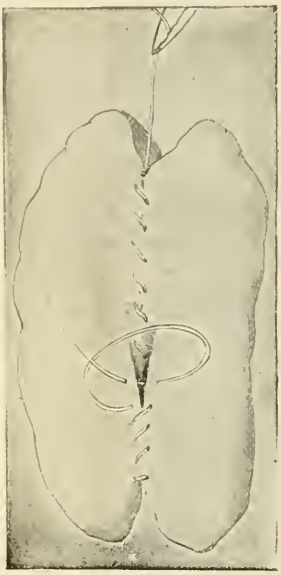

Fig. 765.—Moynihan's method of gastro-enterostomy: The serous suture resumed (Moynihan).

The object is to get as short a piece of jejunum as can be attached without tension. The operation is described as follows (Wm. J. Mayo, in "Annals of Surgery," Nov., 1905):

"(*a*) The abdominal incision is made 4 inches in length, ¾ inch to the right of the middle line, the fibers of the rectus muscle being separated. The lower end of the external wound lies opposite the umbilicus. This opening also enables inspection of the duodenum and gall-bladder and is reliable against hernia when closed.

"(*b*) The transverse colon is pulled out and the mesocolon made taut by traction upward and to the right, in this manner bringing the jejunum into view at its origin.

"(*c*) About 3 to 4 inches of the jejunum opposite the mesentery are drawn into a slightly curved clamp. The handles of the clamps should be to the right, to enable a short grasp on the intestine. Three-fourths of the circumference of the bowel is pulled through; the posterior border is not included, to prevent entanglement of the suture with

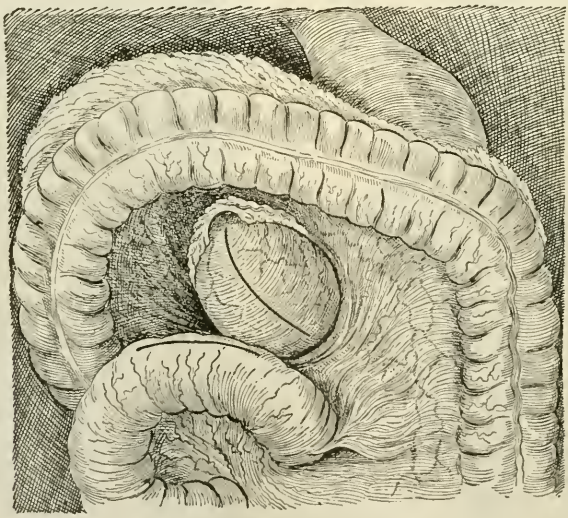

Fig. 766.—Mayo's method of gastro-enterostomy: Showing posterior wall of the stomach drawn through a rent in the transverse mesocolon. Note slight separation of gastrocolic omentum from its attachment to the stomach, permitting anterior wall of stomach to appear, and insuring drainage at lowermost level. Black lines mark site of proposed anastomosis; the jejunum shows at its origin.

the redundant posterior mucous membrane. The holding clamps are applied sufficiently tight to check hemorrhage and prevent extravasation of intestinal contents.

"(*d*) The ligament of Treitz is a short muscular mesentery covered by a variable peritoneal fold (too variable for a reliable landmark) extending upward from the origin of the jejunum on to the mesocolon. This peritoneal fold lies at the base of the arterial loop of the middle colic artery which supplies the

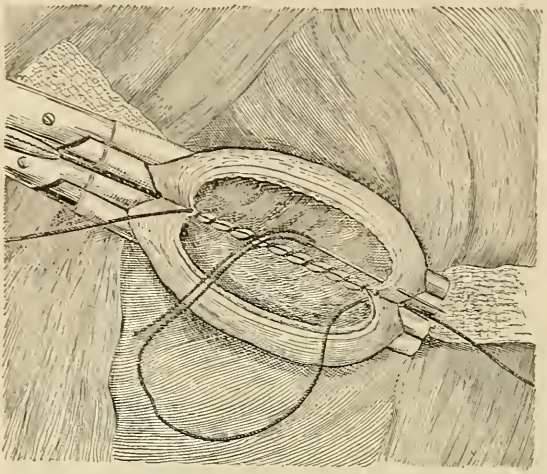

FIG. 767.—Mayo's method of gastro-enterostomy: Forceps in place and anastomosis half completed by suture.

transverse colon. The mesocolon is opened within the vascular loop and the posterior inferior border of the stomach pushed through. A small separation of the greater omental attachment to the stomach enables the anterior gastric

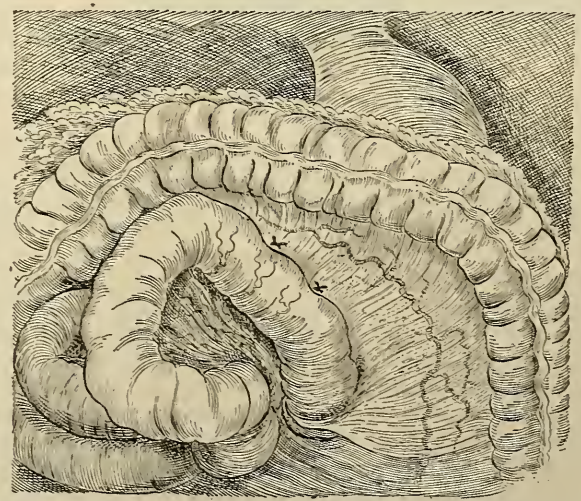

FIG. 768.—Mayo's method of gastro-enterostomy: Completed operation from behind. Margin of torn mesocolon attached by several interrupted sutures to line of union.

wall to be drawn out posteriorly. The posterior gastric wall is drawn into a clamp, with the handles to the right, in such a manner as just to expose the anterior wall at the base.

"(*e*) The two clamps are laid side by side and the field carefully protected by moist gauze pads. With fine celluloidal linen thread on a straight needle

the intestine is sutured to the stomach from left to right by a Cushing suture at least 2½ inches.

"(*f*) The stomach and intestine are incised ⅛ inch in front of the suture line and the redundant mucous membrane excised flush with the retracted peritoneal and muscular coats. With a No. 1 chromic catgut on a straight needle the posterior cut margins of the entire thickness of the gastric and jejunal walls are united by a buttonhole suture from right to left; at the extreme left the suture changes to one which passes through all the coats, of each side alternately, from the peritoneal to the mucous, then directly back on the same side from the mucous to the peritoneal. This acts as a hemostatic suture, and also turns the peritoneal coats into apposition. It passes around the anterior surface and is tied to the original end, which has been left long for the purpose. If silk or linen is used for this suture it may hang *in situ*, suppurating for months.

"(*g*) The clamps are now removed and the linen thread continued around until it is tied to the original end, firmly catching the blood-vessels in sight along the suture line. The parts are carefully cleansed and inspected. If necessary, a suture or two are applied to coapt accurately or to check the oozing.

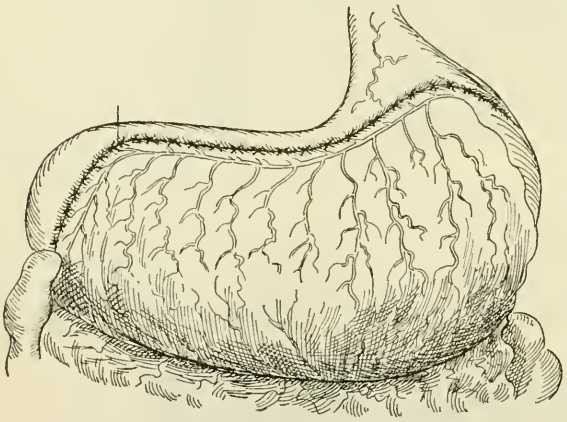

Fig. 769.—Bircher's method of gastroplication.

"(*h*) The margins of the incised mesocolon are now united to the suture line by 3 or 4 interrupted sutures, and the parts returned into the abdomen." In this operation the greatest care must be taken to avoid twisting the gut around its longitudinal axis.

Gastro-anastomosis or **gastrogastrostomy** is an operation performed for hour-glass contraction of the stomach, a condition which occasionally ensues on the healing of an ulcer. In this operation an anastomosis is effected between the pyloric and cardiac pouches. It was devised and practised by Wölfler in 1894. I have performed it twice with success. Watson folds the two stomachs over each other, using the narrow isthmus as a hinge; sutures the pouches together and leaves the ends of the sutures long. He incises the anterior wall of the anterior stomach in order to obtain access to the double septum between the two pouches. He makes an anastomosis opening through the double septum, sutures the edges, and closes the wound in the anterior wall of the anterior stomach. Wölfler made a vertical cut in each pouch and united these openings to make an anastomosis. The best plan is to apply clamps on each side of the isthmus and operate as we would for gastro-enterostomy (Fig. 770).

Gastroplication (Brandt's Operation of Stomach-reefing for Dilated Stomach).—Apply sutures in the anterior wall so as to form reefs, then tear through the great omentum and apply sutures in the posterior wall. The sutures pass through the serous and muscular coats. A continuous suture may be used on the anterior wall and another on the posterior wall, or numerous interrupted sutures may be inserted. This operation is of questionable value, and must never be used if stenosis of the pylorus exists, and stenosis of the pylorus is the most common cause of gastric dilatation.

Bircher's method of gastroplication is shown in Fig. 769.

Gastropexy (Duret's Operation for Gastroptosis).—It has been shown by Duret that dyspepsia of a peculiarly severe type may be produced by prolapse or downward displacement of the stomach. In this condition he advised the following operation: Perform a median laparotomy, but do not incise the peritoneum in the upper portion of the wound. Expose the stomach and fix it by means of a silk suture to the undivided but exposed peritoneum. The suture should be parallel to the lesser curvature and near the pylorus should be horizontal.[1] Rovsing, too, fixes the stomach to the abdominal wall. So do Hartmann and Eve. The operations of Duret, Rovsing, Hartmann, and Eve, of London, fix and distort the stomach. This seems to me an objectional procedure and liable to be followed by pain. To fix an organ which undergoes

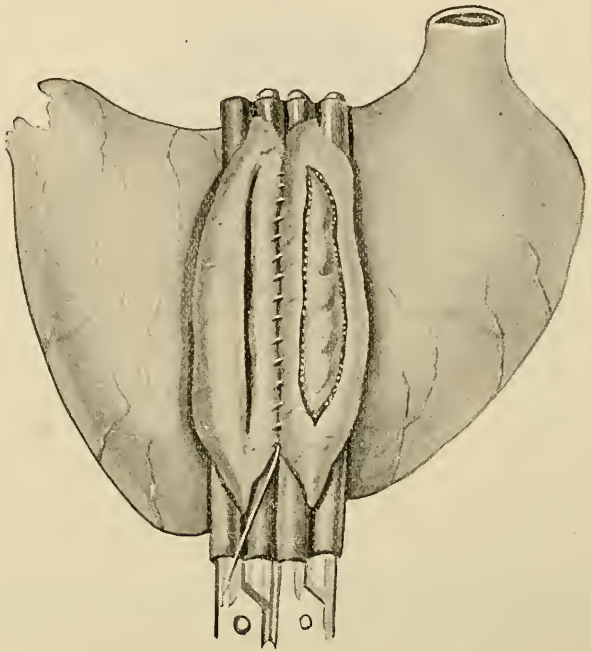

Fig. 770.—Hour-glass stomach. The application of clamps and the method of suture in gastrogastrostomy. The details are the same as in the operation of gastro-enterostomy (Moynihan).

active peristalsis must surely be productive of difficulty. Byron Davis advises the suturing of the gastrohepatic omentum near its attachment to the lesser curvature to the stomach wall as high as possible. Beyea has devised an operation which is free from the objections which may be urged against Duret's operation. Sometimes gastro-enterostomy is also performed.

Beyea's Operation for Gastroptosis.—Insert three rows of interrupted silk sutures through the gastrohepatic omentum and the gastrophrenic ligament. Each suture is passed from above downward and the row begins at the right and passes to the left (Fig. 771). When the sutures are tied, a fold or plication is formed in the ligaments, the supports of the stomach are shortened, and the viscus is elevated to a normal position without any disturbance of its physiological mobility ("Univ. of Penna. Med. Bull.," Feb., 1903).

Ransohoff's Omentopexy for Gastroptosis.—Ransohoff ("Medical Communications of the Mass. Med. Soc.," 1912, vol. xxiii) points out that Beyea's

[1] "Rev. de Chir.," June, 1896.

operation is insufficient because only the right and left borders of the gastro-hepatic omentum act as supports. He uses the omentum to raise and fix the stomach, and at the same time raises and fixes the transverse colon. He makes spaces between the fascia and peritoneum as advised by Coffey and sutures the omentum into these spaces. If necessary he also does gastroplication, or coloplication, or reefs the mesocolon or separates bands and adhesions, or shortens the round ligament of the liver.

Duodenostomy and Jejunostomy.—It has been suggested that one of the above operations should be performed in a case of pyloric obstruction in which neither pylorectomy nor gastro-enterostomy is feasible. Duodenostomy

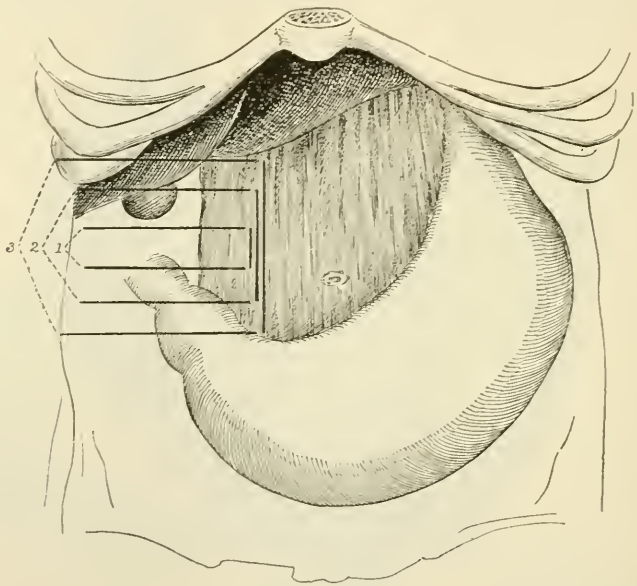

FIG. 771.—Beyea's operation for gastroptosis: 1, Position of one suture of first row; 2, one suture of second row; 3, one suture of third row. Others of each row introduced at intervals to and including the gastrophrenic ligament.

is said by some to be an easy operation because of the mobility of the pylorus and first part of the duodenum, and to be not only easier, but safer, than jejunostomy, because it makes the fistula above the opening of the common bile-duct ("Bull. et Mém. de la Soc. de Chir. de Paris," No. 39, 1901). Cackove advocates the operation in some cases of gastric ulcer with repeated hemorrhages and in some cases of gastric cancer. In the latter cases he asserts that the mortality is about the same as from gastro-enterostomy and the prolongation of life is greater ("Arch. f. klin. Chir.," Bd. lxv, Heft 2). Hartmann's case of duodenostomy lived two months. The operation was performed for extreme cicatricial stenosis of the pylorus due to swallowing hydrochloric acid.

Jacobson disapproves of both procedures, and objects particularly to duodenostomy, because it involves a portion of the intestine which is difficult to deal with, and because important fluids escape constantly from the fistula.[1]

If duodenostomy be performed, it should be done in the same manner as gastrostomy by Witzel's method. I regard jejunostomy as an operation which is occasionally justifiable and as preferable to duodenostomy. As performed to-day there is little danger of leakage, even if the tube slips out. This operation puts the stomach at absolute rest. It is employed in very extensive

[1] Jacobson's "Operations of Surgery."

ulceration, in multiple ulcers, and in some cases of cancer in which gastro-enterostomy is impossible or is contra-indicated, because the opening would be in or too near the malignant growth. Wm. J. Mayo ("Am. Jour. Med. Sciences," April, 1912) regards the operation "as an active competitor of gastrostomy in cases of esophageal and cardiac obstruction." Mayo Robson ("Brit. Med. Jour.," Jan. 6, 1912) advocates the operation. Mayo makes an epigastric incision, picks up the jejunum, makes a little opening at a point from 12 to 16 inches from the jejunal origin, introduces a rubber catheter (No. 9 English) "down stream" for about 3 inches, catches it to the wall of the bowel by one suture of chromic gut, infolds it for 1 inch or more as in Witzel's gastrostomy, using mattress sutures of linen, anchors the gut to the peritoneum by two or three lines of linen sutures at the lower angle of the incision, and closes the abdominal wound (Wm. J. Mayo, Loc. cit.). Food can be given at any time.

If the tube slip out it must be put back at once, as the tract may close in a few hours. When the operation has been done for cancer the fistula is permanently maintained. If for ulcer, it can be allowed to close or can be closed surgically if it persist after the ulceration heals. Billon ("Archiv. prov. de Chir.") has collected 127 cases. The direct mortality was 29 per cent. Sixty-four of the patients lived but three months or less. A single case lived beyond a year. This is not a very gratifying showing.

Maydl does a much more formidable operation (divides the jejunum, attaches the upper end to a far-away portion of gut, and attaches the lower end in the abdominal wound). He has operated on 25 cases, with 4 deaths.

Enterectomy, or Resection of the Intestine with Approximation by Circular Enterorrhaphy.—How much of the intestine can be removed without the patient dying from lack of nutrition? The length of the small intestine varies from 15 to 25 feet. The report of a case with the number of feet removed tells us nothing as to how many feet remain. The question is not settled. It has been stated that the removal from an adult of more than 6⅔ feet produces nutritional disturbance, and that a child tolerates the removal of a piece relatively large better than does an adult. Senn was of the opinion that excision of more than one-third of the intestine makes inanition inevitable. Certain it is that great lengths have been successfully removed, and the patients have not only lived, but have been well nourished. Ruggi removed 11 feet, Whitall removed 10 feet 8 inches, Von Eiselsberg, 11 feet 8 inches, and Obulinski, 12 feet 2 inches. Brougham removed 11 feet 2 inches for mesenteric thrombosis and the patient recovered. Childe successfully removed 9 feet 6 inches of small intestine for embolism of the mesenteric artery. Hayes removed 8 feet 4½ inches from a boy ten years of age, and the patient was well eight months later. Dressman reported 26 cases in each of which more than 3 feet 3 inches had been removed (Alexander Blaney, in "Brit. Med. Jour.," Nov. 16, 1901). Turck removed successfully 10 feet 3½ inches of ileum together with the cecum, ascending colon and part of the transverse colon because of adhesions, sinuses and fistulæ. Blaney adds 7 cases from literature, and tells us that in 9 of the 33 cases death occurred soon after operation.

Alexander Blaney, in the previously quoted article, reviews the subject of the resection of great lengths of intestine. He tells us that how much remains after a resection is important, but uncertain. It is uncertain because, as Treves has shown, the length of the intestine varies from 15 feet 6 inches to 31 feet 10 inches.

Could end-to-end anastomosis be done as safely as lateral anastomosis it would usually be the preferred method. The great danger is infection from soiling. "Occasionally, the circular suture is the only feasible one" (Halsted, "Jour. of Exper. Med.," No. 3, 1912).

Resection of the jejunum is much more dangerous than resection of an equal length of ileum. Resection of the ileum is more dangerous than resection

of the colon. If resection be employed, all diseased or injured bowel must be removed irrespective of ultimate bad consequences (Blaney). The operation is performed as follows: After opening the abdomen isolate the loop of intestine we intend to resect. Push a rubber tube through the mesentery close to the bowel, above the seat of operation, and pass a rubber tube through the mesentery below the seat of operation. Instead of tubes, strips of iodoform gauze may be used to encircle the bowel. Empty this segment of bowel by squeezing

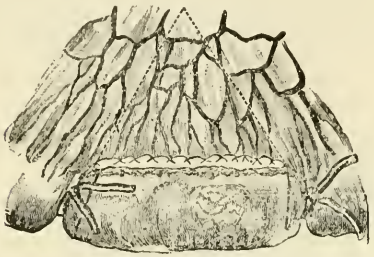

Fig. 772.—Excision of bowel: first step (Esmarch and Kowalzig).

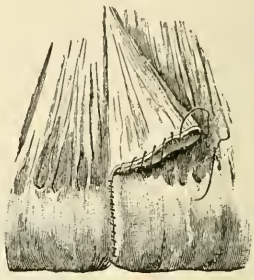

Fig. 773.—Excision of bowel with enterorrhaphy and stitching of the redundant mesentery: second step (Esmarch and Kowalzig).

and stroking, tighten the rubber tubes, and clamp them to keep the bowel empty (Fig. 772). The diseased intestine is resected, each incision being carried through a healthy segment, and care being taken that the cuts are so arranged that at each end a blood-vessel from the mesentery reaches the edge of the cut bowel. Otherwise repair can scarcely occur. The lumen of each end of the divided gut is irrigated with salt solution. The divided surfaces are approximated by a double row of sutures—a continuous suture for the mucous

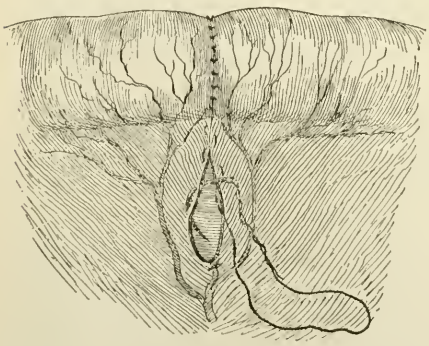

Fig. 774.—Suture of the mesentery after circular enterorrhaphy (Halsted).

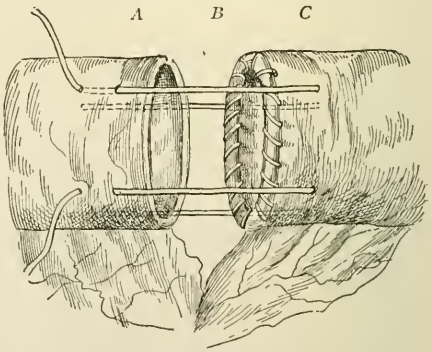

Fig. 775.—Senn's modification of Jobert's invagination method: *A*, Upper end lined with ring; *B*, invagination sutures in place; *C*, lower end.

membrane, and Lembert's, Dupuytren's, Cushing's suture, or Halsted's sutures —to effect inversion. Thoroughly satisfactory approximation can be effected by one row of Halsted mattress sutures (Fig. 774). If a redundant fold of mesentery is left, it can be stitched at its raw edge (Fig. 773). Many surgeons remove a V-shaped piece of mesentery, tie the divided mesenteric vessels (Fig. 772), and introduce sutures so that no mesenteric vessel will be constricted (Fig. 774). The tubes are removed, and the wound is cleansed, closed, and dressed.

Senn effects invagination by means of a bone ring (Fig. 775).

If the two segments of bowel are unequal in size, it was formerly the custom to cut the smaller bowel obliquely and the larger part transversely. To meet this complication Billroth devised *lateral implantation* (see Fig. 803). Suppose the cecum has been resected: its lower end is closed by Lembert sutures, an opening is made in the long axis of the periphery of the colon opposite the attachment of the mesocolon, and the end of the ileum is sutured into this incision. This is called *end-to-side approximation*, or implantation. It is used in the sigmoid, in the cecum, and in any intestinal segment in which the circulation is deficient. Eugene A. Smith ("Amer. Med.," May 10, 1902) sums up the

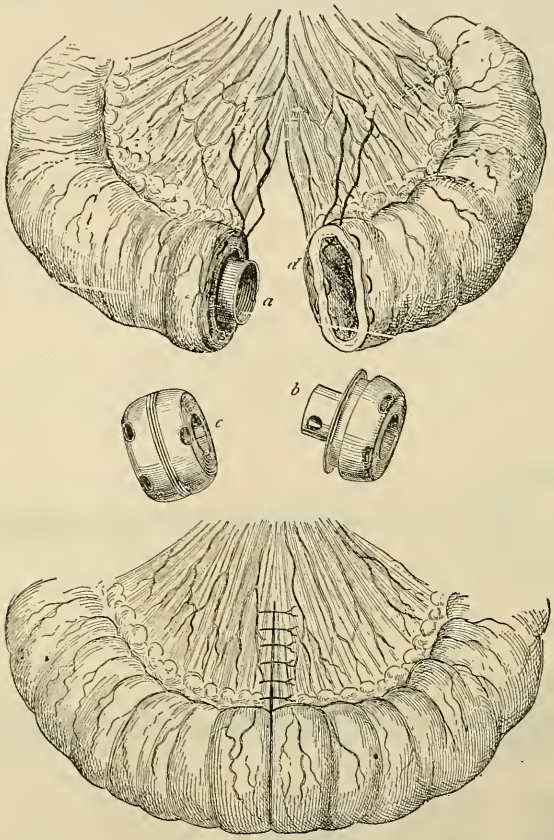

FIG. 776.—Resection of intestine: *a*, *b*, The two halves of the button; *c*, the two portions clamped together; *d*, introduction of the sutures for holding each half of the button in place. The lower figure shows the completed union of the intestine by the Murphy button; the slit in the mesentery has been closed by linear union (after Zuckerkandl).

advantages of end-to-side approximation as follows: The strain of peristalsis is less than in end-to-end union; the circulation of each end of the bowel and the parts of bowel adjacent is better; each cut edge of mesentery is free to recover its circulation, and there is no dead space at the mesenteric border to lead to leakage.

Senn advised the insertion of an anastomosis ring in the ileum, the invagination of the colon as the ring is pulled into place, and firm suturing of the line of junction. By Senn's method the ileum may be implanted into the end of the colon or into a slit in the wall of the large bowel after the end of the colon has been closed. In some cases, in which one portion of bowel is larger than the other, lateral anastomosis is the preferable method. For a full week

after an intestinal resection the patient is fed chiefly by nutrient enemata. During the first twenty-four hours nothing is given by the stomach but small amounts of hot water, and for the next six days only water and a little liquid food is allowed to be swallowed.

The use of *Murphy's button* (Fig. 777) permits of rapid approximation after resection (Fig. 776). This button closely approximates the portions of the intestine within its bite, rapid adhesion taking place. The diaphragm of tissue undergoes pressure-atrophy and liberates the button, which is passed per anum. It is claimed that the button-opening contracts but slightly. For end-to-end or side-to-side approximation of the small intestine a No. 3 button is used. For similar operations on the large intestine a No. 4 button is employed (Murphy). After the resection one-half of a button is inserted into each segment, and is held in place by a purse-string suture of silk which passes through all the coats (Fig. 776). The redundant mucous membrane is tucked in or clipped off, so that it will not be interposed between the serous surfaces. The serous surfaces are scratched with a needle and the halves of the button are locked (Fig. 776). It is not necessary to surround the margin of junction with sutures

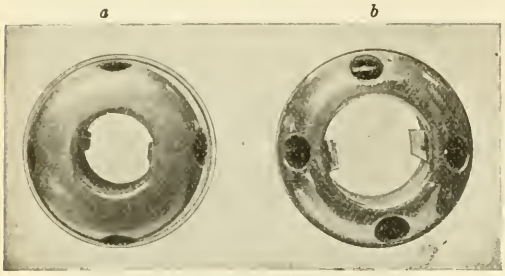

Fig. 777.—Comparison of old (*a*) and new (*b*) Murphy buttons.

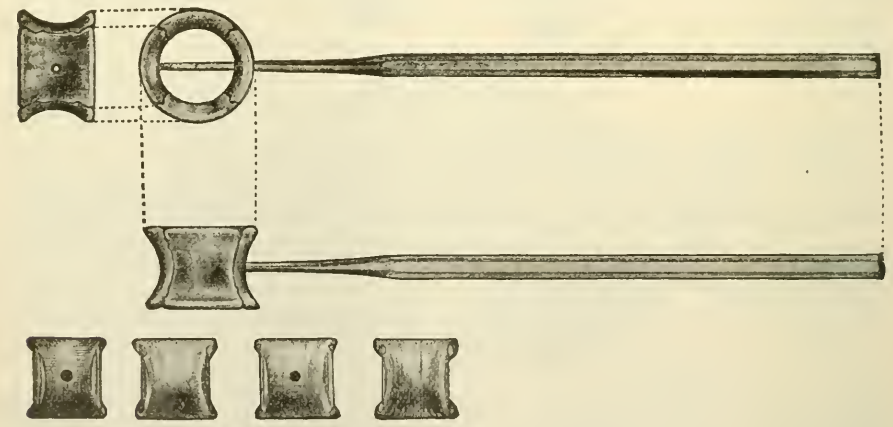

Fig. 778.—The segmented ring of Harrington and Gould.

Murphy says that liquid nourishment should be given as soon as the patient has recovered from the effect of the ether, and that the bowels should be moved at an early period, and frequent evacuations should be maintained. If the button does not pass in four weeks, examine the rectum for it.[1] The situation of the button can be ascertained by the *x*-rays. An objection to the button is that it is a foreign body which must pass per rectum to complete the operation successfully. It may not pass, but trouble does not of necessity follow. In some cases its retention does lead to trouble, and intestinal obstruction ensues. If the caliber of the button blocks before dislodgment, obstruction follows, hence the rule to give saline purgatives the day after the operation.

[1] John B. Murphy, in "Med. News," Feb. 9, 1895.

Some surgeons have sought to make a button which would come apart and be absorbed after it had accomplished its purpose. One of these appli-

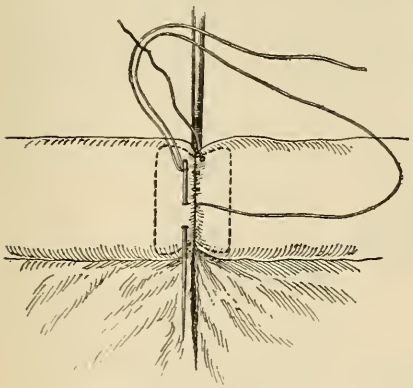

Fig. 779.—End-to-end union with aid of segmented ring. Continuous stitch beginning at one side of the handle (Harrington and Gould).

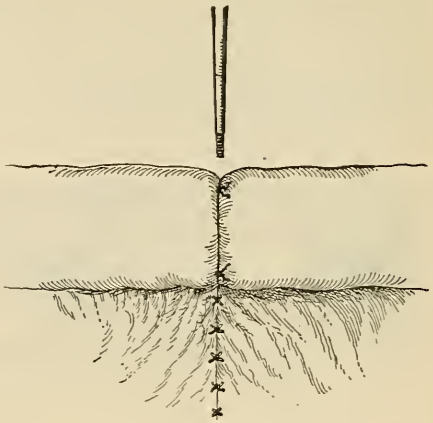

Fig. 780.—End-to-end union with aid of segmented ring. Handle unscrewed, suture completed (Harrington and Gould).

ances is Frank's coupler, which is made of bone, the compression being furnished by rubber. In this apparatus, however, the amount of pressure obtained is always uncertain and the rubber is apt to wear out. The button gives a lower mortality than the suture operation, and some surgeons now use it who once condemned it. Czerny is a strong advocate of the button.

Harrington and Gould use a *segmented aluminum ring*. This ring collapses into small segments after the anastomosis has been effected. By its use the authors believe that the operation is made more rapidly and safely ("Annals of Surgery," Nov., 1904). During the suturing the ring is held by means of a handle, which, after the anastomosis has been effected, is removed. The ring in the handle is shown in Fig. 778 and the operation in Figs. 779 and 780.

Maunsell has devised a most ingenious method of circular enterorrhaphy. The two portions of bowel are attached by two fixation sutures which penetrate all the coats (Fig. 781). An incision 1½ inches in length is made through the wall of the proximal segment of gut, about 1 inch from its edge. The fixation sutures

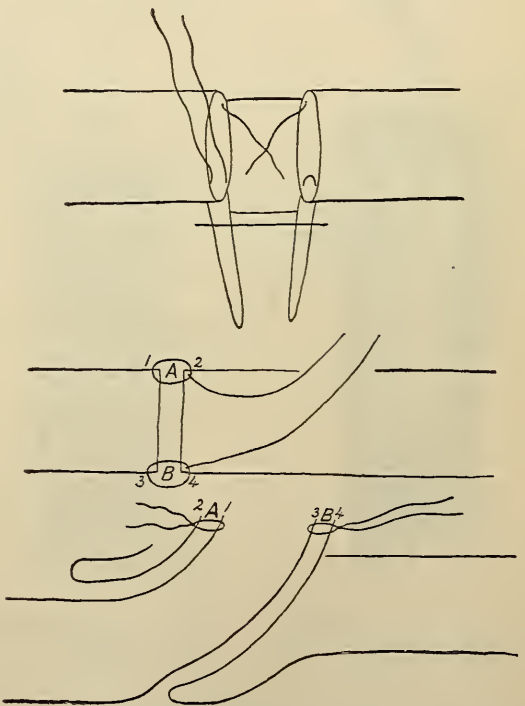

Fig. 781.—Maunsell's method of anastomosis (after Wiggin).

are brought through this opening, traction is made upon them, the distal portion of the bowel is invaginated into the proximal portion, and the ends emerge from the opening, their peritoneal surface being in contact (Fig. 781). Sutures of silk are passed through both sides of the area of invagination, the threads are caught up in the center, cut, and tied on each side. The fixation sutures are cut off. The invagination is reduced by traction. The longitudinal cut is closed by Lembert sutures.

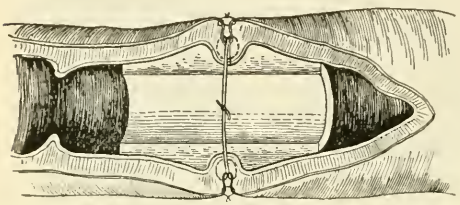

Fig. 782.—Robson's decalcified bone bobbin.

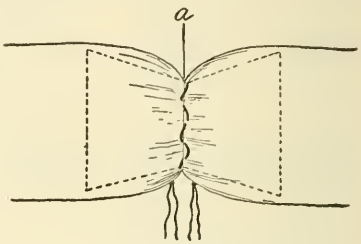

Fig. 783.—Allingham's decalcified bone bobbin.

A. W. Mayo Robson performs circular enterorrhaphy and brings the ends of the gut together over a bobbin of decalcified bone (Fig. 782). Allingham uses a bone bobbin the shape of two cones joined at their apices. The bobbin is decalcified, except an area at the center (Fig. 783, *a*). Kocher performs circular enterorrhaphy as follows: A fixation suture is introduced through the bowel at the mesenteric attachment and another is inserted at an opposite point.

Fig. 784.—Moynihan's method of end-to-end anastomosis (Moynihan).

Fig. 785.—Moynihan's method of end-to-end anastomosis continued.

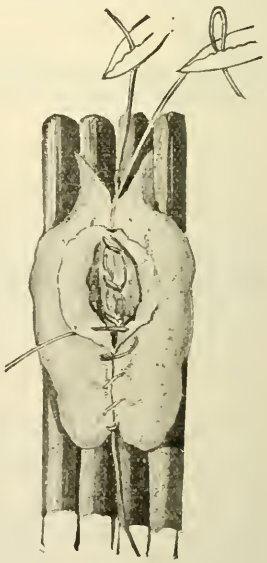

Fig. 786.—Moynihan's method of end-to-end anastomosis continued.

The intestinal ends are approximated by a continuous silk suture, which passes through all of the coats, but which includes more of the serous than of the mucous coat. The suture-line is overlaid by a continuous Lembert suture which includes the serous and a portion of the muscular coat.

In doing an end-to-end approximation I prefer to use the clamp of Moynihan (see Fig. 759), as shown in Figs. 784–786. We thus are able to hold the parts and keep them clean, rapidly make an even and secure stitch line, and have no free-edged septum.

Some surgeons have used inflatable rubber cylinders in making an end-to-end anastomosis (Halsted, Downes, and others). The method was devised by Treves, but was subsequently abandoned by him. Halsted no longer uses the inflatable cylinders.

Connell has devised a method which places the knots in the lumen of the bowel (F. Gregory Connell, "Medicine," April, 1901). He maintains that the placing of the knots within the lumen of the gut has the following advantages: there is no foreign body; the suture passes away early; adhesions to neighboring organs are few; the serous approximation is perfect; the suture line

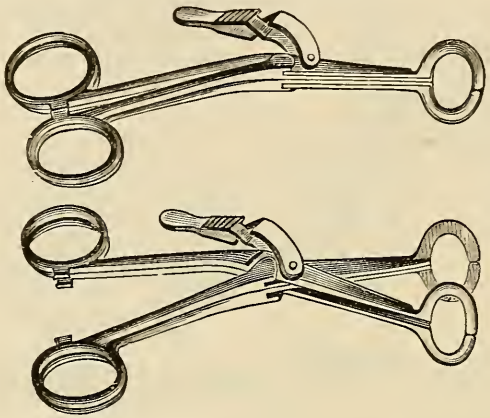

Fig. 787.—Laplace's forceps for intestinal anastomosis.

is more secure; the septum is smaller and the danger of necrosis is less. The suture is shown in Plate 11.

Laplace has devised forceps which greatly facilitate suturing, which make it easy to obtain an even suture line, and which can be withdrawn after the suturing is finished, the small opening through which the instrument has emerged being closed by a stitch (Figs. 787, 788). By aid of Laplace's forceps the operation can be neatly and rapidly performed, but a large diaphragm is formed,

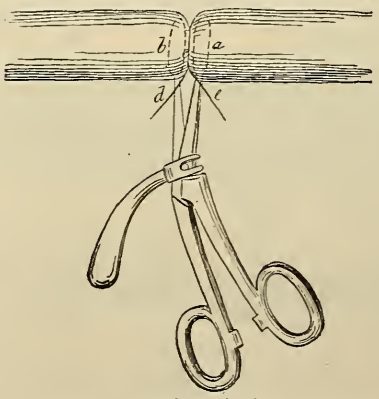

Fig. 788.—End-to-end anastomosis with the aid of Laplace's forceps.

a considerable area is exposed to infection, the tissues of the diaphragm are bruised and may slough, the raw ends may grow together and cause obstruction, and it seems probable that considerable contraction will follow. Another objection is that an infected instrument is withdrawn from the bowel and may contaminate the peritoneum. O'Hara's forceps (Fig. 789) permit of rapid and accurate suturing, but possess the same disadvantages as the Laplace forceps. In 1 case within my knowledge absolute obstruction from adhesion of the

raw edges of the septum followed its employment. Figures 790 and 791 show the use of O'Hara's forceps. Of the operations previously set forth, I prefer the clamp and suture as employed by Moynihan, the operation of Halsted by mattress sutures and without mechanical aids, and in some cases the operation with the Murphy button.

Lateral Intestinal Anastomosis.—Approximation may be effected by other methods than by end-to-end junction or by implantation. In fact, I prefer in most cases of resection to close each end of the divided gut and perform lateral anastomosis. It is a safer operation than end-to-end anastomosis and by it we can obtain as large an opening as we desire. Again, after lateral anastomosis the parts

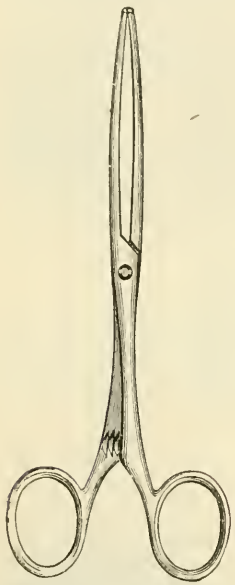

Fig. 789.—O'Hara's anastomosis forceps (about one-third original size).

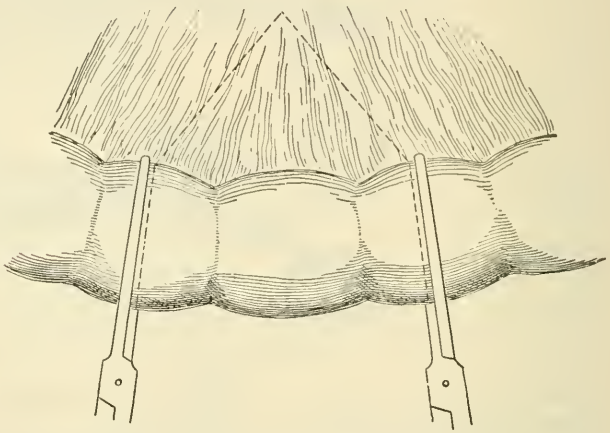

Fig. 790.—Showing the manner of placing forceps in resection of bowel; dotted lines show the incision to be made (O'Hara).

obtain a better blood-supply than after end-to-end suturing, because in the former operation the mesenteric vessels are not interfered with. Further, in lateral anastomosis there is little tendency to cicatricial contraction. Lateral

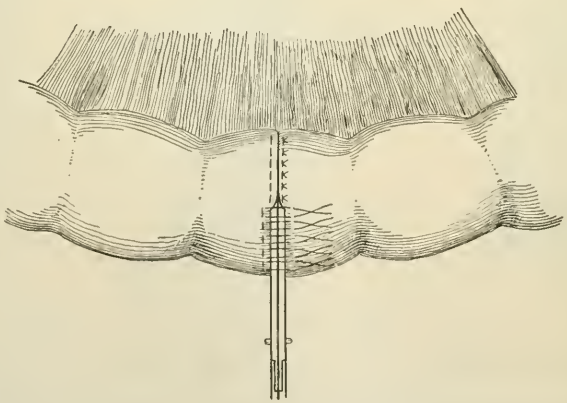

Fig. 791.—End-to-end anastomosis. Forceps brought together and held by serre-fine (not shown); sutures introduced, some of which are tied (O'Hara).

anastomosis may be performed in some cases without a preliminary resection for the purpose of short-circuiting the fecal current, throwing a diseased portion of the bowel out of action, and thus avoiding obstruction (Fig. 792). This operation has the disadvantage that the diseased structure is not removed.

Operation with Rings.—In this operation a portion of bowel above the obstruction and a loop below the obstruction are brought into the wound. These segments are emptied, and are kept empty by fastening around them rubber tubes or iodoform strips. Two tubes are needed for each loop of bowel. Pack in gauze pads. Make an incision in one loop, in the long axis of the bowel, on the surface away from the mesentery; permit the contents to escape externally; irrigate this segment with saline solution, and introduce the bone plate of Senn (Fig. 792, A) or Abbe's catgut ring (Fig. 793). Calyx-eyed needles are used to pass the silk, and the threads of the ring are carried

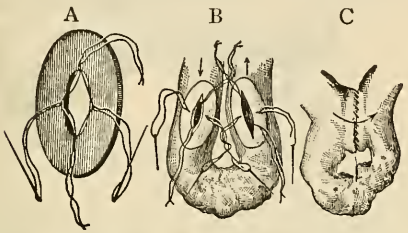

FIG. 792.—Senn's entero-anastomosis: A, Senn's bone plate; B, intestinal anastomosis; C, operation complete.

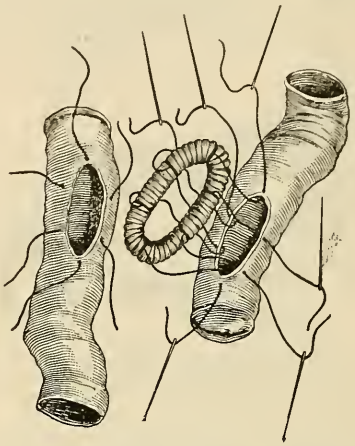

FIG. 793.—Method of passing the silk sutures in inserting the rings of Abbe.

through the coats of the bowel and are gathered together in the bite of a pair of forceps. The other loop of intestine is treated in a similar manner. The two segments of intestine are so brought together that the two wounds are opposite each other, the posterior sutures being tied first, the upper next, then the lower, and finally the anterior threads. The ends of the threads are cut off, and the entire anastomosis is surrounded by a layer of Lembert or Halsted sutures or is encircled by Cushing's suture. Figure 792, B, shows an intestinal anastomosis partly finished, and Fig. 792, C, shows an anastomosis complete. Figure 793 shows the passing of the sutures when the catgut rings of Abbe are employed. After an intestinal resection each end can be closed and anastomosis effected as described above. Lateral anastomosis can be accomplished with a Murphy button, the intestine being prepared for the button as is shown in Fig. 794.

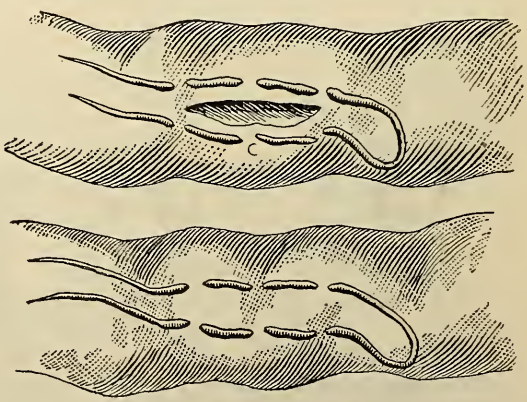

FIG. 794.—Showing relative size of incision and method of introducing sutures in lateral approximation with Murphy's button.

Abbe's method of anastomosis without mechanical aid is as follows: After resecting the bowel and mesentery and closing the ends of the bowel he places the extremities side by side and applies two rows of a Dupuytren suture, ¼ inch apart. These rows of sutures are 1 inch longer than the slit in the bowel will be (Fig. 795), the thread at the end of each row being left long. An incision is made in the bowel, ¼ inch from the sutures, both rows of threads being on the

same side of the cut. This incision is 4 inches long. The other portion of the bowel is then incised in the same way. The adjacent cut edges are united by a whip-stitch which goes through all the coats, and the free cut edges are stitched in the same manner (Fig. 796). The surgeon now utilizes the long threads of the first sutures, and brings the serous surfaces of the opposite sides together by means of Dupuytren's suture. Halsted performs anastomosis as follows: He places the two portions of bowel with their mesenteric borders

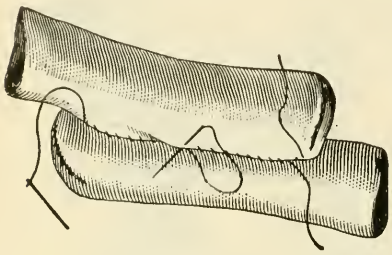

FIG. 795.—Suturing intestines in apposition before incision (Abbe).

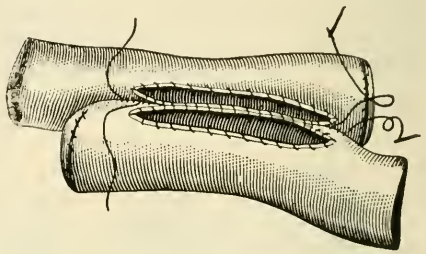

FIG. 796.—Showing the 4-inch incision and sewing of the edges (Abbe).

in contact. Six quilted sutures of silk are introduced, tied, and cut off (Fig. 797, *a*). At each end of this row of sutures two quilted sutures are introduced, tied, and cut (Fig. 797, *b*). A number of quilted sutures are introduced, as is shown in Fig. 797, *c*. The intestinal openings are made with scissors, and the sutures last introduced are tied and cut off (Fig. 797, *d*).

J. Shelton Horsley has suggested an ingenious method of intestinal anastomosis which secures for the sutured portion a greater diameter than that nor-

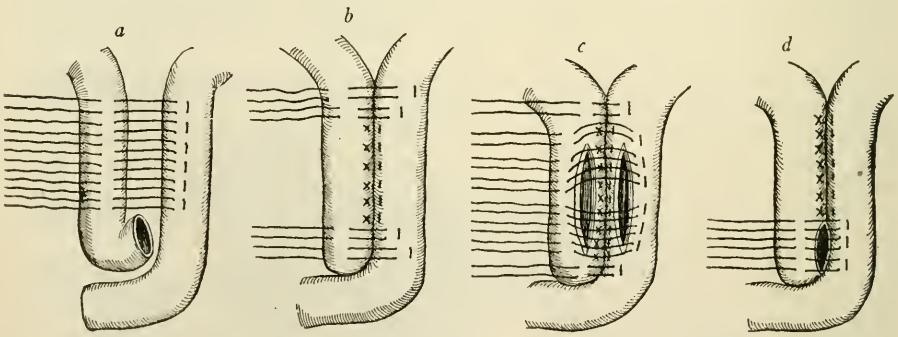

FIG. 797.—Halsted's operation for lateral anastomosis, showing four steps of same (Jessett, from Halsted).

mal to the intestine.[1] After resection of the intestine and a V-shaped piece of mesentery, the ends of the bowel are placed side by side, the openings being in the same direction, and are clamped in place (Fig. 798). The first stitch approximates the two limbs of the bowel near the mesenteric attachment, is carried obliquely for about 2 inches to the border opposite the mesenteric attachment, and continued over the other side (Fig. 798). The septum is cut away, a margin being left ⅓ inch wide. The edge of the shelf made by cutting the septum is sutured. When the suture reaches the end of the shelf, it is continued by invaginating about the rest of the resected ends (Fig. 799).

[1] "New York Polyclinic."

Bodine's method of intestinal anastomosis is referred to on page 1262. Laplace, of Philadelphia, has devised an operation in which temporary approximation is effected by means of forceps, the instrument being withdrawn before

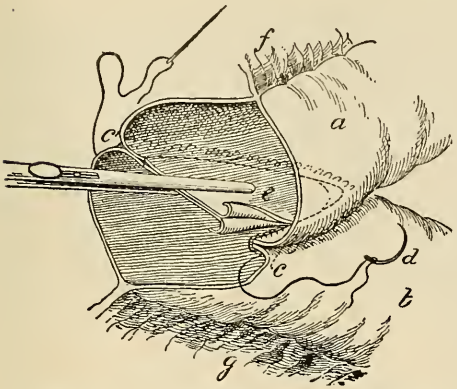

FIG. 798.—Represents the ends of the intestine in position and grasped by the artery forceps. The first row of sutures has been partially applied, the septum partly cut away, and the second row of overhand sutures begun: *a*, *b*, are the two ends of the intestine; *c*, *c'*, the first row of sutures (Cushing); *d*, the second row of sutures (overhand); *e*, the septum; *f*, and *g*, the mesentery (J. Shelton Horsley).

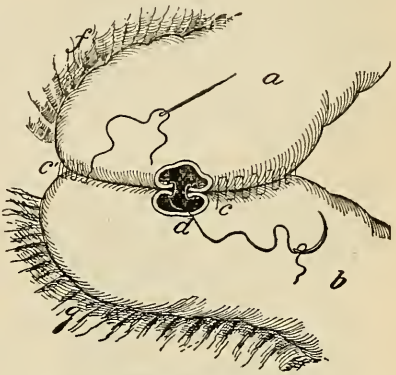

FIG. 799.—Operation nearly completed. The septum has been cut away, and the row of overhand sutures has been brought almost to its point of commencement. The cut also shows the first row of sutures (Cushing) as it should be continued after the overhand sutures are finished (J. Shelton Horsley).

the abdomen is closed. Junction of two segments of intestine can be quickly and neatly effected by this method and the suture line is even and secure. The objections are that an infected instrument is withdrawn from the bowel and may contaminate the surface; that the septum is tightly squeezed and this septum

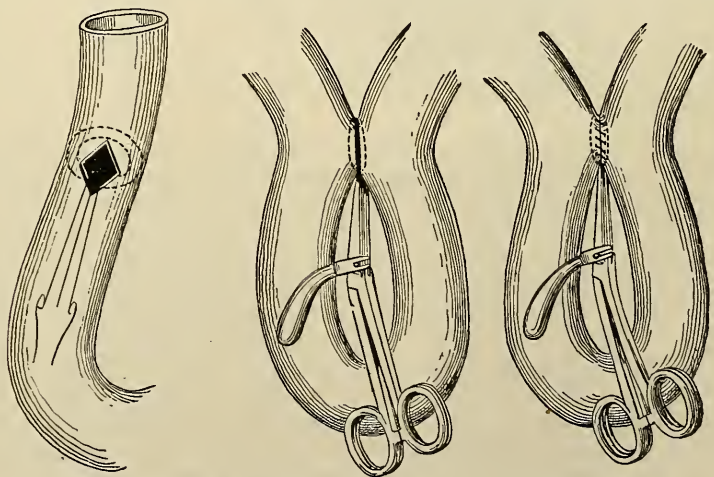

FIG. 800.—Lateral anastomosis with the aid of Laplace's forceps.

may slough or may become infected, conditions which will be followed by infection of the suture line; and that contraction of the collar may ensue. The operation is more liable to be followed by leakage or by partial or complete obstruction than is the operation without forceps. Figures 800 and 801 illus-

trate the use of Laplace's forceps in lateral anastomosis. I usually perform lateral anastomosis with the assistance of Moynihan's clamps, the method being identical with the operation of gastro-enterostomy. Moynihan's operation is shown in Fig. 802.

Consideration of Methods of Intestinal Approximation.—At least 250 methods of uniting a divided intestine have been devised and the best method is a matter of dispute. The essentials of a good method are: rapidity of execution, the formation of an even and reliable line of junction, and the absence of any considerable permanent septum. The Murphy button can be applied with great rapidity, and rapid operation is of immense importance in intestinal work. The opening left by the Murphy button is small (too small, some surgeons think), but it does not strongly tend in most instances to contract because the tissue-diaphragm is separated by tissue-atrophy and not by inflammatory gangrene. The separation of the diaphragm is a most valuable feature. No other instrument thus cuts away the objectionable septum. Occasionally the

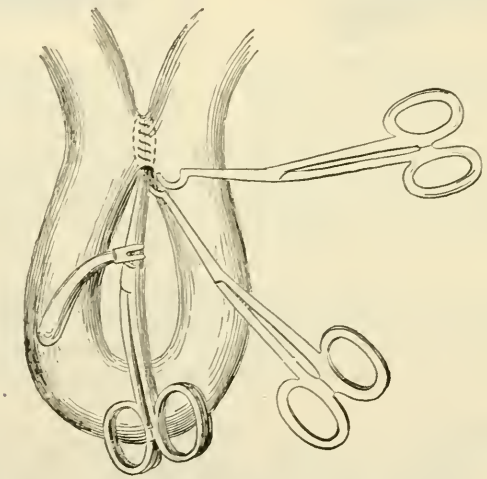

Fig. 801.—Withdrawal of Laplace's forceps.

opening made by the button contracts and gives trouble; occasionally the lumen of the button blocks with feces; occasionally the button is retained, this latter complication being especially frequent after anterior gastro-enterostomy. If the button be used, liquid food should be given soon after the effect of the anesthetic has passed off, and movement of the bowels should be obtained at an early period after operation and frequent evacuations should be maintained. The button gives better results in end-to-end approximation than in lateral anastomosis. Moynihan's forceps, Laplace's forceps, O'Haia's forceps, the decalcified bone plates of Senn, the catgut rings of Abbe, the segmented ring of Harrington, the catgut strands inside of rubber tubing of Brokaw, Chaput's button, Allingham's bone bobbin, Robson's bone bobbin, Frank's coupler, Clark's bobbin, tubes or plates of potato or carrot, and rings or plates of leather, all have their adherents. Of mechanical appliances, the best are Murphy's button, the bone ring, and Moynihan's forceps. Of recent years many surgeons have abandoned all mechanical aids, and have returned to closure by simple sutures. The ideal operation is without mechanical contrivances. But such devices are time-savers, and to lessen the time of operation will often save life. Further, Moynihan's forceps prevent fecal extravasation and consequent infection. What method to follow must be determined in each particular case

by a study of the necessities of the situation. Nevertheless, it may be possible to formulate a few general rules: If the condition of the patient is excellent and the bowel is in a fairly healthy condition, well above and well below the seat of trouble, end-to-end approximation should be performed by circular enterorrhaphy with the aid of Moynihan's clamp, or each end can be closed after resection and a lateral anastomosis be effected with the aid of the clamp. If the condition of the patient is such as to make haste necessary, use a Murphy button. If the bowel below the seat of trouble is much contracted and haste is necessary, do not use a Murphy button, but use Senn's bone plate or Robson's bobbin. If haste is not imperatively necessary, do simple enterorrhaphy. If the surgeon is obliged to join a very much distended bowel to a very much contracted bowel, perform end-to-side approximation (implantation) with the bone plate of Senn or by simple suturing, or else effect side-to-side junction by the method of Abbe or of Moynihan.[1]

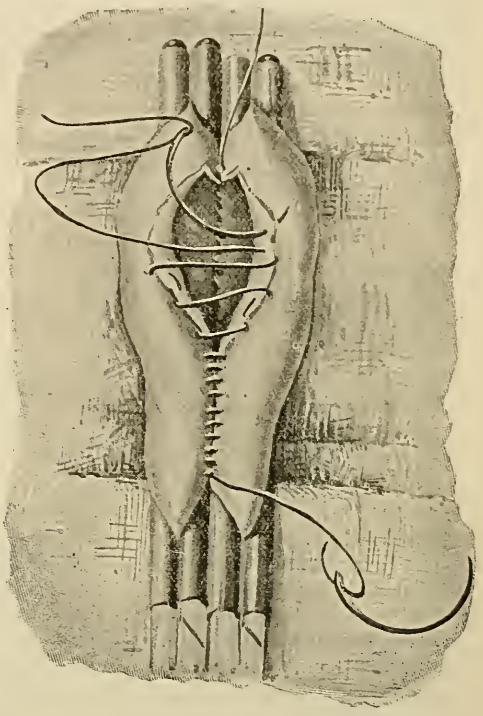

FIG. 802.—Moynihan's inner suture in lateral anastomosis to show the infolding of the mucosa which results. A loop of the suture lies on the mucous surface (Moynihan).

Local Intestinal Exclusion.—This operation was introduced by Salzer in 1891. It excludes the fecal current from a portion of the intestine. In complete exclusion the intestine is cut through above and below the diseased portion, and the ends of the healthy gut are united to each other or the end of one portion of gut is implanted into the side of the other. Both ends of the excluded portion may be fastened to the skin, making a double fistula (von Eiselsberg); the distal end or the proximal end alone may be fastened to the skin, the other end being closed by sutures and replaced within the abdomen. Sometimes each end is closed and dropped back, and a fistula is made in the middle of the excluded portion to permit of drainage. Some operators close each end by suture and drop them back, and do not drain the excluded portion; and others with the same purpose in view suture together the two ends of the excluded part. It seems wisest to suture both ends, or at least one end to the skin (LeDentu, in "Rev. de Gyn. et de Chir.," Jan. and Feb., 1899). It is true this makes a permanent fistula, but if it be not done, the loop may become distended with secretion containing virulent bacteria, a condition which may lead to perforation and death. Exclusion is rarely performed upon the small intestine. It is best suited to the large intestine. If it be done at all, complete exclusion is the best operation (Fig. 803). Partial exclusion is rarely satisfactory. Exclusion has been performed instead of colostomy in cases of intestinal obstruction, but it is best suited to inflammatory areas or tumors, irremovable because of adhesions or some other cause. After the operation the diseased area may improve because of drainage and freedom from

[1] See the discussion of this subject by the late J. Greig Smith, in his "Abdominal Surgery."

irritant fecal matter. In many cases it can be irrigated through the fistula. Sometimes the diseased part improves sufficiently after a time to permit of extirpation.

Surgical Treatment of Ascites Resulting from Hepatic Cirrhosis (Epiplopexy; Talma's Operation; Drummond's Operation; Morison's Operation).—The portal system communicates with the vena cava by means of a number of small vessels. Normally, only an insignificant amount of portal blood passes by this route to the general circulation. When cirrhosis obstructs the flow of blood through the liver, the radicles of communication between the portal system and the vena cava enlarge and an increased amount of blood is thus sent directly to the systemic circulation. Adhesions develop between the parietal peritoneum and some of the viscera and the collateral circulation is further increased. Thus, Nature seeks to prevent ascites. If,

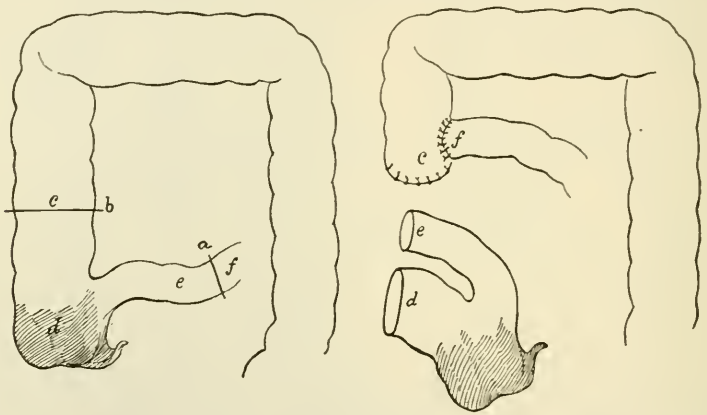

FIG. 803.—Operation of complete exclusion of the cecum: *a* and *b*, Lines of incision; *f* is implanted into *c*; *e* and *d* are sutured to the abdominal wall.

however, the obstruction to the passage of portal blood becomes so great that "the collateral circulation is no longer able to maintain an equilibrium in the blood-pressure in the portal radicles, the pressure thus rises to a point at which transudation takes place and ascites develops" (M. L. Harris, paper read before Chicago Medical Society, Feb., 1902). The theory above set forth is the "mechanical theory;" but, as Harris points out, increased portal tension is not the only factor concerned in the production of ascites, chronic inflammatory changes in the peritoneum being "materially instrumental" in maintaining ascites by lessening the absorbing power of the peritoneum. Influenced by the mechanical theory of causation, Talma, of Utrecht, devised an operation to cure ascites by establishing more free communication between the portal system and the systemic circulation. Drummond and Morison about the same time independently devised a like procedure.[1] This operation is called *epiplopexy*. In some cases the abdomen has been opened and the omentum sutured into the abdominal wound; in others, between the layers of the anterior abdominal wall. The results are slightly better when the omentum is sutured between the layers of the abdominal wall. The gall-bladder may be sutured to the abdominal wall as well as the omentum. The liver and spleen, under surface of the diaphragm, and parietal peritoneum about the liver and spleen are usually rubbed harshly with a piece of gauze. Drainage is not used by most operators. It does not appear to contribute any favorable chances and it exposes the patient to the danger of infection. Morison, however,

[1] "Brit. Med. Jour.," Sept. 19, 1896.

advocates it, and makes suprapubic drainage, a glass tube being carried into the rectovesical or recto-uterine pouch ("Brit. Med. Jour.," Jan. 20, 1912).

The operation ought to be performed early, before the onset of chronic inflammation of the peritoneum. In a great majority of cases the operation proves futile, and not uncommonly death soon follows from complications or because the disease is very far advanced. In exceptional cases the operation proves of distinct benefit. The operation shows the least mortality and the greatest number of apparent cures when the liver is large; the greatest mortality and the fewest cures when the liver is contracted. The greatly lowered vital resistance of these patients is the imminent danger. Renal disease, cardiac disease, other grave complications, and the absence of sufficient functionating liver substance to maintain life contra-indicate operation (Greenough, in "Am. Jour. Med. Sciences," Dec., 1902).

Harris, in the paper previously quoted, collected 46 cases; 23 of these were instances of alcoholic cirrhosis; 30 per cent. were dead within fourteen days; 52 per cent. were dead within two months; 56 per cent. were dead within six months. Ascites had returned in all of those who died late. At the end of one year or longer 13 per cent. had recovered from ascites. The remaining 30 per cent. were either unimproved or were said to be improved with some ascites.

Of the group of mixed cases constituting the remainder of those Harris collected, 10 per cent. were dead in four days, 25 per cent. were dead in four months. In 40 per cent. no improvement took place. In 10 per cent. the report was too early to give any information. About 15 per cent. were free of ascites after one year or longer, and 5 per cent. were cured of intestinal hemorrhage, ascites never having been present. Greenough collected 105 operations: 42 per cent. were improved; 58 per cent. were not improved; 29.5 per cent. died within thirty days. Two years after operation 9 cases were apparently in good health ("Am. Jour. Med. Sciences," Dec., 1902). One of Morison's cases was alive and well eleven years after operation; another was well for six years, when an attack of penumonia lead to death; another patient remained well for two years, but died after an operation for ventral hernia (Morison, in "Brit. Med. Jour.," Jan. 20, 1912). The results of the Talma operation are disappointing. Wm. J. Mayo ("N. Y. Med. Jour.," June 22, 1918) performed the operation 28 times with 4 deaths, 8 died at various times following operation, the rest were benefited. Mayo suggests that we divert the portal circulation by removing the spleen. Blood will then be diverted from the portal to the pulmonary circulation through the channels described by Sappey.

Operation for Intussusception.—Air distention and hydrostatic pressure are uncertain; in an advanced case may rupture the gut; even in a recent case may fail or may reduce the bulk of the intussusception, but not its apex. Russel ("Intercolonial Med. Jour. of Australasia," March 20, 1902) alludes to the uncertainty of the method. He used hydrostatic pressure in 5 cases. Two died and 2 recovered. In 1 case the method failed and operation was then performed. It is safer and better to operate early, but if the conservative plan is tried and fails, operation should certainly be done at once, because an early operation enables the surgeon easily to effect reduction, and also because early complications are unusual. The incision is made in the midline above the umbilicus. The surgeon endeavors by manipulation to reduce the intussusception by pushing it back, not by pulling it out. If the intussusception is gangrenous, perform intestinal resection and circular enterorrhaphy. The same rule maintains when malignant disease of the gut exists (D'Arcy Power). It is inadvisable to make an artificial anus. *Maunsell's operation* is suited to cases of irreducible intussusception. It is performed as follows: A longitudinal incision is made in the intususscipiens. The intussusceptum is gently pulled upon and is caused to protrude from this opening. Two straight needles

threaded with horse-hair are passed so as to transfix the base, and ¼ inch above the needles the intussusceptum is cut off. The needles are carried completely through, the sutures are hooked up in the middle and cut, and the two ends are tied on each side. These sutures unite the intussusceptum to the intussuscipiens. The two surfaces are now carefully approximated by sutures. The sutures are cut. The stump is replaced. The longitudinal incision is closed with Lembert sutures.[1]

Russell (Ibid.) reports 16 cases operated upon: 12 recovered and 4 died. In every one of the 4 fatal cases the diagnosis was not made until the disease had lasted several days. In only 2 of the successful cases the diagnosis was made late. If operation is done in the first twelve hours the mortality, even in infants, will probably be comparatively small. If gangrene exists the mortality is enormous (at least 90 per cent.).

Senn's Operation for Fecal Fistula.—Suture the opening transversely with Czerny sutures of silk in order to prevent infection. Cleanse the surface thoroughly. Open the abdomen and separate the edges of the bowel from the parietes. Deliver the portion of bowel which contains the fistula and apply Lembert sutures over the Czerny sutures. Another method is to open the abdomen above the fistula, insert the fingers, cut out the skin and tissues around the fistula in an elliptical course, leaving them attached to the bowel, draw the bowel from the abdomen, pack gauze around, remove the tissues adherent to it, and suture the fistula transversely.

Enterostomy is the making of an artificial anus. If performed in the large bowel, it is called *colostomy*. In some cases of intestinal obstruction it is necessary to open the small intestine, and if this is required, the artificial anus should be made as near as possible to the cecum. The higher above the cecum it is made, the more apt is the patient to die of lack of nourishment. A small intestinal anus may be made in the middle line or in the right iliac region. The bowel is fixed and opened as directed under Colostomy. In acute intestinal obstruction it may be necessary to open the bowel at once. In such a case Paul's tube (Fig. 804) is very useful. It is made of glass, is bent to a right angle, and has a rim near each end. The large tube is used in the colon, the small tube in the small intestine. A small opening is made in the intestine, the tube is introduced, and is tied in place by a silk suture which surrounds all the coats of the bowel, a gush of feces is caught in a basin, a rubber tube is fastened to the glass tube, and fluid feces are collected in a bottle and beneath an antiseptic fluid.[2] In from three or four days to a week the tube becomes loose and can be removed. Stewart's method of enterostomy was outlined on page 1126.

Valvular Cecostomy (Gibson's Operation).—This operation was devised in 1900 by Charles L. Gibson, of New York. It is used in chronic dysentery. It allows us to flush the large intestine and to apply remedies to it. The incision is made over the caput coli, a small puncture is made in the latter, a soft catheter (No. 30 Fr.) is introduced well ino the bowel, and is fixed there as is the tube in Kader's gastrostomy (see page 1226). After ten or twelve days the tube is not kept in place, but is introduced when needed. The fistula closes spontaneously on the discontinuance of introducing the catheter daily. Appendicostomy has, to a great extent, replaced cecostomy, because, as a rule, it is easier and safer. "The appendix may, however, not be of a suitable size or position (retrocecal) to lend itself properly to the procedure" (Gibson, paper read before the Internat. Surg. Assoc. at Brussels, Sept., 1911).

Inguinal Colostomy (Maydl's Operation) (Fig. 805).—In this operation a vertical or oblique incision 4 inches in length is made over the portion of colon to be incised. In all cases when possible do a left inguinal colostomy. In right inguinal colostomy it is more difficult to deliver the bowel than in a left

[1] T. Pickering Pick, "Quarterly Med. Jour.," Jan., 1897.
[2] Paul, in "Liverpool Med.-Chir. Jour.," July, 1892.

inguinal colostomy, because of shortness or absence of mesocolon at this point of the colon. Right inguinal colostomy has been performed for chronic amebic dysentery. It puts the colon at rest and permits of free irrigation. It is kept open until the dysentery is well. Appendicostomy and valvular cecostomy have replaced it for dysentery. It has also been employed for the treatment of ulceration of the colon. After the incision on the left side the colon usually bulges into the wound, but if it does not, it may easily be found by following with the finger the parietal peritoneum outward, backward, and inward, the first obstruction it encounters being the mesocolon. Draw the colon out of the wound until its mesenteric attachment is level with the abdominal incision. Push a glass bar through a slit in the mesocolon near the bowel, and wrap the

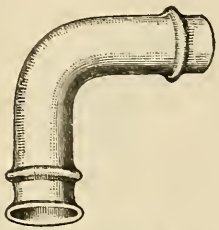

Fig. 804.—Paul's tube.

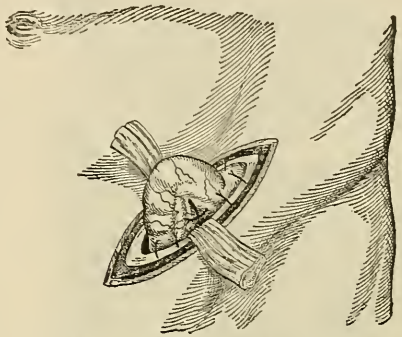

Fig. 805.—Inguinal colostomy (after Zuckerkandl).

ends of the bar with iodoform gauze to prevent slipping. Instead of the bar, a piece of gauze can be employed (Fig. 805), or a bridge of skin can be made under the bowel by suturing the two skin edges. In order to make a spur the two parts of the flexure are stitched together by sutures which penetrate to and catch the submucous coat. Stitch the serous coat of the bowel to the parietal peritoneum (Fig. 805). Whenever possible, wait from twenty-four to forty-eight hours before opening the gut. The colon is opened by the cautery or by scissors. If the artificial anus is to be permanent, make a transverse incision through the bowel. Cut one-fourth way across the colon when it is

Fig. 806.—Stevenson's bag for inguinal colostomy.

first opened, and entirely across at a later period. If the artificial anus is to be temporary, the incision should be longitudinal. Maydl's operation has great advantages: it is quick, certain, reasonably safe, satisfactorily prevents fecal accumulation below the opening, and is rarely followed by absolute fecal incontinence. In many cases the bowels move but two or three times a day. The movements, however, come quickly with but little warning. Sometimes there is no warning. If diarrhea develops, there will be fecal incontinence as long as it lasts. An air-pad covered with gauze may be held in place by a firm belt, or the appliance shown in Figs. 806 and 807 may be worn.

Bodine's Operation (Figs. 808, 809).—Bodine's method of colostomy permits of a future restoration of the fecal current by an easily performed anastomosis. This surgeon maintains that the spur after colostomy should reach to and remain at the level of the skin, a condition impossible of attainment by hanging the bowel over a rod or piece of gauze, because a spur thus formed is not thick and rigid and is inevitably dragged below the skin level, and when this dragging has taken place, some fecal matter will pass into the bowel below the artificial anus. Bodine opens the abdomen, sutures the parietal peritoneum to the skin, seeks for the lesion, and draws it with 6 inches of healthy bowel out of the incision. He lays the limbs of the loop side by side. He inserts a silk stitch, beginning at the point where exsection is to be made, and for 6 inches unites the two segments close to their mesenteric borders. The loop is dropped into the abdomen until the beginning of the suture is on a level with the skin, and at this point it is fastened to the abdominal wound with a continuous catgut suture. The protruding lesion is cut off along the dotted line (Fig. 808). The artificial anus is thus established. When it is desired to close the artificial anus, divide the septum with scissors or a Gant clamp (Fig. 809) and close the abdominal wound.[1]

Fig. 807.—Stevenson's bag applied.

Lumbar colostomy is a most unsatisfactory operation. It does not completely intercept the fecal current, and it leaves the patient in a condition of wretched discomfort because fecal incontinence is inevitable. A patient who has had lumbar colostomy performed upon him either obtains little benefit, because the feces pass into the bowel below the opening which was made to intercept them or else they pour out of the opening uncontrolled, making the poor unfortunate a living horror to himself and others. It is rarely performed at the present day.

The **healthy gall-bladder** has a capacity of about 1 oz., and its hue is bluish. If a gall-bladder contains calculi or has contained them, its hue is grayish-white or yellowish (Moynihan).

Congenital Absence of the Gall-bladder.—When the gall-bladder is shrunken and buried in adhesions, it is very difficult to find it at operation. Sometimes it is not found and one may jump to the conclusion that it is congenitally absent. This is occasionally, but very seldom, the case. Gray collected 19 instances of congenital absence of the gall-bladder ("Trans. of Chicago Path. Soc.," 1902). When it has been absent the subject seems to have done perfectly well without it.

The Incisions for Operations upon the Gall-bladder and Bile-ducts.—I have employed several methods, and have frequently used Bevan's incision (Fig. 810, B). The primary portion of the incision is shaped like the italic letter *f*. It is by the side of or through the right rectus muscle, and

[1] "New York Polyclinic, Feb. 15, 1897.

is shown by the double line in Fig. 810, B. The primary incision is used for exploration and cholecystotomy. The primary incision is from 3 to 4 inches

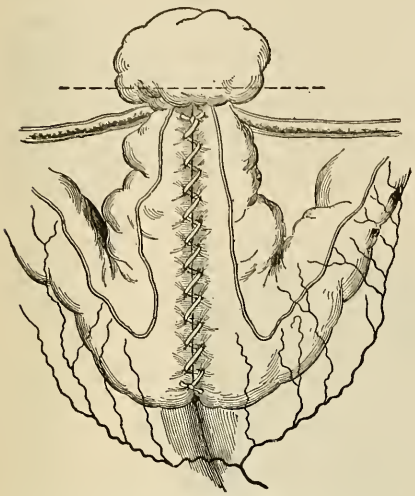

FIG. 808.—Bodine's method of colostomy, showing one side of the loop after it has been sutured, passed back into the cavity and stitched into the abdominal wound. The lesion is left protruding, and the dotted line indicates where the protrusion is to be clipped off.

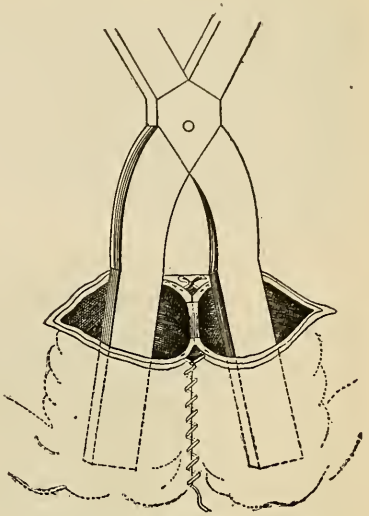

FIG. 809.—Bodine's method of colostomy, showing the septum to be divided in restoring the fecal current; Gant's clamp in position for the division. (In permanent colostomy this septum remains as a rigid and effective spur.)

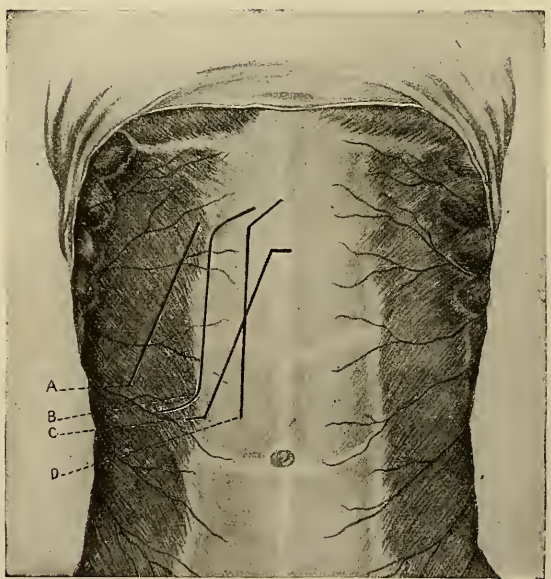

FIG. 810.—Incisions for the surgery of the bile-tracts: A, Kocher's incision; B, Bevan's incision; C, Collins's incision; D, Mayo Robson's incision (Collins).

long, and the extended portions, shown by heavy lines in Fig. 810, B, are added if required (Arthur Dean Bevan, "Annals of Surgery," July, 1899). This

incision gives most satisfactory exposure, its edges can be separated without tension, and it injures but few of the nerves of the abdominal walls.

Kocher's incision (Fig. 810, A) gives a very satisfactory exposure. It cuts the two obliques and the transversalis muscle and divides intercostal nerves, but can be sewed up evenly and is seldom followed by hernia. Mayo-Robson's incision (Fig. 810, D) gives an admirable exposure of the common duct, although it damages the right rectus muscle and the nerve-supply of the inner part of the muscle. None of these incisions is entirely satisfactory. Collins's incision (Figs. 810, C, 811) ("Surg., Gynec., and Obstet.," March, 1909) seems to correct to a great extent the defects of the previous operations. Collins thus describes his incision:

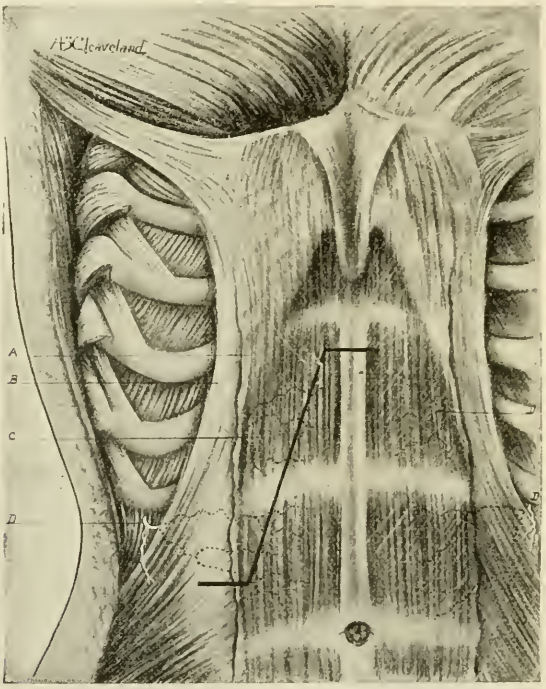

FIG. 811.—A, Anterior wall of sheath of rectus muscle; B, posterior wall of sheath; C, rectus muscle; D, intercostal nerves. The direction of the incision through the skin, fat, and anterior wall of the sheath of the rectus muscle (Collins).

"The incision for the bile-tracts begins at the inner edge of the right muscle, 1 or 2 inches from the ensiform cartilage, and extends diagonally downward and outward to the outer edge of the right rectus, close to the level of the umbilicus. It cuts through the skin, fat, and anterior wall of the sheath of the rectus (Fig. 811). A short transverse incision about 1 inch in length may be made inward from the upper end of the diagonal incision through the skin, fat, and linea alba; and a similar one through the linea semilunaris at the lower end. In case more room is required the upper transverse incision may be extended further into the anterior and posterior walls of the sheath of the left rectus.

"The rectus muscle is then separated from its sheath. It is easily separated from the posterior portion of its sheath by blunt dissection, but the anterior portion presents some difficulty at the insertion of the lineæ transversæ, one of which is found about midway between the ensiform cartilage and umbilicus

and is crossed by this incision. The attachment of the muscle to the anterior wall of its sheath is very close at this linea transversa, and requires sharp dissection with knife or scissors.

"When the muscle is thoroughly freed from its sheath except at its outer border, it is easily retracted outward and allows the posterior wall of its sheath and the peritoneum to be incised in the same direction as the skin and anterior wall. The upper end of this diagonal incision through the posterior wall extends into the short, transverse incision across the linea alba. When this last cut is made the incision pulls open and gives ready access to the right upper abdomen." This incision does not damage the intercostal nerves, hence muscular atrophy is avoided. The openings through the different planes of the abdominal wall are not continuous, hence closure will be more solid. The opening in the posterior portion of the rectus sheath is protected by uninjured muscle.

Cholecystostomy or, as many call it, **cholecystotomy,**[1] is the operation of opening and draining the gall-bladder in order to extract gall-stones or secure the removal of infectious material. In the hands of the Mayos operations for stone exhibit a mortality of less than 1 per cent.; Kocher's mortality is 2 per cent. When death follows an operation on the gall-bladder or ducts, in about one-half the cases it is due to duct infection and is preceded by grave nervous symptoms (Mayo). Cholecystostomy is performed in cases of acute cholecystitis, in hydrops, and in empyema of the gall-bladder; in gall-stone cases in which jaundice has lasted for four weeks or more, and in colic of the gall-bladder with fever, the colic having recurred a second or third time (Carl Beck). The operation completed in one stage is performed as follows: The patient is placed recumbent with a sand-pillow beneath the liver and the incision is made. The peritoneum is opened. If the gall-bladder is distended, it is surrounded with pads and aspirated, and is then opened. Gall-stones are removed by forceps the scoop, or irrigation. The gall-ducts are examined by the fingers external to them before opening the gall-bladder, and are sounded, if possible. If a stone is wedged in the duct, try to manipulate it back into the gall-bladder. If this fails, introduce an instrument from the gall-bladder and break up the stone; if this fails, open the duct, remove the stone, and close the incision in the duct (A. W. Mayo Robson). The only way to be certain that stones have been removed entirely from the cystic ducts is to insert a finger and dilate. Sounds are unreliable. After the removal of all stones and fragments pass a rubber tube which has no side perforations into the gall-bladder, purse up the cut in the gall-bladder around the tube by means of a catgut suture, and suture the gall-bladder to the abdominal aponeurosis. If sutured to the skin, a permanent biliary fistula is apt to follow. It will seldom follow if the gall-bladder is sutured to the aponeurosis. A small piece of gauze is retained under the gall-bladder in case there should be a leak into the peritoneum and in case the peritoneum may have been soiled. If gauze causes no trouble it is retained in place from five to eight days. It can then be removed easily and without breaking encompassing adhesions. The drainage-tube, which drains into a bottle outside of the dressings and below the level of the bed, can usually be dispensed with in from one week to ten days. It should not be dispensed with until the bile becomes sterile.

Some surgeons have advocated immediate suture of the gall-bladder after removing a stone (*ideal cholecystotomy*). I believe this is never advisable when the stones are active for harm, because small calculi may be in the ducts and minute fragments of stone are often left in the bladder, and the drainage will remove them. Drainage also relieves the diseased condition of the gall-ducts and bladder. In Kocher's 31 operations by this method, gall-stones re-formed in 3 cases. Further, the operation with immediate suture is decid-

[1] First performed by Bobbs, of Indianapolis, in 1867.

edly more dangerous when infection exists. The Mayos only employ it in latent cases of gall-stone disease when the existence of stones is discovered during the performance of an abdominal operation.

It is advised by some that the operation of cholecystostomy be performed in *two stages*. First, the bladder is exposed and sutured to the parietal peritoneum. When adhesion takes place, the gall-bladder can be opened without risk of infecting the general peritoneal surface. Riedel advocates operation in two stages, and so did Christian Fenger in certain cases. The two-stage operation is objectionable because it does not permit of satisfactory exploration of the ducts. The *biliary fistula* which is left by cholecystostomy usually closes spontaneously, but may not. If it does not close and the secretion is pure mucus, it is evident that the cystic duct is absolutely blocked and cholecystectomy should be performed.

If the secretion from a persistent fistula is bile and if the common duct is not obstructed, separate the edges of the gall-bladder opening from the parietal peritoneum, endeavoring to avoid entering the abdominal cavity, and close the fistula with Lembert or Halsted sutures. If the secretion is bile and the common duct is obstructed permanently, perform *cholecystenterostomy*. If the secretion does not contain bile and the cystic duct is blocked, remove the gall-bladder. At the end of 1907 Hans Kehr placed his mortality at 2 per cent. ("Jour. de Chir.," Oct., 1908). In the Mayo Clinic from Jan. 1, 1907 to Jan. 1, 1918, there were 5655 operations for gall-stones with a mortality of 2.4 per cent. (Personal communication to the author).

The McArthur Drip.—In 1909 Lewis L. McArthur suggested using a biliary fistula as a means of introducing fluid or food into the duodenum. He proved that if a tube draining bile from the gall-bladder is connected to an irrigator containing salt solution (elevated not more than 20 inches and giving a rate of flow not over 5 or 6 drops a second), there will be a continuous flow of fluid into the duodenum without any discomfort to the patient (McArthur, in "New York Med. Jour.," Jan. 27, 1912). Matas has improved the method by introducing into the duodenum at the time of operation and by way of the common duct a ureteral catheter, through which food, fluid, or medicine can be at any time carried into the duodenum (Rudolph Matas, in "New Orleans Med. and Surg. Jour.," Oct., 1911). The method is used in many cases of obstructive jaundice (after removal of the obstruction). The salt solution relieves thirst, removes toxins, and stimulates the kidneys. It relieves post-operative vomiting, favors intestinal peristalsis, combats flatulent distention, and causes movements of the bowels. Matas points out that liquid food and medicines (strychnin, castor oil, Hunyadi water, etc.) can be given by the biliary route. McArthur believes that the method can be used instead of jejunostomy in certain cases of pyloric obstruction and stomach ulceration.

Cholecystenterostomy[1] consists in making an anastomosis between the gall-bladder and intestine, preferably the duodenum, or, if this cannot be done, the jejunum. It is employed in cases of irremovable obstruction of the common duct. It is done chiefly in cases of malignant obstruction. It is not a suitable operation for gall-stones impacted in the common duct, because it does not remove the cause of trouble, infection of the bile-passages may follow, and the fistula is liable to contract. In those rare cases of common duct obstruction from gall-stones, in which the gall-bladder is distended and the patient is desperately ill, it may be done (Robson). In such a case Robson attaches the gall-bladder to the colon because the operation is easier and because he considers it as useful as the attachment to the duodenum. Cholecystenterostomy can be done most rapidly and successfully by means of a small Murphy button. Before the gall-bladder is incised it is aspirated. Murphy's operation

[1] The operation was suggested by Nussbaum, but was first performed by Winiwarter in 1882 ("A Manual of Operative Surgery," by Sir Frederick Treves).

is shown in Fig. 812, and is similar in performance to intestinal anastomosis. I believe that Brentano is right and that it is best to do posterior cholecystenterostomy, bringing the jejunum through an opening made in the transverse mesocolon.

Cholecystectomy is the extirpation of the gall-bladder. It was first performed by Langenbuch in 1882. The operation is done much more commonly than formerly because we know that in many cases symptoms persist after simple drainage and that an infected gall-bladder is a danger to the pancreas and to the organism. Sometimes primary extirpation is perfomed; at other times cholecystectomy is performed as a secondary operation, cholecystostomy for drainage having been first performed. Its performance may be demanded by the existence of phlegmonous inflammation or gangrene; ulceration; "in chronic cholecystitis from gall-stones where the gall-bladder is shrunken

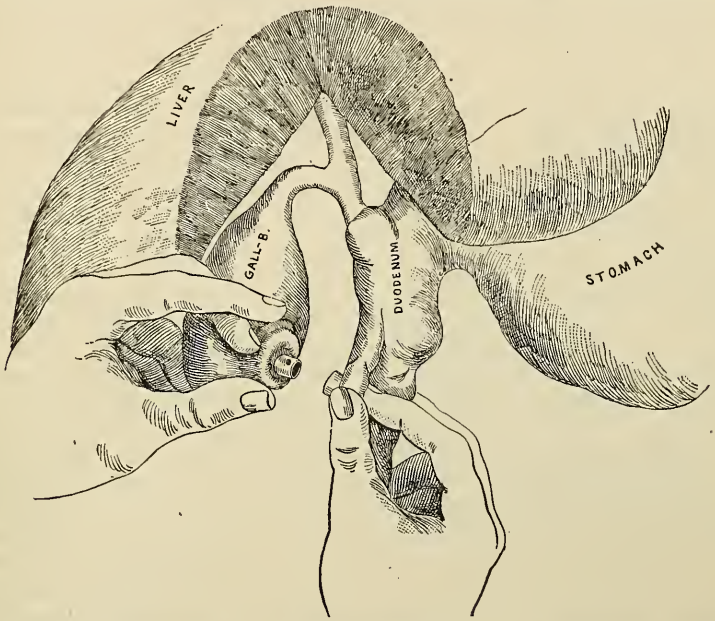

Fig. 812.—Showing method of holding parts while approximating a Murphy button in cholecystenterostomy.

and too small to drain safely, and where the common duct is free from obstruction" (A. W. Mayo Robson); in empyema with greatly damaged walls; in fistula associated with irremediable obstruction of the cystic duct, the common duct being free; in cancer; and in some wounds of the gall-bladder. Objections to the operation are that drainage can only be obtained by putting a tube into the hepatic or the common duct, and that, should renewed drainage be subsequently required, the necessary operation will prove difficult and dangerous (Maurice H. Richardson, "Medical News," May 2, 1903).

After opening the abdomen the gall-bladder is found and is drawn into the wound. If it is distended and tense or if it is thought "to contain infectious fluid" (Lilienthal), it is packed about with iodoform gauze and emptied by an aspirating trocar. "When the walls are very friable, it is even wise to incise and empty the viscus, closing the opening by ligature or clamp before proceeding with the extirpation. The gall-bladder is usually quite a tough organ, and in the majority of cases it may be grasped with an ovarian ring-clamp applied near its fundus, which at the same time closes the aspiration puncture" (Lilienthal, "Annals of Surgery," July, 1904). The peri-

toneum which covers the gall-bladder must be divided just below the liver, the gall-bladder is dissected from the liver until the cystic duct is reached, the cystic artery is tied and divided, and if the liver ducts are healthy, the cystic duct is ligated with silk and divided, the stump is touched with pure carbolic acid and is covered with a layer of peritoneum fastened by sutures of fine silk. In cases free from infection it is not necessary to drain the bile-ducts. In cases with cholangitis external drainage is necessary, and it is obtained by incising the hepatic duct and inserting a drainage-tube, or, better, by leaving the stump of the cystic duct open. Occasionally after cholecystectomy the stump of the cystic duct gradually dilates and forms a new gall-bladder which may be the seat of pain because of adhesions, blocking or stone formation. It would seem that the cystic duct should be divided at its origin. Howard Lilienthal (Ibid.) reported 42 cases with 1 death. Hans Kehr's mortality at the end of 1907 was 3.6 per cent. ("Jour. de Chir.," Oct., 1908). In the Mayo Clinic from Jan. 1, 1907 to Jan. 1, 1918 there were 4064 cholecystectomies with a mortality of only 1.2 per cent. (Personal communication to the author).

Removal of the Mucous Membrane of the Gall-bladder.—Mayo has suggested the removal of the fundus and of all the mucous membrane of the gall-bladder as an occasional substitute for cholecystectomy. By this operation we are enabled to drain the cystic duct and through it the hepatic ducts. A serious objection to the operation is that, as glands pass from the mucous coat to and through the muscular coat, it is impossible absolutely to move the mucous membrane of the gall-bladder alone (Emil Reis).

Drainage of the Hepatic Duct.—This operation is employed for certain hepatic infections. It was first performed by Cabot in 1892. If the cystic duct is dilated throughout, it may be carried out through that. After opening the gall-bladder a tube is passed through the cystic and into the hepatic duct. It is often done after opening the common duct, a tube being carried up into the hepatic duct. The hepatic duct may be exposed and opened directly, a tube being carried into it for a short distance and stitched to the edges of the incision in the duct by catgut. The tube should be surrounded by iodoform gauze.

Supraduodenal choledochotomy is the operation of incising the common bile-duct above the duodenum for the removal of a stone. It is also called *choledocholithotomy*. If drainage is used it is *choledochostomy*. It was first performed by Kümmel in 1889. Courvoisier did his first operation in 1890.

Cases upon which this operation is done are often deeply jaundiced and there is grave danger of infection and perhaps of fatal oozing of blood. In 1 of my cases this happened. The patient was suffering from stones in the common duct, associated with cancer of the head of the pancreas. In every case in which operation is contemplated for obstruction of the bile-ducts take the coagulation time of the blood. Normal coagulation time (taken by Wright's coagulometer) is from three to six minutes. Prolongation to seven or eight minutes calls for pre-operative treatment to hasten coagulability. If jaundice exists, it is customary to endeavor to prevent hemorrhage by employing Robson's plan: Give by the mouth from 30 to 60 gr. of chlorid of calcium three times a day during the twenty-four or forty-eight hours preceding operation, and 60 gr. by enema three times a day for the forty-eight hours following operation. I have followed this course in a number of cases, but am not convinced of its value. Instead of this method we may follow the plan of giving thyroid extract (5 gr. three times a day) for several days preceding operation.

The plan I now pursue I am certain does reduce the coagulation time distinctly. I give an injection of horse serum the day before operation and another the morning of the operation.

When ready to operate, a sand-bag should be placed under the lower ribs. This will bring the liver at least 2 inches nearer to the abdominal wound.

The abdominal incision must be longer than that employed for cholecystostomy. The pylorus and stomach are drawn to the left, the colon and omentum are drawn downward, and the liver and ribs are lifted strongly upward. Gauze packs are inserted.

"The operator should now, after having separated adhesions, have a good view of the common duct within the free border of the lesser omentum, and on inserting his left index-finger into the foramen of Winslow, or on grasping the duct between the index-finger and thumb, he can, without difficulty, bring the duct well within reach, the concretion making a distinct projection."[1] A longitudinal incision is made, the stone is removed, and a probe is introduced into the duct to determine whether other stones are present.

Stones in the second and third portions of the duct are often missed and the second portion of the duodenum should always be palpated with the utmost care. If the lowermost stone removed from the common duct is faceted, we should always search most carefully to find a concretion which is lower still (F. Gregory Connell, "Annals of Surgery," April, 1908).

If a calculus is found in the lower part of the common duct, the surgeon tries to push it up so that he may reach it. This can usually be accomplished. Failing to push the stone up into reach, some try and force it into the duodenum. This attempt will sometimes, but seldom, succeed. If it does not succeed, the surgeon must perform a transduodenal, or a retroduodenal operation. Only in cases so shocked that prolonged operation is impossible is it proper to do cholecystostomy or cholecystenterostomy. If either of these palliative operations is performed a radical operation must be done later.

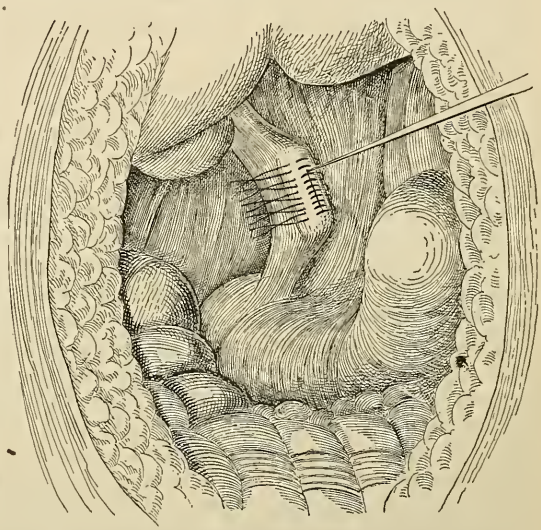

Fig. 813.—Suture of duct over Halsted's hammer.

Many surgeons suture the incision in the duct. This procedure is rendered easier by the use of Halsted's hammer which draws the duct toward the surface and keeps it under control (Fig. 813).

Interrupted sutures of fine catgut are used. The muscular and serous coats may be included in each suture, and over this layer Lembert or Halsted sutures are applied. A drainage-tube is inserted and a piece of iodoform gauze is placed upon the suture line, the other end being brought out of the abdominal wound. This precaution is taken because leakage may occur. If it is found impossible to suture the wound in the duct, the operation then becomes a *choledochostomy* (although this term is usually used only when the incised duct is stitched to the abdominal wall). The surgeon carries a glass tube down to the opening and surrounds it with iodoform gauze, or inserts a rubber drainage-tube into the opening and carries it up toward the hepatic duct, or makes an incision into the right loin after the plan of Rutherford Morison, and carries a tube into the right kidney pouch, which is the most dependent part of the peritoneal cavity when the patient is recumbent. Personally I always drain the duct, when I have opened it for stone, carrying

[1] A. W. Mayo Robson's "Treatise on Diseases of the Gall-bladder and Bile-ducts."

the tube up toward the hepatic duct. The same reasons which cause us to drain the gall-bladder after removing stones should influence us in this case.

Robson ("Lancet," April 22, 1902) has performed the operation of choledochotomy 60 times. In 10 cases of stone in the common duct he manipulated the stone back into the gall-bladder and removed it through an incision in that viscus by means of a scoop. The above maneuver is impossible unless the cystic duct be dilated. In 30 cases he crushed the stones between his finger and thumb, but this is only possible when the stones are soft, and it has the objection that it may leave fragments. If a stone is lodged in the common duct and cannot be manipulated back into the gall-bladder, choledochotomy should be performed. Robson's mortality in 60 cases of choledochotomy was 16.6 per cent. Since 1900 his mortality has been 7.1 per cent. Before that it was 23.8 per cent. Kehr's mortality is 4.1 per cent. During 1912 the Mayos performed choledochotomy 96 times, with 5 deaths ("Report of St. Mary's Hospital for 1912").

Hepaticotomy.—By this term we mean the opening of the hepatic duct. If the opening be drained the procedure is, in reality, *hepaticostomy*, although this term is seldom used to designate it. Hepaticotomy is performed for stone in the hepatic duct. The operation was first performed by Kocher in 1889. There were 7 cases on record in 1903 (Delagenière, in "Bull. et Mém. de Chir. de Paris," No. 10, 1903).

Duodenocholedochotomy (McBurney's Operation; the Transduodenal Route).—This operation is seldom necessary. In the more than 2000 operations performed by the Mayos on the gall-bladder and ducts, it was only required in 4 cases. I have never performed it. In 1891 McBurney proposed the method for the removal of gall-stones impacted near the papilla ("Annals of Surgery," Oct., 1898). McBurney's original suggestion was to open the duodenum, dilate or incise the papilla, remove the stone, and suture the duodenum. The duodenum must be mobilized so that it may be lifted into the wound. If the stone be located in the diverticulum of Vater, it may, in some few cases, be removed by simply stretching the opening of the duct with forceps (Collins's method). If this be not possible, the opening in the papilla may be enlarged by cutting or the duodenal mucous membrane over the stone may be incised (McBurney's plan). When the stone is not impacted at the outlet, but is lodged a little higher up, and when dense adhesions render access by the ordinary supraduodenal route difficult or impossible, the anterior wall of the duodenum may be opened longitudinally, the posterior wall of the duodenum and the common duct incised over the stone, the stone removed, the duodenum and common duct sutured together (Kocher's method, or *internal choledochoduodenostomy*), and the anterior wall of the duodenum closed. (See Charles Otto Thienhaus, in "Annals of Surgery," Dec., 1902.) After finding and removing a stone by the transduodenal route we must make a careful search to see that no stones are left before closing the duodenal incision. Robson opposes the transduodenal route and says he has abandoned it because of the danger of sepsis. Thienhaus (Ibid.) opposes this view of Robson and shows that in 29 operations by the transduodenal route there were but 2 deaths.

Connell ("Annals of Surgery," Jan., 1908) has collected 77 cases in which stones were removed by the transduodenal route. There were 10 deaths. In 2 of these cases duodenal fistula preceded death.

Retroduodenal Choledochotomy.—In this operation the second portion of the common duct is incised back of the duodenum without opening the gut. That this may be done the duodenum must first be drawn toward the midline of the body, and this can be done only by "mobilizing" the duodenum, incising the posterior layer of the parietal peritoneum 1 inch to the right of the descending portion of the duodenum. After freeing the gut and retroperitoneal structures the duodenum becomes sufficiently free to lift toward the left with

a rotation. We thus expose the posterior aspect of the duodenum, the head of the pancreas, and the common duct.

The duct is opened, the stone removed, the duct sutured, and a drain inserted.

This operation has been successfully performed by a number of surgeons, but there is a great objection to it. In nearly all cases the common bile-duct passes *through* the pancreas rather than back of it. Büngner found this to be the case in 55 out of 58 dissections ("Gray's Anatomy," Seventeenth American edition, p. 1352). Hence, incision of the common duct in this situation means in nearly all cases incision of the pancreas and all the grave dangers of leaking of pancreatic fluid. The transduodenal operation is a much better procedure.

Total Splenectomy.—This operation is performed for wounds and rupture of the spleen, tumors, cysts, floating spleen, and non-leukemic splenic hypertrophy. Twisting of the pedicle of an ectopic or wandering spleen calls imperatively for operation. It should not be performed for hypertrophy in leukemia. Splenectomy does not interfere with the development of a young child. An extraordinary thing after splenectomy is how rapidly the normal proportion of red blood corpuscles is restored (Sir J. Bland-Sutton, in "Proc. Royal Soc. of Med.," 1914).

Vedova (quoted in "Practical Medicine Series," 1913, vol. ii) collected 134 cases of splenectomy for traumatic rupture of the spleen. There were 40 deaths. He adds these to Berger's 60 cases, with 25 deaths. This makes a total of 194 cases, with 65 deaths (33.5 per cent.).

In view of the bone-marrow changes in splenomyelogenous leukemia, we cannot hope to cure a patient by removing the spleen. In a leukemic patient the operation has a very high mortality from shock and hemorrhage. Geo. Ben Johnston ("Annals of Surgery," Jan., 1908) has collected 49 splenectomies in leukemia with only 6 operative recoveries (a mortality of 87.7 per cent.). One of the 6 cases lived eight months, 1 lived four years, and it is claimed that 1 was cured. Sir. J. Bland-Sutton states that the removal of a leukemic spleen can do nothing but harm ("Proc. Royal Soc. of Med.," 1914).

Splenectomy has been performed for malarial hypertrophy (ague-cake). The operation has been advocated on the theory that by removing the spleen we get rid of the lurking place of the malarial parasites, but they also lurk in the bone-marrow and in the capillaries of the liver. The operation should not be performed for malarial spleen unless the organ is movable, unless it greatly interferes with the patient's comfort or occupation, or unless we fear rupture, and then, if it is done, it is for the movability, the discomfort, or the danger of rupture, and not for the malaria. It is to be noted that the operation does not cure the malaria. Johnston ("Annals of Surgery," Jan., 1908) collected 58 splenectomies performed for malarial hypertrophy since 1900. There were 50 recoveries and 8 deaths. To these he adds 3 successful ones of his own, making 61 cases, with 8 deaths (a mortality of 13.1 per cent.).

A number of operations have been done for splenic anemia or its terminal stage, which is known as Banti's disease. Those who believe that the splenic enlargement and anemia result from some underlying condition common to both do not operate. The theory of the operation is that removal of the spleen stops the production of some toxic material which causes anemia and cirrhosis of the liver, in other words, that the splenic disease causes the anemia. There seems ample evidence that splenectomy, if done early, may save the patient. It is useless and highly dangerous to do it after the development of the second stage of Banti's disease. Cushing's case was alive and well eight years after the operation. I had a case alive and well three years ofter operation at which time he died of cerebrospinal meningitis. Splenectomy may cure hemolytic jaundice (Peck, in "Jour. Am. Med. Assoc." Sept. 9, 1916). Banti reported the first cure in 1911. The operation should be done in Hanot's cirrhosis and

in hypertrophic cirrhosis of the liver. Primary pernicious anemia is probably due to a toxin which is intensified by splenic action. Hence splenectomy may be done. It produces, at the least, great temporary improvement.

Johnston (Ibid.) has collected 61 splenectomies for splenic anemia or Banti's disease. There were 49 recoveries and 12 deaths, a mortality of 19.5 per cent. I have performed splenectomy twice for Banti's disease, with one recovery and one death.

Johnston (Ibid.) notes 12 splenectomies for sarcoma of the spleen, with 9 recoveries. One lived eight and one-half years and died of heart disease; 3 are known to have died from recurrent sarcoma.

It is stated that there are on record 4 splenectomies for cancer. Moynihan doubts the diagnostic accuracy of the three earlier reports. Mary A. Smith records a case of colloid cancer occurring in a woman who had been operated on ten years before for ovarian cyst associated with pseudomyxoma of the peritoneum. The pathologist reported that the growth in the spleen was a metastasis of colloid carcinoma. This patient died seven months after the splenectomy from peritoneal and omental cancer ("Annals of Surg.," Jan., 1908).

In Johnston's table of 708 splenectomies for various causes (Loc. cit.) the mortality is 27.4 per cent. In the cases operated upon from 1900 to 1907 inclusive the mortality is 18.5 per cent. In anemias transfusion before splenectomy may prove of great service.

In order to remove the spleen most operators make an incision from the anterosuperior spine of the ilium to the ribs. I prefer to make an incision below the left costal margin like Kocher's incision on the right side to reach the gall-bladder. This incision can be extended to any necessary degree, and posterior drainage of the pancreas region can emerge from its outer end. Open the peritoneum and divide adhesions between ligatures. If the spleen be adherent to the pancreas, it may be necessary to remove a fragment of the last-named organ. It is a very undesirable thing to have to do, and I lost a case from pancreatic leakage after having done it. Ligate the suspensory ligament and divide it. Bring the spleen well out of the wound. Surround it with gauze pads. Transfix the pedicle with stout silk. Tie it firmly, leaving the ends of the ligature long for a time, and cut through the pedicle beyond the ligature. Ligate the vessels separately with catugt. Cut off the long ends of the silk ligature and drop the pedicle back, unless apprehensive of bleeding, when it may be fastened to the surface. The wound is closed without drainage, unless the pancreas has been injured, in which case posterior drainage is employed. Traction upon and ligation of the vessels in the pedicle may cause profound shock by injuring the splenic plexus, which is in close relation to the solar plexus (Jordan, in "Lancet," Jan. 22, 1899).

If splenectomy is found to present great difficulties the splenic artery may be tied and the spleen left in place (Lanz). John C. Gerster ("Jour. Am. Med. Assoc.," Aug. 7, 1915) suggests tying the splenic artery and the gastro-epiploica sinistra where it reaches the stomach-wall, before removing the spleen. Then after splenectomy the hemorrhage will be venous only. For the "Technic of Splenectomy" as practised in the Mayo Clinic, see Donald C. Balfour, in "Surgery, Gynecology, and Obstetrics," July, 1916.

Changes After Splenectomy.—About two weeks after the removal of a normal spleen certain definite changes happen in adults, but not in children. These changes last for several weeks, and are manifested by enlargement of the lymph-glands, pain in and tenderness of bones, blood changes, loss of weight, weakness, thirst, polyuria, abdominal pain, elevation of temperature, and rapid pulse.[1] Tizzoni says that these changes are not obvious in children, because in them compensatory organs act at once, whereas in adults compensatory organs act slowly and with painful effort. Such symptoms are noticed when

[1] Ballance in "Practitioner," April, 1898; W. Martyn Jordan, in "Lancet," Jan. 22, 1898.

the spleen is removed because of a wound or a rupture, but rarely after removal of a diseased spleen. It is likely that compensating organs become active when the spleen is diseased, and consequently are in full operation when such a spleen is removed. After partial splenectomy these changes are not noted (Jordan). Changes can be prevented after splenectomy by the administration of tablets of extract of spleen, and red bone-marrow (Ballance), and iron (especially in foods) is of value.

The blood changes after splenectomy consist of diminution in hemoglobin and red blood-cells. The coloring-matter and cells do not become normal for two or three months.

Splenopexy.—This is the operation of anchoring a movable spleen. It should only be used when the spleen is not enlarged and is not diseased. Rydygier in 1895 published the first case, although both Tuffier and Kouwer operated before this date. Sutures should not be passed through the spleen: the structure is so soft that stitches are bound to loosen and the insertion will cause bleeding. A promising method is to create adhesions by the use of iodoform gauze, as is done for movable kidney, and as was done by Kouwer. Some advocate making a pocket outside of the peritoneum and bringing the spleen into this pocket, making it extra-peritoneal.

Abdominal Hernia or Rupture.—A hernia is a protrusion of peritoneum liable to contain, containing at times, or permanently containing any viscus or part of a viscus from the abdominal cavity. MacCormac says the term implies that the protruded viscus is covered with integument; hence a protrusion of viscera through a wound does not constitute a hernia. A hernia has three parts—the sac, the sac-contents, and the sac-coverings (Fig. 814). The *sac* is formed of peritoneum. A *congenital sac* is due to developmental defect, and may be in the inguinal region, the femoral region, the umbilical region, the lumbar region, or in the epigastric region. In the epigastric region it is a result of a congenital slit in the transversalis fascia. It used to be stated that femoral hernia was never congenital, but Russell and Coley both say that a femoral hernia may have a congenital sac. In 100 necropsies Murray found 20 potential femoral sacs (sacs into which a hernia had not entered). An *acquired sac* is due to intra-abdominal pressure bulging the peritoneal covering of an abdominal ring and converting it into a pouch. The sac comprises a *body*, a *neck*, and a *mouth*. A sac once formed is almost certain to persist, because it adheres by its outer surface to surrounding parts, and hence the sac of a hernia is usually irreducible even when the contents are reducible. The *neck of the sac* is due to the constriction through which the sac passes; it becomes furrowed and folded, and the adhesion of these folds causes thickening and rigidity. Hernia of the bladder or of the cecum may have no sac or but a partial sac. A ventral hernia following an abdominal operation may be without a sac. The *contents of the sac* depend chiefly on the situation, a portion of the ileum being the usual contents. The colon, the stomach, the great omentum, the bladder, and other structures may enter the hernial sac. An *enterocele*

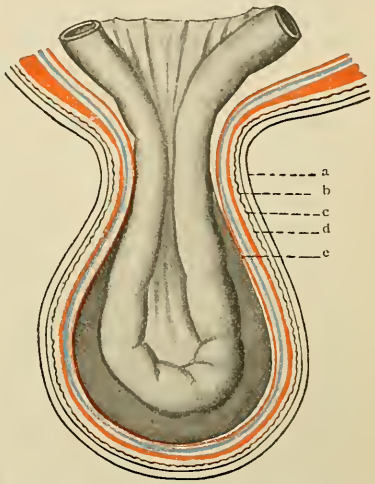

FIG. 814.—A diagrammatic representation of the coverings of a hernia: *a*, The skin,; *b*, the superficial fascia; *c*, the muscular layer—*e. g.*, the cremaster muscle in an inguinal hernia; *d*, the transversalis fascia; *c*, *d*, have also been called the fascia propria herniæ; *e*, the peritoneum—*i. e.*, the sac of the hernia (Sultan).

contains intestine only; an *epiplocele* contains omentum only; an *entero-epiplocele* contains both omentum and intestine; a *cystocele* contains a portion of the bladder. The *coverings of the sac*, which vary with its situation, will be set forth during the consideration of special forms of hernia. In old hernia the layers are never distinct, fat and muscle waste, tissues adhere, and the skin stretches and atrophies. The sac of an old hernia occasionally becomes tuberculous, and the disease may remain local in the hernial sac or spread to the general peritoneum. Renault tells us that *tuberculosis of a hernia* is made manifest by increase in size, pain on pressure, and loss of body weight.

Causes of Hernia.—Hernia is a common trouble. According to Berger, in 1000 people 4.4 per cent. suffer from hernia. It occurs at all periods of life, and hereditary predisposition sometimes seems to exist. The male sex is three times as liable to hernia as the female sex. That increase of intra-abdominal tension is a common cause in children has been amply demonstrated. (See Hernia in Childhood, page 1297.) Excessive length of the mesentery has been assigned as a cause. In some instances a mass of fat forms (*fat hernia*) and advances before the hernia, and seems to bear a causative relation to it. Lucas-Championnière explains this as follows: When a person begins to take on fat, it is deposited not only under the skin, but also in the omentum, mesentery, and subperitoneal tissues. The semifluid fat is easily influenced by pressure. The deposit of fat within the abdomen lessens the size of that cavity, intra-abdominal pressure is increased, and subperitoneal fat protrudes at any weak spot in the wall. The protruding mass of fat adheres to and makes traction upon the peritoneum, and this membrane is drawn upon to form a sac, and the sac is surrounded by fat. This method of formation is frequently noticed in umbilical herniæ, and occasionally in inguinal herniæ. Any laborious occupation predisposes to rupture. Any condition which weakens the abdominal wall predisposes to rupture (muscular relaxation from ill-health, relaxation of abdominal walls following the termination of pregnancy, the removal of a large tumor or tapping for ascites, and wounds or abscesses of the abdominal wall). The commonly assigned cause is repeated muscular effort which increases intra-abdominal tension (straining at stool, coughing, lifting weights, jumping, the sexual act, and straining during micturition). In 25 per cent. of cases the cause is supposed to have been lifting or carrying a weight (Coley). I am satisfied that in some cases at least the external abdominal ring enlarges before it has been stretched by a descending hernia. Such a condition predisposes to hernia by weakening muscular support of the abdomen. A hernia may appear gradually or suddenly. Berger and Coley state that nearly 70 per cent. of herniæ in adult males appear gradually. The sac of an acquired hernia exists for a longer or shorter time before the hernia enters it. The sac of a congenital hernia is present at birth. The sac of an acquired hernia forms gradually. A sac may exist for years and yet remain empty. When bowel or omentum enters it from some strain or effort, the parts have been long prepared to receive the extruded mass. This extrusion may occur gradually or it may occur suddenly. If it occurs suddenly, the sufferer believes that his hernia was formed then and there, but, as a matter of fact, the extrusion of bowel or omentum and its entrance into the sac were but the last of a long series of antecedent and preparatory changes. Finally, a hernia appears and often does so during effort. In rare cases traumatism may cause a hernia immediately, no sac existing before the accident. It does so in the inguinal region by stretching or tearing the internal ring, the inguinal canal at once enlarging. Such a condition is a true *traumatic hernia*, traumatism being the sole cause and not simply the exciting cause.

The old and erroneous idea was that a hernia was always formed by tearing of the peritoneum; hence the term *rupture*. This mode of formation is extremely unusual, but occasionally does occur. Coley saw such a case. An

ordinary non-traumatic hernia, when the bowel suddenly and for the first time enters the sac, is the seat of some pain, but the pain is not disabling and the lump disappears on recumbency. In many cases the bowel or omentum gradually finds a way into the sac, and in such cases pain is usually trivial and may even be absent. In true traumatic hernia there are violent pain, collapse, vomiting, inability to walk and stand, and the mass does not return to the belly on recumbency, but must be reduced by taxis or operation. True traumatic herniæ may occur anywhere in the abdomen, but are most common in the inguinal region, where they are direct herniæ. (The relation born by accidents to the development of hernia is discussed by Paul Berger, in "Rev. de Chir.," April and May, 1906, and by Wm. B. Coley, in "Internat. Jour. of Surg.," Feb., 1908). All congenital herniæ are due to structural defects. Herniæ are divided clinically into *reducible*, *irreducible*, *incarcerated*, *inflamed*, and *strangulated*.

Reducible Hernia.—In this form of hernia the contents of the sac can be reduced into the abdominal cavity. At a known hernial opening the patient has a smooth enlargement (narrower above than below), which began to grow above and extended downward. A distinct neck can often be felt. In enterocele, straining, lifting, or standing enlarges the mass; the protrusion becomes smaller and may disappear on lying down; cough causes impulse or succussion, the protrusion is elastic, and may be tympanitic on percussion, and on reduction the mass suddenly disappears and there is a gurgling sound. In epiplocele the mass is often irregular and compressible, and feels boggy rather than elastic; muscular effort does not have much influence in enlarging it; impulse on coughing is slight; percussion gives a dull note, and reduction is accomplished gradually and produces no gurgling sound. In entero-epiplocele some parts of the mass are smooth, elastic, and perhaps tympanitic; others are dull on percussion, irregular, and flabby, but the diagnosis of this especial form from the other forms is often uncertain. The victims of reducible hernia complain of some pain on exertion, of dyspepsia, and often of constipation.

When a hernia is beginning to form there is often *premonitory uneasiness;* the patient complains of muscular pain in the lower abdomen, and this condition may exist for weeks or months before it is recognized that a hernia is present. An inguinal hernia can be recognized before it protrudes from the external ring. The tip of the finger is inserted in the ring and the patient is asked to cough. If a hernia has entered the canal, succussion will be detected on coughing. In a healthy man the external ring should admit the tip of the little finger, but not the end of the index-finger. If the end of the index-finger can be made to enter the ring that aperture is dilated, and even if there is no hernia in the canal, in future a hernia will probably descend. In a man, if the surgeon desires to examine the ring, he inverts the skin of the scrotum over the finger and carries the finger to or in the ring. When the hernia first appears there may be pain, faintness, and some sick stomach, but often there is no pain or any discomfort.

Treatment of Reducible Hernia.—*Palliative Treatment.*—Prevent constipation and forbid sudden strains and violent exercise. If operation is refused or inadvisable, order a truss. The continued employment of a truss in young persons may bring about a cure. The day truss should be applied before rising in the morning and be removed after lying down at night, when a light truss should be substituted. A special truss is applied before bathing. In very fat people there is always trouble in adjusting a truss. A femoral hernia is more difficult to keep reduced than an inguinal hernia. In a hernia in which the gut is replaceable, but a portion of omentum is irreducible, it is difficult to maintain reduction of the gut with a truss, and an operation should be performed. In an oblique inguinal hernia the pad of the truss fits over the internal abdominal ring; in a direct inguinal hernia, over the external abdominal ring; in a femoral hernia, over the femoral ring at the level of Gimbernat's

ligament. MacCormac's method of measuring for a truss is as follows: In either inguinal or femoral hernia start the tape from the *lower part* of the hernial opening, carry it up to the anterior superior iliac spine of the same side, then take it around the body, 1 inch below the crest of the ilium, to the other anterior superior iliac spine, and then to the upper part of the hernial opening.[1] A well-fitting truss will keep the hernia up even when the patient sits in a position to relax the abdominal walls and coughs and strains. A truss is always uncomfortable at first, but a person usually becomes accustomed to it. It should be kept scrupulously clean, and borated talc powder should be dusted upon the skin under the pad at least once a day. A truss which does not keep the hernia up or which causes pain does harm. Too strong a spring tends to enlarge the hernial orifice, and thus aggravates the case. Even after an apparent cure with a truss this device must be worn for a long time.

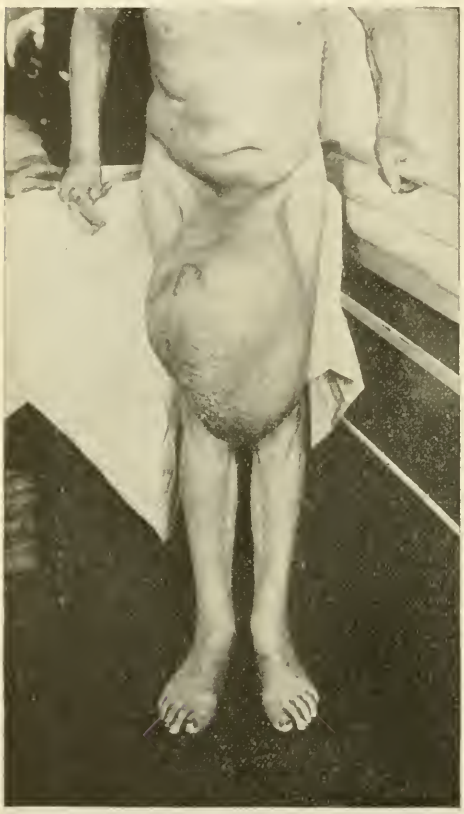

FIG. 815.—Hernia which has "forfeited the right of domicile."

Radical treatment of reducible and of non-strangulated hernia seeks to obtain cure by plugging the mouth of the sac or by obliterating the canal of descent. Radical operations should be performed upon strangulated hernia in ordinary cases of reducible hernia, particularly if a truss is very painful or does not keep the bowel up, in most cases of irreducible hernia, and in any case of hernia in which there are occasional attacks of obstruction. It was formerly believed that a cure would fail if the subject was under three years of age, but Coley and others have proved that it is a very successful operation in childhood. It is rarely recommended under the age of four, because in two-thirds of the cases a truss will cure very young subjects. It is strongly advised in children after the age of four when a truss has failed, when there is irreducible omentum, or when there is a reducible hydrocele which prevents the truss from holding (Wm. B. Coley, in "Annals of Surgery," June, 1903). The radical operation is almost without danger in properly selected cases, and is one of the most successful of surgical procedures. We are justified in doing the operation upon an individual under fifty years of age and free from complications, purely to relieve him or her from the annoyance of wearing a truss. If, however, a patient is sixty years of age or over and a truss keeps the hernia up satisfactorily, the operation should not be performed unless it is demanded by some complication. Organic diseases of the heart, lungs, and kidneys are contra-indications. Enormous herniæ (Figs. 815 and 816) are unfavorable for operation. Restoration is difficult or impossible, the forcible handling produces much shock, and recurrence is to be expected. Restoration is difficult or impossible because the

[1] Treves's "Manual of Surgery," "Hernia."

abdominal cavity has contracted and holds with difficulty or cannot hold the huge hernia. As J. L. Petit said, the hernia has *forfeited the right of domicile* (Fig. 815). In an operation for an enormous hernia a great quantity of omentum will require removal, and it may be necessary to resect a considerable piece of intestine. If we decide to operate upon an enormous hernia, treat the patient some time before with the object of making him lose flesh. The absorption of mesenteric fat lessens intra-abdominal pressure. That operation may succeed in such cases is shown by Figs. 816 and 817. In any operation for the radical cure of inguinal hernia always remember that the *bladder* may be part of the hernia, and be on the lookout for it. Eggenberger's table of 6778 hernial operations shows 75 bladder herniæ (1 per cent.). As a rule, the bladder is covered with cellular fat, which differs in color and consistence from omental fat and from other fat which may be found about a hernia. The presence of a quantity of extraperitoneal fat outside of the sac suggests the adjacency of the bladder and warns us not to tie off the sac verv high up. It was the author's misfortune on

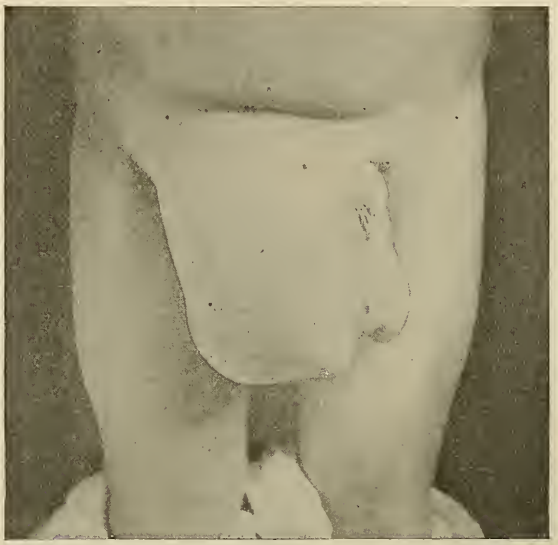

Fig. 816.—Oblique inguinal hernia of large size (duration, sixteen years).

two occasions to open a bladder in operating for inguinal hernia. In each case the bladder was sutured and both patients recovered. It has been estimated that the mortality after this accident, even when the bladder is sutured, is from 6 to 16 per cent. Among other possible accidents which may occur during hernia operations are: injury of an iliac vessel, of a femoral vessel, of an epigastric vessel, or of the obturator artery.

The success of an operation for the radical cure of a hernia depends upon the attainment of primary union. Primary union is favored by thorough cleanliness; by wearing gloves while operating; by cutting the parts with a sharp knife instead of tearing them with a dissector; by removing some fat and any superfluous tissue fragments; by tying the stitches firmly, but not tightly (a tight stitch causes necrosis and creates a point of least resistance); by careful closure; by dressing with pressure; and by keeping the patient recumbent for from fifteen days to three weeks.

A truss is not to be used after operation. Ten years ago Wm. B. Coley ("Annals of Surgery," June, 1903) had operated upon 1075 cases of inguinal and femoral hernia. In his report he did not consider operations performed

within the preceding six months, and so presented a study of 1003 cases. Of these, 937 cases were inguinal, 66 cases were femoral. In the 1003 cases, 647 were traced and were found well from one to eleven years after operation; 705 were well from six months to eleven years; 460 were well from two to eleven years. If the patient is well one year after operation, he will probably remain well. This is proved by Coley's study of relapses, an investigation which shows that 65 per cent. of relapses occur within six months of operation and 80 per cent. within the first year. Only 13⅔ per cent. occur from one to two years, and only 6⅔ per cent. after two years. Coley had 2 deaths in 1075 cases (less than ⅕ of 1 per cent.). After Bassini's operation there are about 1 per cent. of relapses. Coley reports that from Dec., 1891, to Jan., 1909, there were performed by Drs. Bull, Walker, and himself, in the Hospital for Ruptured and Crippled, 2384 operations for the radical cure of hernia. Of these, 2218 were inguinal (only 445 in females). In the 1773 male cases the typical or modified Bassini operation was done with 12 relapses, or 0.68 per cent. ("Progressive Medicine," June, 1909).

Fig. 817.—The case shown in Fig. 816 six months after operation.

Lannelongue's Method.—Lannelongue has for certain cases returned to the old injection plan, using a 10 per cent. solution of chlorid of zinc instead of white oak bark. The hernia is first reduced and is held up by an assistant, who closes the internal ring with a finger and also holds the cord aside. Several injections of 10 min. each are thrown in the region of the internal pillar, the region of the external pillar, and into the canal behind and outside of the cord. The surgeon must be careful that no zinc solution escapes into the subcutaneous tissue. The effect of the chlorid of zinc is to cause the formation of quantities of fibrous tissue. It is scarcely to be expected that a cure so produced will be permanent in an adult, though it may be in a child.

Macewen's Operation for Inguinal Hernia.—A hernia director (Fig. 818, A) and special hernia needles (Fig. 818, B) are required for this operation. The patient lies recumbent, the thigh being abducted and partly flexed and resting on a pillow beneath the knee. The bowel is reduced, and an incision 3 inches long is made in the direction of the inguinal canal, the center of the incision corresponding to the external ring. The sac is freed from its attach-

ments below and is lifted up. The surgeon introduces a finger into the inguinal canal and separates the sac from the cord and from the walls of the canal, and then carries the finger through the internal ring and separates the peritoneum for 1 inch about the periphery of this aperture (Fig. 819, A). A chromicized catgut stitch is fastened to the lowest portion of the sac, and is passed through the sac several times, so that pulling on the stitch will purse the sac (Fig. 819, B). The free end of this stitch is carried through the internal ring into the belly, and is pushed out through the abdominal muscles 1 inch above the internal ring, the skin being pushed aside so as to escape perforation by the needle. The thread is tightened so as to fold up the sac and pull it into the belly. This plugs the ring. The thread is handed to an assistant to keep tight until the sutures are introduced into the ring, when the sac is permanently anchored by taking several stitches in the external oblique muscle. A strong catgut suture is passed with a Macewen needle through the conjoined tendon from below upward, the ends of this suture being carried through Poupart's ligament and the outer border of the internal ring from within outward. This suture is tightened and closes

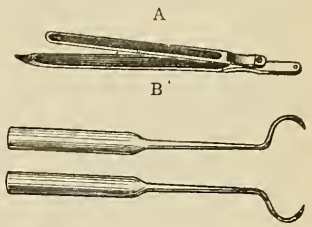

FIG. 818.—A, Hinged hernia director; B, hernia needles.

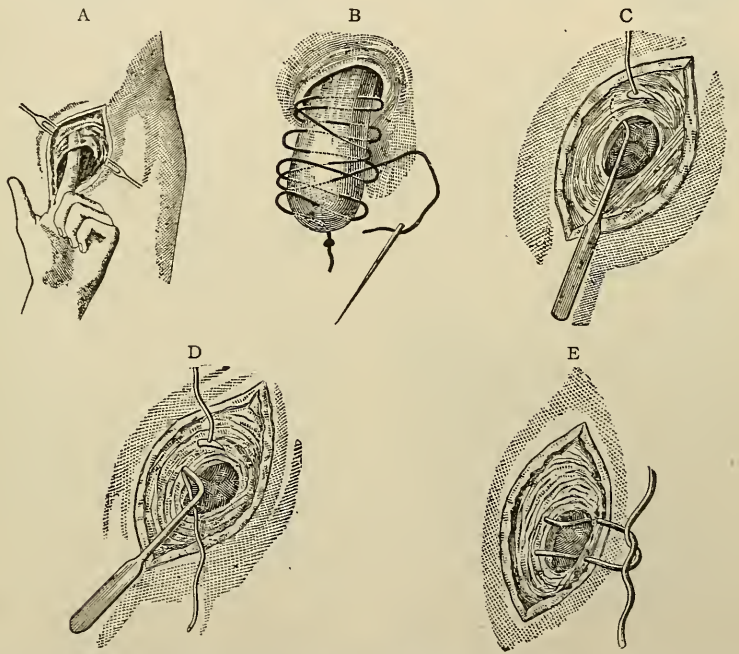

FIG. 819.—Macewen's operation for radical cure of inguinal hernia: A, Stripping of the sac; B, purse-string suture; C, fastening the purse-string suture; D, passing, and E, tying, the sutures for the internal ring.

the internal ring. The external ring is sutured and the skin is stitched (Fig. 819, C, D, and E).

In congenital hernia the sac is divided in its middle, and the lower part is closed by stitches of chromicized catgut, forming a tunica vaginalis. The upper part of the sac is slit posteriorly to permit the escape of the cord, and is closed by stitches of chromicized catgut (Fig. 820). The operation is finished as in the

acquired form. After Macewen's operation the patient should stay in bed for at least three weeks, and must not work for eight or nine weeks. Workmen after this operation should always wear for a time a pad and a spica bandage. Children require no pad. Never apply a truss, as strong pressure will produce atrophy of the curative scar.

Bassini's Operation for Oblique Inguinal Hernia.—(See E. Wyllys Andrews, in "Med. Record," Oct. 28, 1899, who describes from personal observation how Bassini does his operation. I have drawn upon his description in the following section.) Bassini's operation displaces the spermatic cord from the old canal and places it in a new canal, and this new canal is oblique. Curved and rounded needles are employed to insert the stitches. The suture material is kangaroo-tendon or chromicized catgut. Silk or silver wire is apt to make trouble—perhaps long after the operation. The patient is placed supine with the thighs extended. An incision is made parallel to Poupart's ligament and extending from the external ring to a point external to the internal ring. The incision is about 1½ inches above the ligament and is from 5 to 7 inches in length. By this incision the aponeurosis of the external oblique and the pillars of the external ring are exposed. All bleeding is arrested, the aponeurosis is incised in the direction of its fibers and from above downward, and the inguinal canal is opened. The aponeurosis of the external oblique is dissected up with a blunt instrument until Poupart's ligament is exposed. We speak of this ligament as the shelf. A mass containing the sac of the hernia, the cord, the cremaster muscle, and considerable fat is lifted up. Bassini employs blunt dissection. Coley advocates the use of the knife. Masses of fat and usually the cremaster muscle are removed. The sac is isolated first at its neck and the neck is stripped from the inner aspect of the internal ring for the distance of ⅘ inch. The object of this stripping is to permit the removal of the sac at a high level. High removal obviates the leaving of a funnel-shaped depression of peritoneum. Such a depression would predispose to relapse. The sac is opened at the fundus, the interior is investigated, and if the contents are reducible, they are restored to the abdominal cavity and the neck of the sac is clamped high up. If adherent masses of omentum are found, the adhesions are separated, bleeding is arrested, and the omentum is restored to the abdomen unless it is in a hard and thick mass, when it is tied off and removed. Bassini ties off the neck of the sac above the clamp with a strong ligature of silkworm-gut. If the sac is large and thick, he also threads both ends of a ligature upon a needle, passes the strand through the stump, and ties around over the first loop. (See E. Wyllys Andrews, "Med. Record," Oct. 28, 1899.) Coley and many other operators prefer to tie off the sac with a catgut suture rather than with silkworm-gut or silk. It is my usual custom to employ fine black silk, catching it to prevent slipping by running a stitch through the wall of the neck of the sac. After ligating the neck of the sac the sac is cut across and removed. The cord is now lifted out of the way (Fig. 821, A), the inner surface of Poupart's ligament is exposed by retraction, and the deep sutures are passed (Fig. 821, A). Bassini uses silk which has been boiled in glycerin. Most American operators use kangaroo-tendon or chromicized catgut. Bassini inserts first the sutures nearest to the pubes. The first suture—and sometimes also the second—includes part of the rectus sheath and rectus muscle. Each stitch includes the internal oblique and transversalis muscle in the upper edge and the shelf of Poupart's ligament below the lower margin, and from four to six stitches are passed behind the cord (Fig. 821, B). The last stitch narrows

FIG. 820.—Macewen's operation for the radical cure of congenital hernia.

the internal ring so that it fits tightly around the cord (E. Wyllys Andrews, Ibid.). Coley's rule for passing this suture is to insert it so "that it just touches the lower border of the cord when the latter is brought vertically to the plane of the abdomen" ("Annals of Surgery," June, 1903). He always places a suture above the cord, and believes it tends to prevent relapse (Fig.

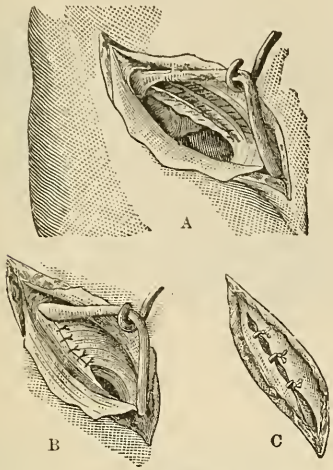

FIG. 821.—A–C, Bassini's operation for the cure of inguinal hernia (Esmarch and Kowalzig).

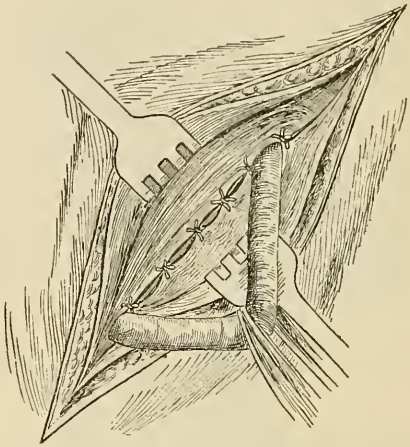

FIG. 822.—Bassini's operation (deep sutures), showing extra suture above the cord, as advised by Coley.

822). The sutures are tied from above downward. The cord is laid upon this new floor and the aponeurosis of the external oblique is sutured over it (Fig. 821, C). I close the aponeurosis by a continuous suture of chromic catgut and the skin with interrupted sutures of silkworm-gut or fine silk. *Drainage* is not used except when there is excess of subcutaneous fat. The wound is covered with a roll of iodoform gauze and some pieces of sterile gauze, and compression is made by strips of adhesive plaster, and a piece of adhesive plaster run from one thigh to the other acts as a shelf for the testicles to rest upon. The adhesive plaster is overlaid with dry gauze, and this is covered with absorbent cotton and the dressing is retained in place by a firm spica of the groin (*Coley's dressing*). The wound is dressed on the seventh or eighth day, the stitches are removed, the patient is kept in bed for about two weeks longer and is allowed to get about in two and one-half to three weeks, wearing a bandage until four weeks after operation.

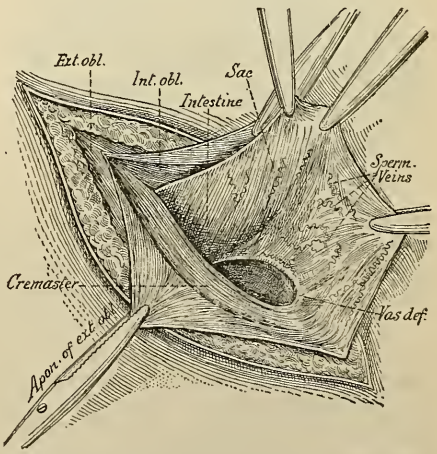

FIG. 823.—Exposure of the sac, the vas, and the spermatic veins (Halsted).

In Bassini's operation some surgeons treat the sac as in Macewen's operation, carrying out the rest of the procedure as directed above. In a pure Bassini operation the funnel-shaped depression in the peritoneum at the point of emergence of the cord may remain and predispose to hernia, but the use of Macewen's plan for treating the sac obviates this.

The Halsted Operation.—A description of the original Halsted operation is found in "Johns Hopkins Hosp. Reports," vol. vii. The operation at present performed by Professor Halsted and his assistants has been evolved from the former operation so long associated with his name, and has been greatly modified by him and by Dr. Bloodgood. In this operation the skin and the aponeurosis of the external oblique are incised exactly as in performing Bassini's operation, and flaps of aponeurosis are raised. Next, the cremaster muscle and the cremaster fascia are incised in a line slightly above the center of the spermatic cord. The internal oblique muscle is then brought into distinct view at the side of the inguinal canal and the hernia is carefully inspected (Fig. 823). If the veins are found to be large they should be excised; but the surgeon does not lift the vas from its bed, and even avoids touching it, if he possibly can, for fear that thrombosis may occur in its veins. The veins are tied above, well up in the abdomen; and below, well above the testicle, and excised between the ligatures. The sac is then ligated or sutured with a purse-string suture. One end of the thread that ties or sutures the sac is carried, by means of a long, curved needle, in an outward direction under the internal oblique muscle,

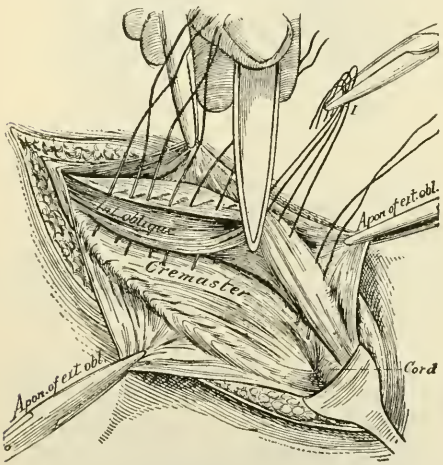

Fig. 824.—Suture of the cremaster to the internal oblique (Halsted).

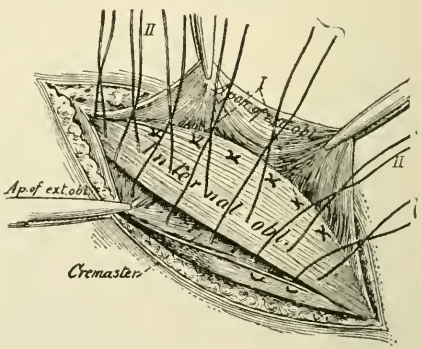

Fig. 825.—Suture of the lower edge of the internal oblique to Poupart's ligament (Halsted).

through which it is then pulled. The other end of the thread is also pulled through the muscle ½ inch from the first end, and these two ends are tied together. It will be observed that this treatment of the neck of the sac is somewhat similar to the method practised by Kocher.

The next step is to carry the inferior flap, composed of cremaster muscle and fascia, under the internal oblique muscle, and suture it there (Fig. 824). We next suture the internal oblique muscle and the conjoined tendon to Poupart's ligament, the lower edge of the internal oblique being tucked under the edge of the ligament (Fig. 825). In order to accomplish this, it may be necessary to release the muscle by incising the anterior rectal sheath. The incision in the external oblique is now closed with sutures that overlap the margins (Figs. 826 and 827), and the skin wound is also closed.

Halsted's Operation Plus Bloodgood's Method of Transplanting the Rectus Muscle.—(See Jos. C. Bloodgood, in "Johns Hopkins Hosp. Reports," vol. vii.) When the conjoined tendon is very thin or obliterated, the ordinary operation is not enough. Insufficiency of the conjoined tendon is known to exist when a finger does not meet any obstruction after passing through the external abdominal ring, but can be introduced for some distance into the

abdominal cavity (Bloodgood). To meet this condition of affairs, Bloodgood devised "a plastic operation on the rectus muscle, bringing this muscle down and suturing it with the other available tissue to Poupart's ligament and to

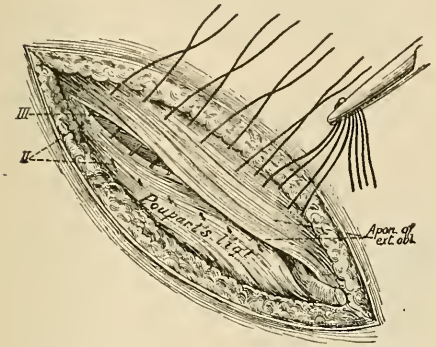

FIG. 826.—Suture of the aponeurosis of the external oblique (Halsted).

FIG. 827.—Suture of the margin of aponeurosis to Poupart's ligament (Halsted).

the aponeurosis of the external oblique from the arch of the pubis up to the position of the transplanted cord" (Bloodgood, in previously mentioned report). The first steps of the operation are identical with those previously

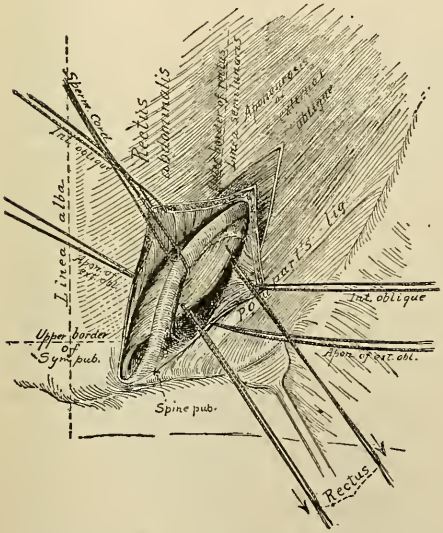

FIG. 828.—The method of transplanting the rectus muscle. The sac has been excised and the peritoneal cavity closed; internal oblique muscle has been divided, the rectus exposed and transplanted; at this stage the wound is ready for the deep sutures. This illustration shows how perfectly the transplanted rectus muscle lines the lower half of the wound (Bloodgood).

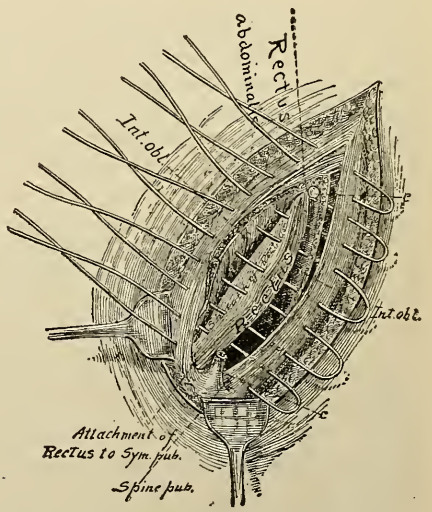

FIG. 829.—The transplanted rectus included by the deep sutures. In this illustration the cord has been excised in order to demonstrate the operation more clearly (Bloodgood).

described, but before the insertion of the deep stitches the rectus sheath is exposed and divided in the direction of the muscle-fibers, from the pubic insertion upward for 5 cm. The muscle bulges from the cut and is caught with

silk sutures (Fig. 828). Deep sutures are now introduced as in Halsted's operation, except that they include the rectus and its sheath (Fig. 829). The operation is completed as is Halsted's. I have performed this operation a number of times with entire satisfaction.

Kocher's Operation.—Kocher exposes the aponeurosis of the external oblique, makes a small incision through the aponeurosis above and external to the internal ring, and draws the sac through this incision and sutures it in place.

Fowler's operation is as follows: An incision is made parallel with Poupart's ligament from the spine of the pubis to the level of the internal ring, and a flap is turned up. The inguinal canal is opened and the sac and cord are isolated. The sac is opened, its contents reduced, it is cut off, and its edges grasped with forceps. The deep epigastric artery and vein are sought for, each is tied in two places and divided between the ligatures. The index-finger is introduced into the belly, and on this as a guide the floor of the canal is divided (transversalis fascia, subserous tissue, and peritoneum). The cord is placed in the peritoneal cavity. The edges of the opening are sutured so that broad serous surfaces are approximated, through-and-through sutures being passed from side to side. The cord is brought out at the inner end of the incision, the lower angle of the cut being at such a level that the cord curves upward and forward as it leaves the abdomen. The inguinal canal, the gap in the aponeurosis, and the skin wound are closed.[1]

Ferguson's Operation.—In studying a number of recurrences after operation A. H. Ferguson observed that a hernial protrusion is apt to return at the upper and outer portion of the scar, above the cord and near Poupart's ligament. When he operated upon relapsed cases, he discovered a slit of the aponeurosis of the external abdominal wall, through which the sac and some fat protruded. In order to determine the cause of the failure of these operations, he thought it proper to make a semilunar incision and raise a flap of skin, fascia, and aponeurosis of the external oblique. On doing this, he was surprised to find an angle between the lower border of the internal oblique muscle and the inner aspect of Poupart's ligament absolutely unprotected by the internal oblique or the transversalis muscle. In some cases this angle extended upward and outward to the anterior superior iliac spine. He, therefore, concluded positively that the cause of a rupture returning in this angle after an operation for radical cure is deficient origin of the internal oblique muscle and of the transversalis muscle at Poupart's ligament. He is now persuaded that in all cases of hernia there is a deficient origin of these muscles, and he has demonstrated the same thing in a series of dissections in the inguinal region. Ferguson describes his operation as follows ("Jour. Am. Med. Assoc.," July 1, 1899): He begins his incision over Poupart's ligament, 1½ inches below the anterior superior iliac spine, carries it inward and downward in a semilunar curve, and terminates it over the conjoined tendon, near the pubic bone. The incision goes down to the aponeurosis of the external oblique, and the flap, with its fat and fascia, is turned downward and outward (Figs. 830 and 831). The next step is to incise the external abdominal ring to the intercolumnar fascia and separate the longitudinal fibers of the external oblique over the inguinal canal to beyond the internal ring, at a point nearly opposite the anterior superior spine of the ilium. Any transverse fibers that may be encountered are severed. The separated aponeurosis of the external oblique muscle is then retracted. One has then brought into view the contents of the inguinal canal, the hernial sac and its adhesions, the spermatic cord, the ilio-inguinal nerve, the internal abdominal ring, the subserous fat, the cremaster muscle, the conjoined tendon, the internal oblique and its deficient origin at Poupart's ligament, the transversalis fascia, and the internal surface of Poupart's ligament. The sac is now dissected from

[1] "Annals of Surgery," Nov., 1897.

the cord and the internal ring. It is opened and its contents are inspected and properly dealt with. It is tied high up and cut off, and the stump is dropped into the abdomen (Fig. 832). If the sac be congenital it is divided into two parts: the distal portion is used to make a tunic for the testicle and the proximal portion is treated as above directed. The cord is not disturbed, and it is be-

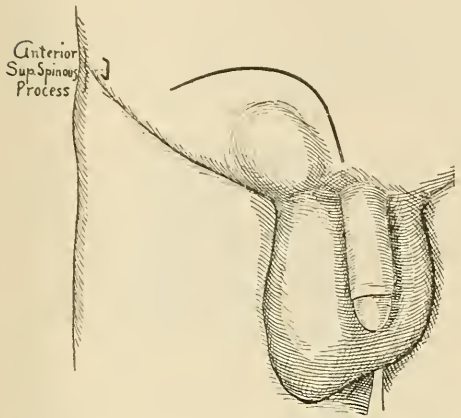

FIG. 830.—Ferguson's operation: The semilunar skin incision ("Jour. Am. Med. Assoc.").

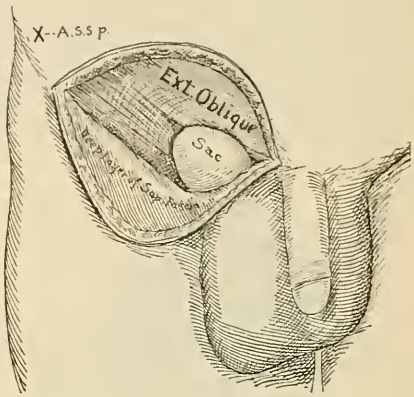

FIG. 831.—Ferguson's operation: Flap turned back exposing the aponeurosis and the sac of the hernia ("Jour. Am. Med. Assoc.").

yond doubt that Ferguson is right in saying that the testicle frequently comes to harm after operations that disturb the cord. The veins in the cord should not be touched unless a varicocele also exists. Any excessive quantity of subserous adipose tissue should be removed. The next step in the operation is to restore the structures to their normal position; and one should remember that

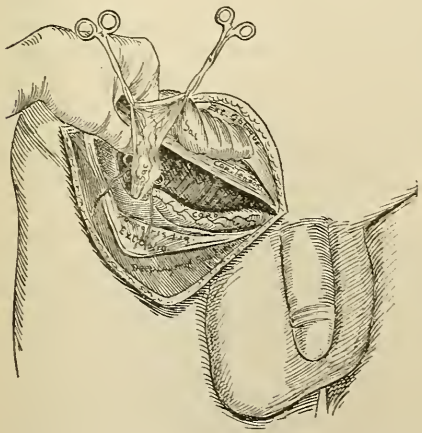

FIG. 832.—Ferguson's operation: Dealing with the sac and its contents ("Jour. Am. Med. Assoc.").

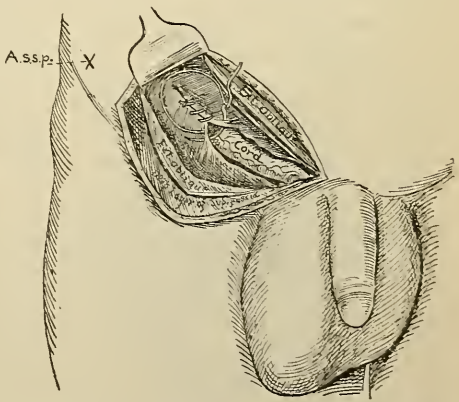

FIG. 833.—Ferguson's operation: Suture of the slack in the transversalis fascia ("Jour. Am. Med. Assoc."

in the transversalis fascia is the internal ring. In hernia the internal ring is large and the transversalis fascia bulges outward; one must, therefore, take up the slack in this fascia and make a well-fitting ring for the cord by means of a catgut suture, either interrupted or continuous (Fig. 833). After this has been accomplished the internal oblique and transversalis muscles are sutured to the

internal aspect of Poupart's ligament, after the lower borders of the muscles have been freshened and Poupart's ligament has been scarified. The sutures must be carried two-thirds of the way down Poupart's ligament, which is about the normal origin of this muscle in the female (Fig. 834). The next step is to suture the edges of the divided aponeurosis of the external oblique; this restores the external abdominal ring. The skin-flap is then carefully sutured.

Radical Cure of Direct Inguinal Hernia.—If the hernia goes through the conjoined tendon or pushes that structure before it, the operation should consist in transplanting the rectus muscle as practised by Bloodgood (see page 1283) and suturing the arched fibers of the internal oblique and conjoined tendon to Poupart's ligament and beneath the cord.

If the hernia passes around the outer edge of the conjoined tendon an overlapping operation, like the Mayo operation for umbilical hernia, should be performed (G. G. Davis, in "Annals of Surgery," Jan., 1906).

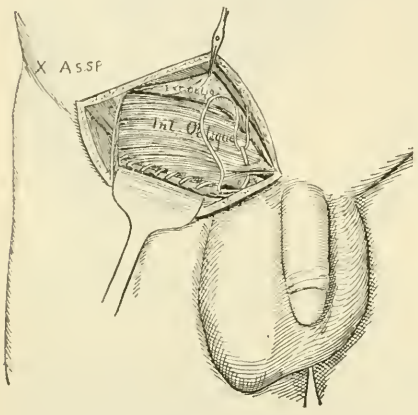

FIG. 834.—Ferguson's operation: Suture of the internal oblique and of the transversalis muscles to the internal aspect of Poupart's ligament ("Jour. Am. Med. Assoc.").

Radical Cure of Umbilical Hernia.—The results of operations for umbilical herniæ have not been satisfactory. Recurrences are frequent. This is probably due to the fact that most of the subjects are fat, and that the muscles are thin and flabby. The usual operation may be thus described: Make a longitudinally elliptical incision through the skin around the mass. Endeavor to separate the sac from the superficial tissue. If this cannot be done, open the sac and separate it from the contents. Even if the sac can be stripped from the skin, always open it and separate the contents. Return any bowel which may be present, and do not forget that there may be a small portion of bowel completely encased in omentum. Tie into segments and cut off the superfluous omentum and return the stump into the belly. Excise the umbilicus (*omphalectomy*). Suture the peritoneum with a continuous catgut suture. Close the musculofascial wall with two layers of interrupted sutures of kangaroo-tendon or chromic catgut, or one layer of silver wire mattress sutures. Close the skin by interrupted sutures of silkworm-gut or by a subcuticular stitch.

Mayo's Operation.—This is a vast improvement on the older operation. It gives a firm cicatrix free from disastrous traction. Mayo believes that the defect in the old operation is that the recti muscles are naturally separated at the level of the umbilicus, and in bringing the recti together we have virtually performed muscle transplantation, and these thin muscles are of no great value in preventing relapse, and in a large hernia it is not even possible to cover the gap by muscle. Mayo now operates as follows: Transverse elliptical incisions are made around the umbilicus and hernia and the base of the protrusion is exposed (Fig. 835). The surface of the aponeurosis is cleared for 1½ inches around the neck of the sac. The fibrous and peritoneal coverings of the hernia are divided by a circular incision around the neck of the sac. Intestine is freed from adhesions and placed within the abdomen. Omentum is ligated and removed with the sac. The margins of the ring are grasped and overlapped in order to indicate in which direction closure can be most easily effected. An incision is made through the fibrous and peritoneal coverings of the ring 1 inch or more transversely on each side, and the

peritoneum is stripped from the under surface of the upper flap. Several mattress sutures of silver wire are introduced 1 inch above the edge of the upper flap and are carried through the margin of the lower flap; sufficient traction is made to permit of the closing of the peritoneum with a continuous catgut suture (Fig. 836). When this has been accomplished, the silver wire sutures are drawn so as to slide the lower flap into the pocket between the peritoneum and the under surface of the upper flap (Fig. 837). The free margin of the upper flap is

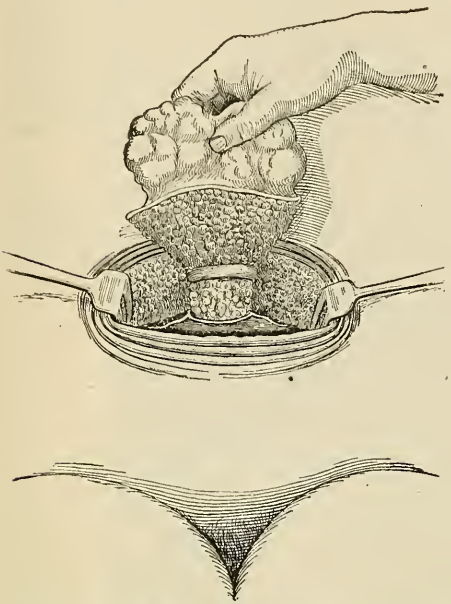

FIG. 835.—Mayo's operation for the radical cure of umbilical hernia: Exposure of hernia and lateral incision.

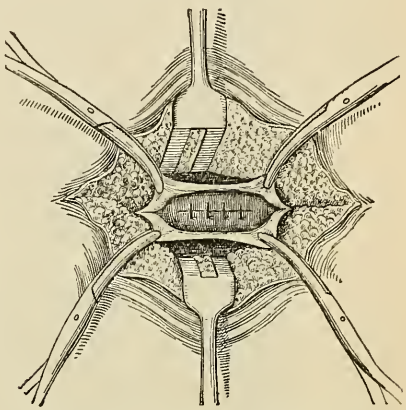

FIG. 836.—Mayo's operation for the radical cure of umbilical hernia: Peritoneum sutured.

fixed by catgut sutures to the aponeurosis (Fig. 838), and the superficial incision is closed as usual. Wm. J. Mayo ("Jour. Am. Med. Assoc.," June 1, 1907) reported upon 88 operations for umbilical hernia by this method between 1894

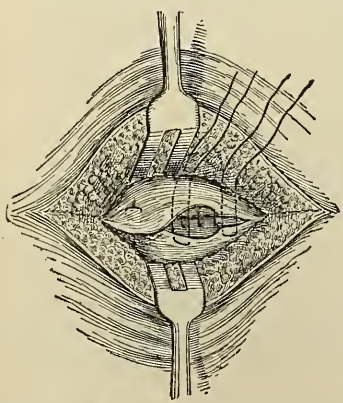

FIG. 837.—Mayo's operation for the radical cure of umbilical hernia: Aponeurosis sutured.

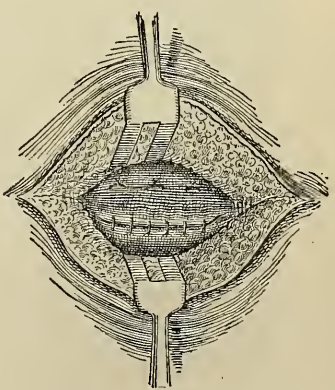

FIG. 838.—Mayo's operation for the radical cure of umbilical hernia: Aponeurosis sutured second time with gut sutures.

and 1905; 75 were traced; 1 had a partial relapse; 1 was supposed to have a relapse, but operation disclosed a second opening above and outside of the closed umbilical opening.

Radical Cure of Femoral Hernia.—It is a mistake to suppose that relapses are less common than after operations for inguinal hernia. They are more common in an adult. Cheyne ligates the neck of the sac, stitches the stump to the abdominal wall, dissects out a flap from the pectineus muscle, stitches this flap to Poupart's ligament and to the abdominal wall, and thus fills up the crural canal. Bassini makes an incision parallel to Poupart's ligament, ties the neck of the sac, cuts off the sac below the ligature, and returns the stump into the belly. He attaches by deep sutures Poupart's ligament to the pectineal aponeurosis as high up as the pectineal eminence, the cord or round ligament being drawn out of the way. Superficial sutures are passed between the pubic portion and the iliac portion of the fascia lata.

The *operation of Fabricius* is performed as follows: An incision is begun over the pubic spine and is carried outward for 5 inches parallel with Poupart's ligament. The sac is exposed, isolated, and opened, its contents are reduced, its neck is ligated, the sac is cut off, and the stump is dropped back (Fig. 839).

Fig. 839—Fabricius's operation for the radical cure of femoral hernia: Neck of sac shown. Sac cut away. Dotted line shows line of separation of Poupart's ligament and fascia lata (Fowler).

An incision is now made below Poupart's ligament so as to separate this structure and the fascia lata, and the flap of fascia is turned down (Fig. 840). The crural sheath and the vessels are retracted outward. The surgeon is careful not to injure the obturator artery and vein. The origin of the pectineus muscle is sutured to Poupart's ligament. The lower stitches include the periosteum of the horizontal ramus of the pubes as well as the beginning of the muscle (Fig. 841). Care must be taken in passing certain of them to avoid injuring the deep epigastric vessels. When these stitches are tied, the femoral canal is obliterated. The flap of fascia lata is sutured to the aponeurosis of the external oblique, and the skin is sutured.

The best operation is that of *Moschcowitz* by the inguinal route. It gives a thorough exposure of the parts and enables the surgeon absolutely to close the femoral ring. The incision is like that for inguinal hernia except that it more nearly reaches the pubic region. The aponeurosis of the external oblique is divided. The internal oblique and transversalis are retracted upward. The lower flap of the external oblique is retracted downward. The round ligament or cord is held aside. The transversalis fascia is divided and the peritoneum

is opened. The bowel or omentum is withdrawn from the sac. The sac is seldom adherent to the thigh tissue and can usually be pulled up with its contents;

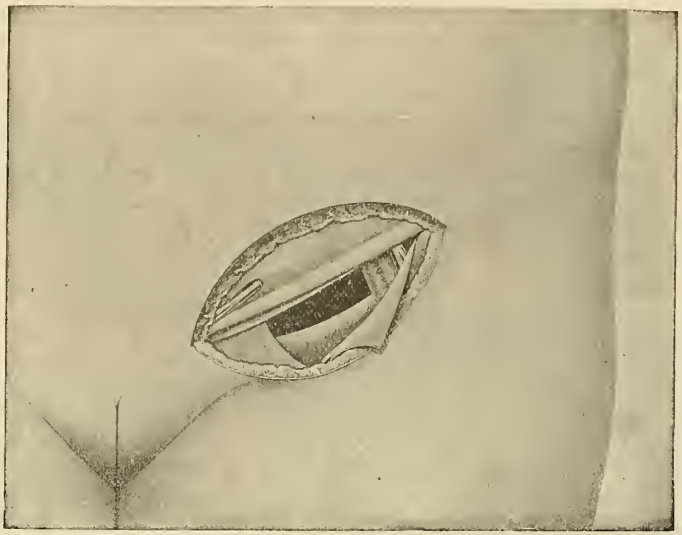

Fig. 840.—Fabricius's operation for femoral hernia: Fascia lata turned back, exposing crural sheath and origin of pectineus muscle (Fowler).

so that adhesions between sac and contents can be separated. If the sac is adherent in the thigh the incision is extended on to the thigh and the sac dis-

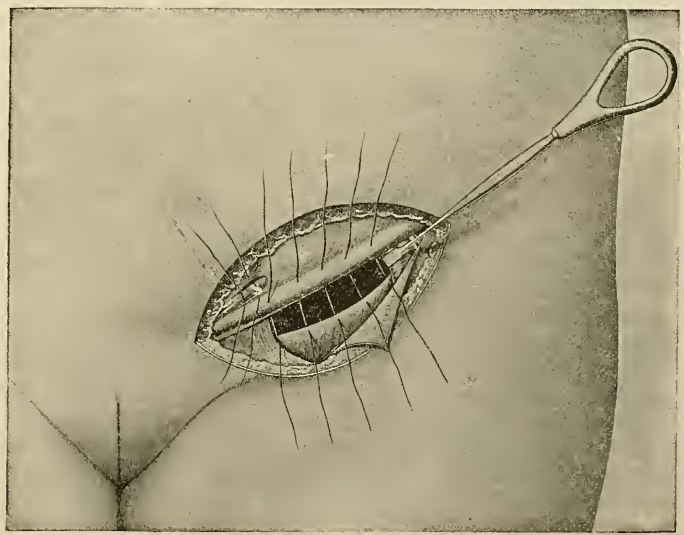

Fig. 841—Fabricius's operation for femoral hernia: Crural sheath and vessels retracted and kangaroo-tendon sutures applied to Poupart's ligament and origin of pectineus, ready for tying. Two sutures are placed in position to approximate the pillars of the external ring (Fowler).

sected loose. The sac is tied off. The femoral canal is closed by suturing Cooper's ligament (which covers the pectineal line) to Poupart's ligament. The most internal suture catches Gimbernat's ligament. The rest of the wound

is then closed (the above description is abbreviated from the admirable article by Seelig and Tuholske, in "Surgery, Gynecology, and Obstetrics," Jan., 1914).

Operative Treatment of Adherent (Sliding) Hernia of the Ascending and Descending Colon.—My personal experience consists of 8 cases of right and 2 cases of left inguinal hernia. The sac is deficient posteriorly and externally (see page 1300). In order to restore the bowel into the abdomen many operators have sought to force up the adherent intestine to the external ring, and others have stripped the gut from the subperitoneal tissues in order to permit of reduction. The first plan should never be followed. If it should be employed, sutures will fail to hold the bowel up. The second plan is risky and may be followed by gangrene of the bowel. In my cases I followed Weir's plan ("Med. Record," Feb. 24, 1900), and, after dissecting up the peritoneum on each side to a little above the internal ring, freed the bowel from its bed and covered the new surface with the peritoneal flaps (Fig. 842). The bowel was then restored and a radical cure was performed.

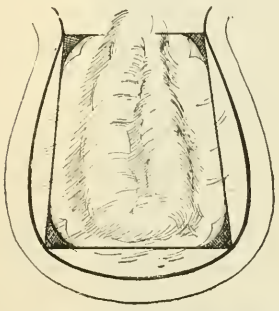

FIG. 842.—Outline of peritoneal lining of sac utilized as a flap to cover posterior surface after it has been freed by dissection (Weir).

Epiploitis Following a Hernia Operation.—This is a postoperative inflammation of the omentum due to ligation of that structure. The condition was pointed out by Lucas-Championnière in 1892 (William Hessert, in Surgery, Gynecology, and Obstetrics, Sept., 1916). In acute cases signs of peritonitis arise a few days after operation and suppurative peritonitis ensues. Such cases are due to replacement of an infected stump. In most cases trouble does not begin until four weeks or more after operation, when pain begins and is accentuated by motion or pressure. Such cases may recover but usually terminate in abscess. In another group the symptoms come on insidiously and late, a palpable mass develops and cancer is suspected. In such cases there has been an inflammatory growth from the ligated stump and in most of them the stump has been tied with silk (see Hessert's illuminating paper, Ibid.).

Irreducible Hernia.—The swelling in irreducible rupture presents the usual evidences of hernia, imparts an impulse on coughing, but cannot be replaced in the abdomen. Sometimes a portion is reducible and a portion is irreducible. A hernia may become irreducible because of the size of the mass, because of adhesions, or because of excessive growth of omental fat. An irreducible hernia is liable to be bruised and to cause much distress and pain, and is always a menace to life because of the danger of obstruction and strangulation. It was formerly the custom to support a small irreducible hernia by a hollow, padded truss, but now operation should be advised. A large hernia of this variety, if operation be refused, must be carried in a bag truss. The patient must not take very active exercise, must keep the bowels regular, and must live upon a plain diet. Most cases of irreducible hernia should be treated by operation.

Incarcerated or Obstructed Hernia.—Obstruction takes place by the damming up of feces or of undigested food, the fecal current being arrested, but the blood-current in the wall of the bowel not being cut off. Incarceration is commonest in irreducible hernia, especially umbilical hernia, and during the existence of constipation. The hernia enlarges and becomes tender, painful, and dull on percussion; pressure may diminish it somewhat in size. It remains irreducible, but still presents impulse on coughing. The abdomen is somewhat distended and painful; there are nausea, constipation, and not unusually slight

vomiting. Constitutional disturbance is trivial and constipation is not absolute, gas at least usually passing. Vomiting is not fecal.

The *treatment* is rest in bed in a position to relax the belly, an ice-bag over the hernia for a very few hours, and a little opium for pain. Do not give a particle of food for twenty-four hours; when the active symptoms subside give an enema, and, after this acts, a dose of castor oil. Do not employ taxis, as bruising the bowel may produce strangulation. If improvement does not rapidly occur, operate. Prompt operation saves the patient from the danger of strangulation and cures the hernia.

Inflamed Hernia.—Inflammation of a hernia is local peritonitis due to injury of an irreducible hernia. The mass becomes tender and painful, and perhaps heat is noted. In enterocele much fluid forms; in epiplocele the mass becomes hard. The hernia cannot be reduced; there is constipation, often vomiting, usually elevated temperature, but the mass still shows impulse on coughing. Vomiting is not fecal. Some gas is usually passed through the bowels. Constitutional symptoms are slight.

The *treatment* usually recommended is rest in bed with abdominal relaxation, an ice-bag to the tumor for a few hours, a small amount of opium by the mouth if pain be severe, an enema, and, after this acts, a saline. In an inflamed hernia there is great danger of strangulation, and operation should be performed in preference to relying upon the conservative plan.

Fig. 843.—Strangulated umbilical hernia containing nearly all the intestines and part of stomach. Strangulation under bands within the sac.

Strangulated hernia is a condition in which, if the hernia contains bowel, not only is the fecal circulation arrested and gas prevented from passing, but the circulation of blood in the bowel wall is also arrested. The bowel is irreducible and obstructed, and the blood ceases to circulate. If the hernia contains omentum, the omental vessels are tightly constricted. In both bowel and omentum gangrene soon occurs, but sooner in bowel than in omentum. Strangulation is commonest in old inguinal ruptures in active, middle-aged men, and is more frequent in enteroceles than in epiploceles. It is most common when the hernial orifice is small and is seldom seen in large ruptures.[1] Strangulation is rare in childhood. Strangulation is much more dangerous when bowel is present in the sac than when omentum only is present. If in a subject of hernia the abdominal pressure is suddenly increased, as by a violent cough or a muscular effort, the hernial orifice is dilated for a moment, more intestine or omentum may enter the sac, and if it does, it may be caught and constricted by the now constricted hernial orifice and strangulation begins. Strangulation so caused is called *elastic strangulation.* A sudden increase of intra-abdominal pressure may force a quantity of fecal matter into the herniated intestine. The sudden entry of a quantity of fluid and gas into the herniated coil causes *fecal strangulation,* the mechanism of which is obscure. By *retrograde strangulation*

[1] Strangulation developed in the large herniæ shown in Figs. 816 and 843.

we mean a condition in which the end of a loop of bowel or a piece of omentum in a hernia re-enters the abdomen and then becomes strangulated, the balance of the hernia not being strangulated. Strangulation may be due to active peristalsis or to congestion, and it may arise from inflammation or from incarceration. The constriction may be at the neck of the sac, in the outside tissues, or even in the sac itself. In an hour-glass hernia the constriction may be in the body of the sac. In inguinal hernia a tight external ring is a common cause of strangulation and is the commonest cause in children. As Coley shows, the neck of the sac is very seldom the cause in children. Adhesions within the sac may cause strangulation. Spasmodic contraction of the tissues about the neck of the sac is an exploded hypothesis. The obstructed veins dilate and the blood in them ceases to move, the bowel becomes deep bluish and finally black, effusions of blood occur beneath the peritoneum, and the intestinal wall becomes edematous. Fluid transudes into the sac, and the fluid, at first clear, assumes a bloody hue, and finally becomes foul. The peritoneum ceases to glisten, becomes dry and rough, and coated here and there with lymph. Strangulated omentum undergoes edema and hemorrhagic infarction and thrombosis occur. When strangulation once begins the hernia swells, a furrow forms on the bowel at the seat of constriction, the bowel and omentum below the constriction become deeply congested and edematous, and, finally, the hernia passes into a state of moist gangrene (Fig. 844). The gangrene may be in spots or the entire mass may be gangrenous. The mucous membrane may be gangrenous when the serous coat looks fairly sound. When gangrene is once established, the bowel is in danger of rupturing. At the point of constriction there may be a line of ulceration or of gangrene even when the balance of the gut looks fairly safe. A strangulated femoral hernia becomes gangrenous more rapidly than a strangulated inguinal hernia.

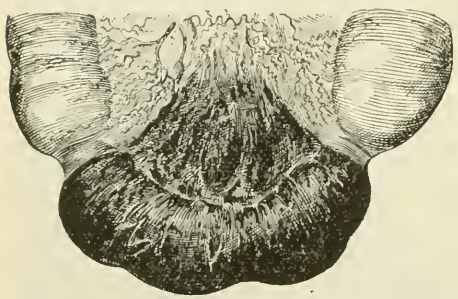

Fig. 844.—A strangulated coil of intestine after the strangulation existed for a considerable period of time. The color has become almost black and the peritoneal surface is dull and covered with flakes of fibrin. The constriction rings are deeply sunken, their walls markedly thinned, relaxed, and dirty gray in color. Both constriction rings are gangrenous and hemorrhages are observed in the mesentery (Sultan).

Symptoms.—This condition is sometimes preceded by diarrhea and uneasiness or pain about the hernial orifice. When strangulation begins the victim is seized with pain in and about the hernia and with violent colicky pain about the umbilicus, and the paroxysms of colic become more and more frequent, until finally the pain may become continuous. The hernia is found to be irreducible; larger than usual, tender, painful, dull on percussion, without impulse on coughing, and the skin above it may be reddened. Eructations of gas are frequent, and generally uncontrollable vomiting and prostration come on. Vomiting, as a rule, is an early symptom, and one which increases in severity. Occasionally it only follows the swallowing of liquids. Not unusually there is retching rather than vomiting. In rare cases vomiting does not begin for twenty-four to forty-eight hours. Vomiting is earlier and more violent when bowel is present in the sac than when the hernia is purely omental. During the course of a strangulation, vomiting may cease for a day or more; and it not unusually ceases toward the end, when prostration is profound. The early vomiting is due to reflex causes; the later vomiting is due to waves of peristalsis which produce regurgitation (Macready's "Treatise on Ruptures"). The

vomiting is first of the alimentary contents of the stomach, next of mucus and bilious matter, and finally of the contents of the small bowel (*fecal* or *stercoraceous vomiting*). Stercoraceous vomiting rarely arises until strangulation has lasted forty-eight hours, and may not appear until much later. "It is seldom met with in inguinal, more often in femoral, and more often still in obturator, hernia" (Macready, Ibid.). Prostration is a marked symptom of a strangulated hernia, and it increases hour by hour and goes on to collapse. Early in the case there may be some elevation of temperature, but later it becomes normal or subnormal. The pulse is small, irregular, rapid, and very weak; the extremities cold; the face becomes Hippocratic. Constipation is absolute, no gas even being passed, though in the very beginning there may be some diarrheal passages from below the constriction. The urine is scanty and high colored, and contains only a small amount of the chlorids; the tongue becomes dry and brown; the thirst is torturing, and the patient often has an imperative desire to go to stool. Pains in the abdomen and in the hernia become more and more violent, and collapse rapidly increases. When gangrene begins the symptoms apparently lessen in violence; there is a *delusive calm*. Vomiting usually ceases, though regurgitation may take its place; hiccup begins; the pain abates or disappears; the pulse becomes very frequent, feeble, and intermittent; collapse deepens, and delirium is usual. It is a safe clinical rule that in strangulated hernia sudden cessation of pain without the relief of constriction, the disappearance of the lump, or the use of opiates means that gangrene has begun. In some cases of strangulation there are muscular cramps in the legs (Berger). In children convulsions are not unusual. In a pure omental hernia strangulation produces similar but less decided symptoms. It may be that only a portion of the circumference of the bowel is caught and constricted in a hernial orifice (see Fig. 851, A). Such a condition is encountered occasionally in the femoral ring, and is called *partial enterocele* or *Richter's hernia*. The name *Littrê's hernia* is often wrongly given to this condition. What Littré described was a hernia of Meckel's diverticulum (see Fig. 851, B). In a strangulated Richter's hernia constipation is rarely absolute and often no protrusion is discovered.

Treatment.—In treating strangulated hernia place the patient upon his back, bend the knees over a pillow, and rigidly interdict the administration of food. An attempt may usually be made to effect reduction by gentle manipulation or *taxis*. In applying taxis to a femoral or inguinal hernia, flex and adduct the thigh of the affected side. In applying taxis to an umbilical hernia both thighs should be flexed upon the abdomen. Always lower the shoulders and head and raise the pelvis, and accomplish this by lifting the foot of the bed and placing pillows under the pelvis. In some cases raise the entire body and lower the head. Grasp the neck of the sac with the fingers and thumb of one hand, and employ the other hand to squeeze the hernia and urge it toward the belly. In direct inguinal hernia the pressure should be backward and a little upward; in umbilical hernia it should be backward; in oblique inguinal hernia it should be upward, outward, and backward; in femoral hernia it should be downward until the hernia enters the saphenous opening, and then "backward toward the pubic spine" (MacCormac, in Treves's "Manual of Surgery"). If the bowel should be reduced, it will pass from the hand with a sudden slip and enter the belly with an audible gurgle; omentum, when reduced, slowly glides back without gurgling. Taxis is never to be continued long, and it is not even to be attempted in cases of great acuteness, in cases in which strangulation has lasted for several days, in cases known to have been previously irreducible, in cases associated with stercoraceous vomiting, or in inflamed or gangrenous herniæ.

If taxis fails, obtain the patient's permission to operate. Anesthetize; in some cases try taxis again upon the unconscious patient and while ether is

being dropped upon the hernia to make it cold; if reduction fails, at once perform herniotomy. Taxis possesses certain dangers: It may rupture the bowel; it may rupture the neck of the sac and force the bowel through the rent into the tissues of the abdominal wall; it may strip the peritoneum from around the hernial orifice and force the bowel between the detached peritoneum and the abdominal wall; it may reduce a hernia into the belly when the bowel is still strangulated by adhesions; it may reduce the hernia *en masse* or *en bloc*. By the term "reduction *en masse*" we mean that the sac has been separated and dislocated and with the constricted bowel within it has been forced through the internal ring. By "reduction *en bissac*" is meant the forcing of a congenital hernia into a congenital pouch or diverticulum. Reduction *en masse* is a rare accident. Corner and Howitt ("Annals of Surgery," vol. xlvii) collected 137 cases of reduction *en masse* of strangulated hernia. Of these, 110 were males, 113 were inguinal, 22 femoral, and 2 obturator herniæ. No ventral or umbilical cases are recorded. The accident is a very dangerous one. According to Corner and Howitt (Ibid.), the mortality after inguinal reductions *en masse* is 48 per cent., and after femoral reductions, 72 per cent. Strange to say, reduction *en masse* can occur spontaneously. The subject most liable to reduction *en masse* is an elderly person with an old hernia. In acute cases the small bowel is the viscus which has been reduced. In subacute and chronic reductions *en masse* the omentum, large bowel, or bladder has been reduced (Corner and Howitt, Ibid.). Subacute and chronic

Fig. 845.—Cooper's curved herniotome.

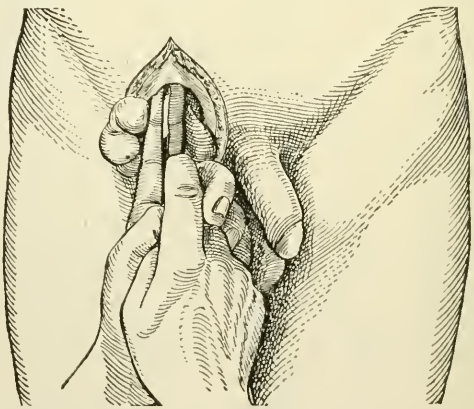

Fig. 846.—The division of the constriction from within outward (Sultan).

cases may happen in non-strangulated hernia. In any of the above accidents obstruction may persist after apparent reduction by taxis. Persisting obstruction means strangulation or peritonitis and calls for instant laparotomy—in most instances through the hernial aperture. If taxis is successful, put the patient to bed, apply a pad and bandage, allow no food until vomiting ceases, merely permit him to take a little hot water during the first twenty-four hours, and keep him on a liquid diet for several days. At the end of the first week give solid food. Do not disturb the bowels for a few days, but if they have not acted when four or five days have elapsed since the operation, give a saline cathartic followed in a few hours by a purgative enema. There is usually a spontaneous movement within twenty-four hours after reduction by taxis.

Herniotomy.—If there has been stercoraceous vomiting the stomach must be washed out before giving the anesthetic, and during the administration of

the anesthetic the head should be turned upon its side. In most cases a general anesthetic can be given, but in desperate cases it is not justifiable to give ether or chloroform, and a local anesthetic must be used (infiltration anesthesia). Wrap the patient up in blankets. In most cases try gentle taxis for a brief time after the patient has been anesthetized and while ether is being dropped upon the hernia to make it cold. Never try taxis if stercoraceous vomiting has occurred. If taxis fails, at once sterilize the parts and operate. Always lay out a hernia knife (Fig. 845), a director (see Fig. 818, A), and Murphy buttons. During the *operation* the patient lies upon his back with the shoulders raised, the surgeon standing to the patient's right side. In *oblique inguinal hernia* it has been the custom since the days of Scultetus to raise a fold of skin at a right angle to the axis of the external ring and transfix it, the wound which results being extended until it becomes 3 inches in length. This incision possesses no special merit. It is better to cut from without inward, and to make the same incision as for the performance of a radical cure in a non-strangulated case. The superficial tissues are divided, the aponeurosis is opened as in Bassini's operation, and the sac is reached. In most cases the constriction is relieved as soon as the external ring is nicked, and in many cases fibrous adhesions will be found in that region, gluing the sac to the ring. The sac must be identified; and it is known by the fat which usually covers it, by the fluid within the sac, by the arborescent arrangement of its vessels, and by the fact that it can be pinched up between the finger and thumb and the layers rolled over each other. Should the sac be opened? It may not be actually necessary in every recent case, but if there is any doubt as to the condition of the bowel or if a radical cure is to be attempted, open the sac and be certain as to the condition of its contents. As there is always some doubt as to the condition of the contents, and as a radical cure is to be made, make it a rule always to open the sac. The sac is opened and the contents examined for fecal odor (which is not unusual) and for gangrenous smell; the thickness of the bowel is estimated and the color and luster are determined. If a constriction exists at the neck, it is nicked with a hernia knife. If the hernia is oblique inguinal and is caught at the internal ring, nick the constriction upward and outward or directly upward, as shown in Fig. 846. In direct inguinal hernia and in an oblique inguinal hernia caught at the external ring the cut is made upward and inward. Always pull the bowel down and examine the seat of constriction to see what damage has been inflicted at that point. If the serous coat glistens; if the proper color comes back to the bowel wall after irrigation with very hot water; and if there are no spots of gangrene, restore the bowel to the abdomen and do a radical cure. If the bowel is in a doubtful condition, fasten it to the incision, apply a dressing, and watch the development of events. If the bowel is gangrenous, our action depends upon the condition of the patient. If the patient is in good condition, resect the gangrenous portion and perform end-to-end approximation. If the patient's condition is bad, draw the gangrenous portion well out, anchor it to prevent leakage and retraction, make an artificial anus, and at a later period perform anastomosis. An artificial anus can be made by the method of Bodine (see page 1262). Unfortunately in these cases the artificial anus must usually be made in the small intestine. In many cases in which there is some uncertainty as to the need for an artificial anus prepare the bowel for the opening, but do not open at once, because the bowel may recover in a day or two, when it can be restored to the belly, or it may slough and form an artificial anus. In such doubtful cases fasten the bowel to the belly wall with sutures, dust it with iodoform, dress it with hot antiseptic fomentations, and await future developments. Gangrenous omentum requires ligation and resection. If the bowel is fit to reduce, push it just inside the ring, irrigate the parts, suture, and perform a radical cure. In *femoral hernia* we can make the incision 1 inch internal to and parallel with the femoral vessels and crossing the tumor and ligament (Barker);

but it is better to make the incision of Fabricius for radical cure. Divide the constriction by cutting upward and a little inward. If the gut is found gangrenous or in a doubtful condition, follow Blake's advice ("Surg., Gynec., and Obstet.," May, 1906), make an incision at the edge of the rectus, draw the affected portion of gut into the abdomen and out of the incision, and either resect, fix it under or out of the incision, or wait for return of circulation, as may be indicated in the case. To draw the gut out of the femoral ring makes so much traction that return of circulation may be prevented, and any intestinal operation is difficult in this region without splitting Poupart's ligament. I greatly prefer the inguinal incision of Moschcowitz to any crural incision. It gives free exposure, makes treatment of bowel and sac easier and safer, and enables us to see Gimbernat's ligament and recognize an anomalous obturator artery if one exists. It is a perilous thing to divide the constricting Gimbernat's ligament by touch alone. An anomalous obturator artery has been called the *corona mortis*. The radical cure by the inguinal route is described on page 1286. In *umbilical hernia* make a slightly curved incision a little to one side of the middle of the tumor, open the sac, separate adhesions, and divide the constriction by cutting upward or downward, and sometimes also laterally, or, better, operate as for radical cure (see page 1286).

FIG. 847.—Double inguinal rupture.

After an operation for strangulated hernia put the patient to bed; bend the knees over a pillow; give no food by the mouth for thirty-six hours (MacCormac), only allowing hot water, and every sixth hour give an enema of salt solution containing brandy. Abdominal pain and tenderness call for the administration of saline cathartics and enemata containing turpentine or oil of rue. The enema rutæ is a favorite preparation in St. George's Hospital, London. It is made as follows: Take 16 oz. of an infusion of camomile, warm it, and pour it upon 3 dr. of confection of senna (Sheild). If there is no abdominal pain and no tenderness the bowels need not be disturbed for a few days; but if at the end of four or five days they have not acted, give a saline cathartic and a few hours later a purgative enema. At the end of about three weeks get the patient up. If a radical cure has not been attempted, apply a pad and a spica bandage to the groin, and later a truss. A truss should not be worn if a radical cure has been made.

Mortality.—Cases of strangulated hernia irreducible by taxis will practically all die without operation. The mortality following operation is large; it is not due to operation, but is due to the condition, and is due particularly to delay in operating or to forcible antecedent taxis. Sultan, from a total of 1429 herniotomies, estimates the mortality at 20.7 per cent. Estimating the mortality according to the time of strangulation, Henggeler reaches the following conclusions: The mortality of cases operated upon "the first day after the strangulation is 8.09 per cent.; during the second day, 22.2 per cent.; during

the third day, 45.5 per cent.; during the fourth day, 60 per cent." ("Atlas and Epitome of Abdominal Hernias," by Dr. George Sultan. Translated and edited by Wm. B. Coley, M. D.). Deaver and Ross ("Annals of Surgery," 1915, lxi) had a mortality of 33.5 per cent. in 156 cases and umbilical and ventral herniæ showed the highest mortality. The mortality in children is smaller than in adults. In Coley's 12 cases of children under two years of age there was not a death.

Hernia in Childhood.—Umbilical and inguinal herniæ are extremely common in infants and children. Femoral hernia is very seldom seen in infants because of the small size of the ring. The condition is rare in children. It is an interesting fact that if one conducts a careful investigation of hernia in adults, it will be found that but 5 or 6 per cent. of them have suffered from the hernia in childhood. This fact seems to demonstrate positively that the majority of cases of hernia in childhood are recovered from. A. J. Ochsner ("Jour. Am. Med. Assoc.," Dec. 22, 1900), in commenting upon the frequency of hernia in childhood, alludes to Malgaigne's statistics. Malgaigne estimated that during the first year of life 1 child in every 21 has hernia, and that this proportion is maintained until the age of six. Then it diminishes rapidly until the age of thirteen, at which age there is 1 hernia in every 77 children. It is, therefore, obvious that 75 per cent. of all herniæ in children of six years will heal spontaneously before the age of thirteen. Ochsner states that 95 per cent. of herniæ in children will be cured without operation. He points out that between the ages of thirteen and twenty hernia is fairly common among boys, but very rare among girls. The reason for the tendency to cure is somewhat uncertain. The view advocated by Thomas C. Martin is that, as the pelvis broadens, the parietal peritoneum enlarges. It does this at the expense of the mesentery, which is shortened, and the internal abdominal ring is displaced. In a very instructive analysis of this condition Ochsner shows that in 25 per cent. of cases of hernia in childhood hereditary weakness exists; that the condition is commoner among the poorer classes than among the rich; that in many cases there is an undescended testicle; and that the chief cause is an excess of intra-abdominal pressure. This excess of intra-abdominal pressure may result from flatulent distention of the stomach and intestines, the product of bad feeding; constipation and straining; straining on urinating, due to the existence of phimosis; vomiting, or cough. He thinks that, as a rule, indigestion causes flatulence and pain; that the child cries; that this increases the pressure; that the mother then feeds it in order to keep it quiet, and that this makes it worse. Strangulation is rare in childhood.

A hernia may be overlooked in a child. In childhood a hernia may make a large bulge to-day and to-morrow it may have withdrawn entirely. We cannot get a young child to cough, a lump may fail to appear even when the child strains or cries, and hence a surgeon may deny the existence of a hernia which has been recently in the scrotum. Another curious fact is that a hernia of a child, when once reduced, may not "come out" again for weeks or even for months ("A Treatise on Rupture," by Jonathan Macready). Camper, much over 100 years ago, pointed out the difficulty of diagnosis in children.

Treatment.—Strangulated herniæ, irreducible herniæ, herniæ with very large rings, cases in which trusses fail, and cases associated with reducible hydrocele require operation (Ochsner). Most cases are curable without operation, the ring being guarded by a truss of rubber or a pad of lamb's wool. Ochsner believes that many cases can be cured by keeping the child recumbent, with the foot of the bed raised, from four to six weeks. If phimosis exists, it should be operated upon, and any other causative condition should be treated (cough, vomiting, constipation, flatulent indigestion, etc.). An umbilical hernia can usually be cured by the use of a cork. The cork should be 1 inch in diameter and 1¼ inches in length, and shaped like a cone. The

smaller end is pushed into the ring and the cork is held in place by adhesive plaster. In two weeks a smaller cork must be used, and in six or eight weeks it can usually be dispensed with. Radical cure operations are seldom done before the age of four (see page 1276).

Varieties of Hernia.—*Direct inguinal herniæ* comprise less than 2 per cent. of cases of inguinal herniæ. In direct hernia the contents pass out through Hesselbach's triangle internal to the deep epigastric artery. They enter the inguinal canal low down, and pass outside the conjoined tendon or force the conjoined tendon before them or split through the tendon. They do not enter the scrotum. The neck of the sac is internal to the deep epigastric artery. The protrusion is globular in shape, unless it emerges around the edge of the tendon, in which case it is pear shaped. The coverings of this hernia, when it passes external to the conjoined tendon, are the same as those of an indirect inguinal hernia, except that the transversalis fascia instead of the infundibuliform process of the transversalis fascia is one of the layers. When a direct hernia pushes before it the conjoined tendon, its coverings are skin, superficial fascia, intercolumnar fascia, conjoined tendon, transversalis fascia, subserous tissue, and peritoneum.

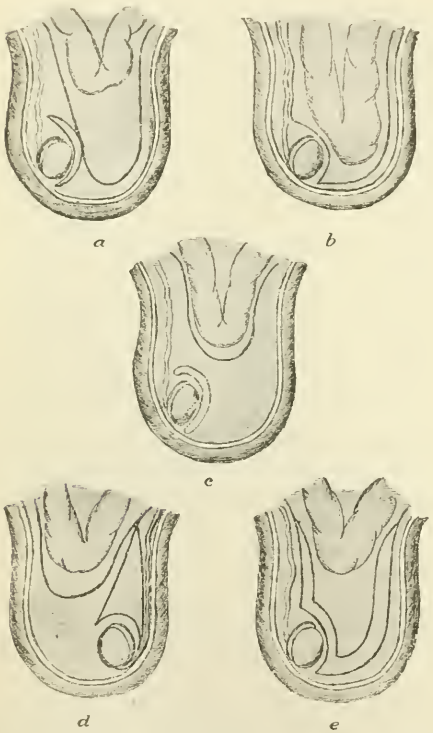

Fig. 848.—*a*, Scrotal hernia; *b*, congenital hernia; *c*, funicular hernia; *d*, infantile hernia; *e*, encysted hernia.

In *indirect inguinal hernia* the contents pass through the internal abdominal ring external to Hesselbach's triangle and external to the deep epigastric artery. They pass down the inguinal canal and emerge from the external ring; and may or may not enter the scrotum or labium (*scrotal* or *labial hernia*). The protrusion is pear shaped. The neck of the sac is external to the deep epigastric artery. Its coverings are skin, superficial fascia, intercolumnar fascia, cremaster muscle, infundibuliform fascia, subserous tissue, and peritoneum.

Congenital inguinal hernia is a portion of bowel within an unclosed vaginal process. The bowel in congenital hernia has one layer of peritoneum in front of it. The testicle is posterior and below (Fig. 848, *b*). Always remember that bowel may not enter the sac of a congenital hernia for several months or longer after birth. Congenital hernia conceals or buries the testicle; acquired hernia does not. If a vaginal process, open above and closed below, contains a hernia, the condition is called *hernia into the funicular process* (Fig. 848, *c*).

If the funicular process is closed at the abdominal end, but not below, a hernia in a special sac may descend back of the vaginal tunic. This condition is known as *infantile hernia*. In infantile hernia there are three layers of peritoneum in front of the bowel—the two layers of the vaginal tunic and the one layer of sac. The testicle is in front (Fig. 848, *d*).

If the tunica vaginalis is closed above and not below, and a hernia pushes

down the vaginal process and causes it to double on itself, the condition is known as *encysted infantile hernia* (Fig. 848, *e*).

In *femoral hernia* the contents descend along the femoral canal to the inner side of the vein, and the neck of the sac is at the femoral ring. The neck of a femoral rupture is always external to the pubic spine; the neck of an inguinal rupture is always internal to the pubic spine. Femoral hernia contains omentum, but seldom intestine, except in strangulated cases. It used to be said that femoral hernia was never congenital. Russell and Coley show that it may be (see page 1273). Thirty per cent. of herniæ in women are femoral. The broad female pelvis means a large femoral ring. The coverings of a femoral hernia are skin, superficial fascia, cribriform fascia, crural sheath, septum crurale, subserous tissue, and peritoneum.

Occasionally a femoral hernia may pass in front of the vessels (*prevascular femoral hernia*). Moschcowitz operated upon such a case ("Annals of Surgery," June, 1912). A hernia may be external to the femoral artery (*Hesselbach's hernia*); may pass through an opening in Gimbernat's ligament (*Laugier's hernia*); may come down alongside of the femoral vein, but instead of emerging from the saphenous opening spread into the pectineus muscle (*Cloquet's hernia*). *Hernia pectinea* is beneath the pectineal fascia and in the pectineal muscle.

Umbilical hernia may be congenital (the ventral plates having closed incompletely), infantile (the cicatrix of the umbilicus having stretched), or acquired. An acquired hernia may be through the opening for the right or left umbilical artery, the opening for the urachus, the opening for the umbilical vein, or through the center of the umbilicus when Richet's fascia (the thickened layer of transversalis fascia beneath the umbilicus) is thinned or destroyed (Moschcowitz, in "Annals of Surgery," May, 1915). Far and away the most common form of hernia is through the opening for the umbilical vein. It appears at the upper margin of the ring. Its coverings are skin, subcutaneous fat only in the upper part, thin superficial fascia, thinned transversalis fascia and peritoneum. All of these layers are fused together (Moschcowitz, Ibid.).

Ventral hernia is a protrusion through any part of the anterior abdominal wall except at the umbilical or inguinal regions. A ventral hernia may be median (*hernia of the linea alba*) or lateral. The treatment is radical operation.

Epigastric hernia is a form of ventral hernia. In this condition there is a protrusion of the peritoneum in the space bounded by the ensiform cartilage, the ribs, and the umbilicus. The sac of peritoneum may be empty, may contain omentum, or omentum and bowel. The stomach very rarely passes into the sac. The protrusion is usually, but not invariably, through the linea alba. The condition may be due to a congenital gap in the transversalis fascia or to the growth of a fat hernia. This condition may cause abdominal pain, epigastric pain, nausea and vomiting after eating or effort, and, according to Farrar Cobb ("Annals of Surgery," Jan., 1912), chronic diarrhea. It is very seldom strangulated. In some cases the omentum strangulates. Moschcowitz reported a case and 10 cases in literature ("Surgery, Gynecology and Obstetrics," 1914, xix).

Cecal hernia is very uncommon in women. It may be either congenital, infantile, or acquired. If a vaginal process is open the cecum may readily enter it, it may be drawn in by the plica vascularis as the testicle descends (Wrisberg), it may be drawn in by a descending testicle, the posterior peritoneum over which has formed adhesions to the cecum. Most acquired cecal herniæ are preceded and caused by hernia of the small gut, but they may occur alone. In the simple form the cecum is completely covered by a coat of peritoneum and lies within the sac. Usually there is a complete surrounding sac, but sometimes the sac only partially covers the cecum lying in front and to the inner side of the bowel. In these cases the cecum is on the posterior and external aspect of the wall of the sac. The appendix may be in the sac, outside

of the sac, or part may be within and part without. If the sac is incomplete, it means that we have one of the 18 per cent. of cases in which the cecum is not completely covered with peritoneum. A cecal hernia may be and usually is right inguinal, but may be right femoral, left inguinal, or left femoral. It is most common in advanced life and is frequently irreducible.

Hernia of the appendix may occur alone, and Merigot de Treigney collected 22 cases of it ("Thèse de Paris," 1887). In 17 the hernia was inguinal; in 5 it was femoral. I operated upon a case of appendicitis in which the inflamed appendix was the sole occupant of an incomplete right inguinal hernia sac. In some cases the appendix accompanies the cecum into a hernia.

Adherent hernia of the large intestine (*sliding hernia*) is a condition first described by Scarpa, in which the sac of a right-sided hernia contains ascending colon; of a left-sided hernia, descending colon. The sac is complete on the anterior, but apparently absent on the posterolateral aspect, where the bowel seems as though fused to it. This condition has often been called "hernia with incomplete sac." A commonly accepted theory is that because of

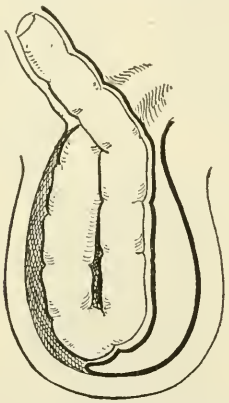

Fig. 849.—The large intestine behind the peritoneum (Weir).

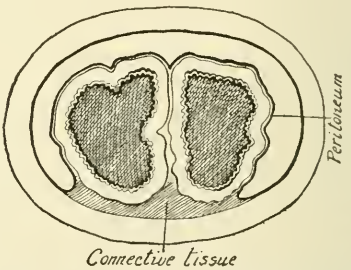

Fig. 850.—The retroperitoneal large intestine in a cross-section of the hernia with its incomplete sac (Weir).

looseness of the peritoneum of the iliac region a portion of the large bowel slides into the hernia. In such a case the posterolateral aspect of the sac is absent (Figs. 849 and 850). In a right-sided condition the descending bowel carries with it into the scrotum a fold of loosened peritoneum, just as in the descent of the testis (Weir, in "Med. Record," Feb. 24, 1900). Sliding hernia of the ascending colon is wrongly called sliding hernia of the cecum. In most cases of sliding hernia of the left side the descending colon is dragged into a preëxisting hernia sac containing small bowel, omentum, or both. The large bowel is covered with peritoneum except posteriorly, where the mesocolon is attached. This form is nearly always irreducible and occurs particularly in elderly men. In another group of cases the large bowel makes a direct inguinal hernia and the sac is limited to the anterior surface of the protruded gut.

In this edition I have adopted the name "adherent hernia" instead of "sliding hernia." L. J. Ransohoff ("Annals of Surgery," August, 1912) seems to demonstrate that the condition is not due to sliding of the peritoneum, and hence is not a sliding hernia; that an incomplete sac is a secondary process, the sac having been complete in its incipiency, but obliterated posteriorly "by secondary adhesions of the embryonic type." The immobile loop of intestine in the sac has been originally mobile; "the hernia is primary, the adhesions secondary" (Ransohoff, "Annals of Surgery," Aug., 1912).

In *properitoneal hernia* the sac is between the peritoneum and transversalis fascia. This form of hernia is sometimes produced by making taxis on an inguinal hernia, when the internal ring is small or is blocked by an undescended

testicle. In properitoneal inguinal hernia, which is the most common form, there are two sacs, one in the scrotum, the other parallel with Poupart's ligament, and as one sac is emptied, the other distends (Breiter, of Zürich).

In *interstitial* or *interparietal inguinal hernia* the hernia sac is between the transversalis muscle and fascia, or between the external and internal oblique muscles, or in the midst of the fibers of the internal oblique muscle, or between the external oblique muscle and the transversalis fascia, the internal oblique and transversalis muscles being pushed aside (Sultan's "Atlas of Abdominal Hernias").

In *superficial inguinal hernia* the sac is between the aponeurosis of the external oblique muscle and the superficial fascia. This variety of hernia is always congenital and the testicle is invariably misplaced.

Obturator hernia passes through the obturator membrane or the obturator canal, and is felt below the horizontal ramus of the pubes, internal to the femoral vessels. The obturator nerve is pressed upon and pain arises in its trajectory.

Lumbar hernia is a very rare condition. It may be congenital, traumatic, or spontaneous, and may follow a lumbar abscess. Braacz collected 68 cases. It occurs through the triangle of Petit, or just below the twelfth rib through the superior lumbar triangle, or through a congenital defect in the aponeurosis of the latissimus dorsi muscle, or through a defect near the triangle of Petit (Dowd, in "Annals of Surgery," Feb., 1907). A lumbar hernia may be present at the edge of or through the quadratus lumborum muscles. In 1738 Ravaton operated upon a strangulated lumbar hernia.

The *triangle of Petit* is bounded in front by the external oblique, behind by the latissimus dorsi, below by the iliac crest, and its floor is formed by the internal oblique. The *superior lumbar* triangle (of Grynfelt and Lesshaft) is bounded anteriorly by the external oblique, posteriorly by the iliocostal muscle, above by the serratus posticus inferior and the end of the twelfth rib, and below by the internal oblique. The latissimus dorsi overlies it.

Sciatic or *gluteal hernia* passes through the great sacrosciatic foramen, above or below the pyriformis muscle, or through the lesser sacrosciatic foramen.

Pudenal hernia protrudes into the lower part of the labium, the bowel having descended between the ischial ramus and the vagina.

Perineal hernia presents in the perineum, between the rectum and the prostate gland or between the rectum and the vagina.

Internal, retroperitoneal, or *intra-abdominal herniæ* include hernia into the *foramen of Winslow,* hernia into the *retroduodenal fossæ,* the *retrocecal fossæ,* and the *intersigmoid fossa* (see page 1115), and hernia into the lesser peritoneal cavity through a slit in the transverse mesocolon.

Vaginal hernia is associated with uterine prolapse or ensues upon destruction of the vaginal wall.

Richter's hernia (partial enterocele or hernia of the intestinal wall, Fig. 851, A) was described by Richter in 1778. He called it "the small rupture." It occurs in adults only and is most common in women. It is the catching of a portion of the circumference of the bowel, usually a portion of the lower part of the ileum. It is usually femoral, but may be inguinal, and even epigastric or obturator. It arises usually in an old, reducible hernia (Royal Hamilton Fowler, "Am. Jour. Surg.," Jan., 1912). Some cases are due to adhesions. It may be due to truss pressure on an incompletely reduced hernia (Fowler, Ibid.). Strangulation of a partial enterocele may not completely close the lumen of the gut. There may not be stercoraceous vomiting or absolute constipation, and the protrusion is barely perceptible or cannot be palpated.

Littré's hernia is hernia of Meckel's diverticulum (Fig. 851, B). It was described by Littré in 1700. This diverticulum is the persistent vitelline duct and comes off from the ileum from 12 to 36 inches above the ileocecal valve. It arises from the convex side of the gut and rarely has a mesentery (see pages 1115 and 1122).

Rokitansky's diverticular herniæ are due to separation of the muscular fibers of the bowel, permitting the sacculation of mucous membrane and peritoneum. These false diverticula may be no larger than peas or may be larger than walnuts, and there may be scores of them in one patient. They may produce no symptoms or may lead to peritonitis, abscess about the bowel, perforation, or to symptoms of intestinal obstruction.

Hernia of the Bladder.—This is a protrusion of a portion of the bladder wall through a hernial opening. Eggenberger adds 110 cases to Brunner's 182 cases, a total of 292 cases ("Deutsch. Zeitschr. f. Chir.," Oct., 1908). Most cases are instances of false hernia, there being no sac of peritoneum. The protrusion may or may not be covered with peritoneum, and in most cases it is not so covered, but lies by the side of a hernial sac and not inside of it. Brunner's table shows only 5 cases of true bladder hernia, that is, of intraperitoneal hernia. It is most frequently met with in the inguinal region. Brunner describes three forms: (1) Entirely without a peritoneal covering (extraperitoneal); (2) partly covered with peritoneum (paraperitoneal—the commonest form); (3) completely covered with peritoneum (intraperitoneal). The bladder may constitute the hernia, or there may be an ordinary hernia and also a cystocele. In an inguinal hernia the bladder will be internal and somewhat behind the other constituent parts of the protrusion. Hernia of the bladder is much more common in men than in women.

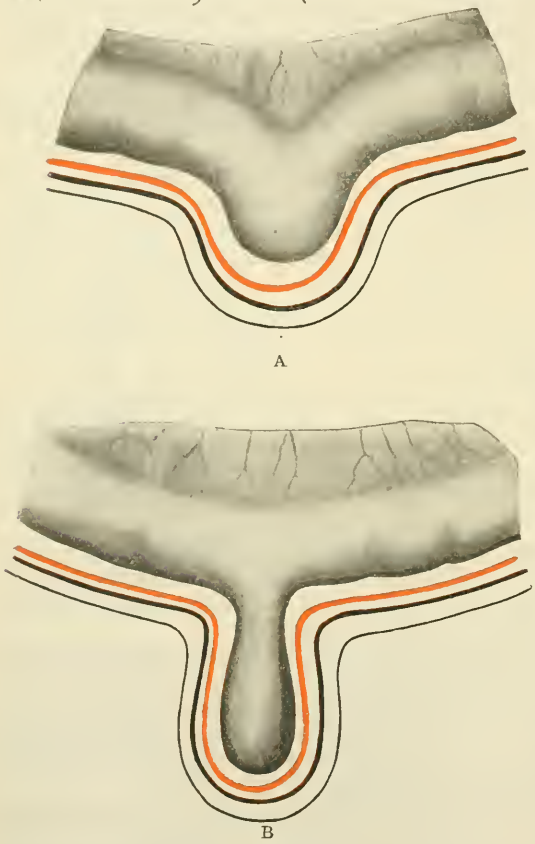

FIG. 851.—A, Diagrammatic representation of Richter's hernia of intestinal wall. B, Diagrammatic representation of Littré's hernia, which is a hernia of Meckel's diverticulum (Sultan).

A hernia of the bladder may become strangulated. In some cases a diagnosis of hernia of the bladder can be made by the fact that the protrusion lessens in size when the patient micturates, and increases in size as urine gathers or when the bladder is injected with fluid. The treatment should be operative. When the bladder is exposed it is replaced if possible without resection.

Diaphragmatic Hernia.—The majority of cases are congenital and in 90 per cent. of them there is no sac. The hernia may pass through a natural opening or through a gap due to congenital defect. The hernia is most common on the left side, and the stomach is the organ which is most often found in the hernia, but the colon, the omentum, the small intestine, the spleen, liver, duodenum, cecum, pancreas, or kidney may be found (Cranwell, "Rev. de Chir.," 1908, No. 1). Violent traumatism may be the cause. When the

stomach passes suddenly through the left side of the diaphragm there will be dyspnea, cyanosis, displacement of the heart to the right, pain in the upper abdomen, thirst, and in most cases rapid death. When the stomach or intestine has entered the left side of the thorax, there is a tympanitic note on percussing over that area of the thorax, the heart is displaced to the right, and the side of the chest is unduly prominent. The upper border of the tympanitic area does not move with respiration. There are no breath sounds audible over the tympanitic area, but gurgling is heard. In 250 cases of traumatic diaphragmatic hernia collected by Leichtenstern the diagnosis was made before death in but 5 cases. The *x*-rays are of value in diagnosis, especially if the stomach is in the hernia. Strangulation of a diaphragmatic hernia produces severe pain in the upper abdomen, violent vomiting, constipation, boat-shaped abdomen, great thirst, rapid wasting, and the excretion of a very small amount of urea (Mackenzie and Battle, "Lancet," Dec. 7, 1901). Diaphragmatic hernia may be confused with *eventration of the diaphragm*, an unnaturally high position of the left half of the diaphragm, with ascent of the viscera of the abdomen, especially the stomach. It was first described by Petit in 1790. Sailer and Rhein reported a case and collected 12 others ("Am. Jour. Med. Sciences," April, 1905). J. D. S. Davis reported 5 cases ("Trans. Southern Surgical and Gynecological Assoc.," Dec., 1914). The physical signs of eventration are practically identical with those of diaphragmatic hernia, except that in the former the upper border of the tympany moves on respiration.

Treatment.—Open the belly for exploration. If a hernia be found, return it to the abdomen; open the chest and suture the diaphragm from above (transpleural suturing). Mackenzie and Battle, Mikulicz, Humbert, and others have operated for this condition.

Hernia of the Ovary.—The ovary, because of failure of descent, may remain in the lumbar region. It may pass into the inguinal canal or labium majus (inguinal hernia); into the gluteal region (gluteal hernia); into the region of the obturator foramen (obturator hernia); or into the front of the abdomen (ventral hernia). In congenital inguinal hernia there may be ovary alone, or ovary, tube, omentum, and even part of a bicornate uterus (Garrigues). It is impossible to restore a congenital hernia. Acquired hernia may follow a fall and sometimes it can be restored. A femoral or crural ovarian hernia, a condition in which the ovary passes to the front of the thigh below Poupart's ligament, is never congenital. In some cases a herniated ovary can be returned within the abdomen. Any herniated ovary may inflame.

Treatment.—If the ovary can be restored, a truss will probably retain it, but even in such a case operative cure is better. If it cannot be restored or if it is painful or undesirable to wear a truss, operation must be done. Expose the ovary, return it to the belly if healthy, and do a radical cure of the hernia. In some conditions of disease remove the ovary.

Hernia of the Uterus.—This condition is a surgical curiosity, but a few cases have been reported (John Howard Jopson's case in "Annals of Surgery," July, 1904). The hernia may be umbilical, ventral, inguinal, or femoral. Hernia of the unimpregnated womb may be congenital or acquired; impregnation may occur when the uterus is herniated, or an impregnated uterus may pass into a preëxisting hernia sac. If a herniated uterus becomes impregnated or if an impregnated uterus becomes herniated, pregnancy may go on to term. Multiple pregnancies predispose to uterine hernia. Ovarian hernia may precede uterine hernia, or hernia of omentum adherent to the uterus may pull that organ into the sac. In many cases congenital anomalies have been found to exist (bicornate uterus, rudimentary uterus, shortness of the round ligament, imperforate vagina, etc.). A hernia of the uterus enlarges and becomes painful during menstruation, and a vaginal examination shows that the uterus is absent from its normal position and that the direction

of the cervix and vagina are abnormal (Jopson, Ibid). A uterine sound cannot be passed at all or can be passed with great difficulty. The hernia is hard and probably pyriform. If impregnation occurs, there are the ordinary signs of pregnancy and progressive enlargement of the hernia.

Treatment.—Expose the mass by incision. If conditions justify such a course, return the uterus and adnexa, if they be present (one or both ovaries and tubes may be present), to the abdomen and do a radical cure. If the uterus be infected, remove it. Jopson in his case removed the uterus and right ovary and fastened the uterine stump into the wound.

XXIX. DISEASES AND INJURIES OF THE RECTUM AND ANUS

Teratoids and Dermoids in the Sacrococcygeal Region.—In the sacrococcygeal region there are many opportunities for developmental error. In this region the caudal end of the primitive streak must undergo evolution and involution, the neurenteric canal must form and disappear, the anus must be formed, the posterior fissure must close, the sacrum and coccyx must develop, and various other processes must go on correctly and uniformly if complete development is to be obtained. As Coplin puts it: "Perfect evolution of the tissues embraced in this part of the body is beset by many narrow escapes" ("Publications from the Laboratories of Jefferson Med. College Hospital," 1906, vol. iii). Fissures and clefts may fail to close, fragments from one blastodermic layer may be lodged in another layer, groups of cells may be sequestered, closing clefts may include tissue elements, and parts that should normally atrophy may do so late or not at all.

In order to understand teratomata and dermoids arising in the rectal region we must recall some facts of development.

Early in embryonic life the central canal of the spinal cord and the alimentary canal are continuous around the caudal end of the notochord by a communicating path called the neurenteric canal.

When the anal pit undergoes invagination it meets the gut considerably in front of the region where the neurenteric canal joins the gut. The portion of intestine between the anus and the opening of the neurenteric canal is called the *postanal* gut. The postanal gut disappears during normal development. If it persists it causes tumor formation.

The congenital tumors of the sacrococcygeal region are: (1) Tumors of the postanal gut; (2) dermoids back of the rectum; (3) rectal dermoids.

According to Bland-Sutton, tumors of the postanal gut "are composed of closed vesicles lined with glandular epithelium and contain glue-like fluid" ("Tumors, Innocent and Malignant," by Sir J. Bland-Sutton). These tumors grow to a large size.

Dermoids back of the rectum often contain teeth, may attain large size, are apt to mount up behind the peritoneum, and may rupture and form a fistula. I helped Prof. Keen operate on such a case. The skin over the mass showed a growth of hair, there was a gap or cleft in the sacrum, and through this there was a clear passage from the rectum to the skin. This sinus closely resembled the trachea in structure.

Dermoids occasionally grow from the mucous membrane of the rectum and are apt to contain an abundant growth of hair.

Examination of the Anus and Rectum.—There are four positions in which we may place the patient for rectal examination, the one to be selected depending upon the probable local difficulty. These positions are the left lateral prone, the knee-chest, the exaggerated lithotomy, and the squatting position. The knee-chest position is desirable if the sigmoidoscope is to be

used. A commonly employed position is the *left lateral prone position of Sims*, in which the patient lies on the left side, the chest on the table, the left arm behind the back, the knees drawn up, and the pelvis elevated on a hard pillow.

Very stout people should be placed in the *knee-chest position* or *exaggerated lithotomy position*, as the rectum cannot be seen when they lie on the side.

A *squatting position*, when the patient is placed as though on a commode, is best adapted to cases of prolapse and hemorrhoids. It is also used to bring within the range of the finger strictures or new growths that in the other attitudes would be beyond digital reach.

Sometimes the surgeon is able to pass a sigmoidoscope upon a patient in the exaggerated lithotomy position when it has been found impossible to carry the instrument high enough with the patient in any other position.

While making a rectal examination the patient should have no constriction about the abdomen, such as corsets, bandages, or tight clothing.

It is important that the first examination be made when no cathartics or enemata have been administered, so that the condition of the excretions and secretions may be noted. By such first examination pus, blood, mucus, or inspissated fecal matter if present may be seen, and from their varying characteristics, quantities, and locations inferences as to causation may be drawn. After these observations have been made an enema should be given and the anus and rectum be well cleansed. When the parts have been cleaned and the bowel washed out the anus is carefully inspected, the anal folds being opened during the process. By inspection the surgeon can notice the external opening of a fistula, external piles, protruding internal piles, mixed piles, pruritus, discharge from the rectum, eczema, fissure, tumor, ulcer, condylomata, abscess, whether or not the anus is retracted and funnel-shaped or protruding, or if there be parasites on the anal hairs.

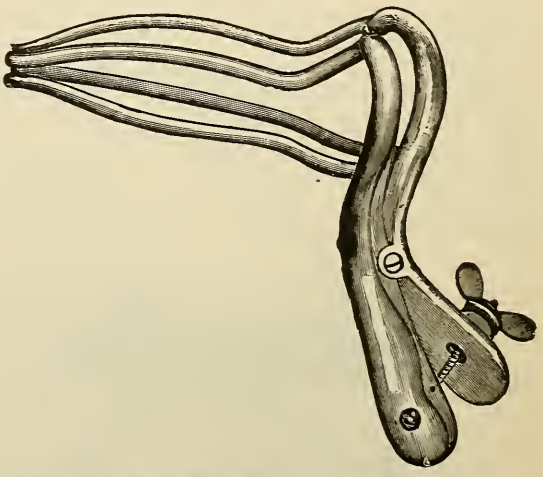

Fig. 852.—Mathews's self-retaining rectal speculum.

Next the thumbs should be placed on either side of the anus and gently separated; this maneuver, aided by a bearing down effort on the part of the patient, will often cause piles to protrude, exhibit fissures and polypi, and reveal the condition of the mucocutaneous border.

Next, a digital examination of the rectum is made. The nail of the index-finger is filled with soap and the finger is oiled or, better, is covered with a rubber finger-tip which is oiled. The digit is gently inserted through the sphincter, the patient being asked to strain lightly during its insertion. The finger is inserted with a gentle boring motion and is pointed toward the umbilicus until the sphincter is passed. A digital examination enables the surgeon to detect an ulcer, a polypus, a tumor, a stricture, and to determine certain points regarding the condition of the prostate in the male and the uterus in the female. Non-indurated piles cannot be detected by the finger. A speculum will be needed to discover them if they are not protruding.

Next, in some cases, the rectum must be examined by means of a speculum. It is not often necessary to give ether. Mathews's speculum (Fig. 852)

is very serviceable. Sims's duck-bill speculum is a valuable instrument for certain cases. The speculum is warmed, oiled, and slowly introduced. It is first directed toward the umbilicus, and when it passes the sphincter its direction is gradually altered until it is toward the promontory of the sacrum. Illumination is obtained by direct sunlight or by a forehead mirror and an electric light. This examination will extend, confirm, or disprove the findings of the digital examination; ulcers, hemorrhoids, and malignant growths can be

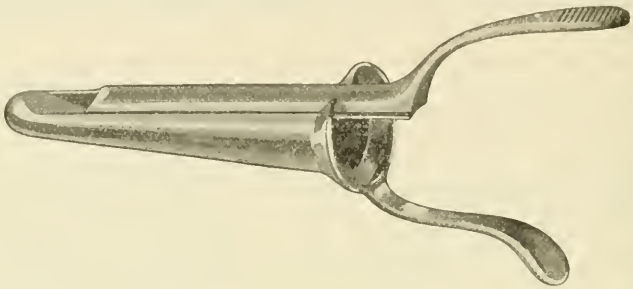

Fig. 853.—Brinkerhoff's speculum.

carefully examined, and the condition of the rectal mucous membrane can be thoroughly investigated.

Marion Sims in 1845 demonstrated the ballooning of the vagina by atmospheric pressure, and in 1870 Van Buren applied this method to the rectum. Kelly in 1895 put forth his straight tubes and described in detail the methods and advantages of examination by them, and the great diagnostic value of ballooning the rectum. Kelly's method of examination is shown in Fig. 856. The tubes are shown in Fig. 857. It is not necessary to give ether. The patient is placed in the knee-chest position. A tube containing an obtu-

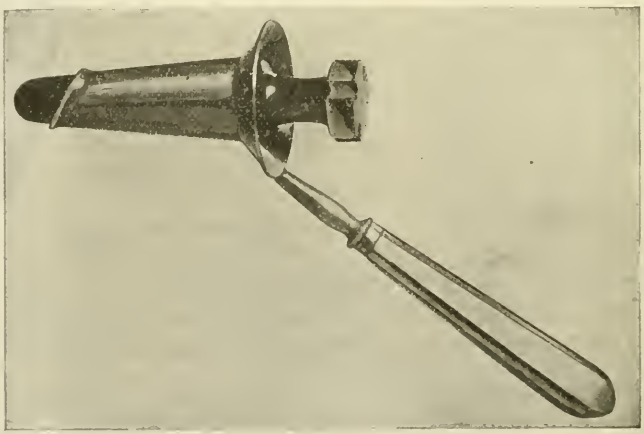

Fig. 854.—Martin's speculum.

rator is well greased with vaselin. "The buttocks are drawn apart, and the blunt end of the obturator is laid on the anus, which is also coated with vaselin. The direction of the instrument should be first downward and forward, and, when the sphincter is well passed, up under the sacral promontory. The moment the speculum clears the sphincter ani and the obturator is withdrawn, air rushes in audibly and distends the bowel." When the entering instrument is pressed gently against the sphincter a sharp muscular contraction ensues. If the instrument is gently and slightly withdrawn, relaxation occurs, and the

moment of relaxation may be seized to make an entry. An entry so made is rapid and unresisted. The bowel being distended with air, the mucous membrane is plainly seen as the tube is slowly withdrawn and the electric light is reflected into the speculum by a forehead mirror. The normal mucous mem-

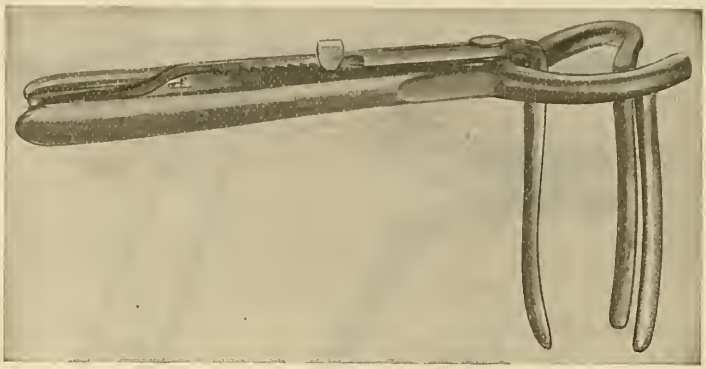

Fig. 855.—Cook's operating speculum.

brane is dull red, like the nasal mucosa, and the blood-vessels are plainly distinguishable. The Kelly tube must be used with great care, as harm may be done by it, and the longest tube should be used in exceptional cases only.

Fig. 856.—Examination of the rectum by reflected light (Kelly).

I use with the greatest satisfaction James P. Tuttle's pneumatic proctoscope (Fig. 858). Dr. Tuttle describes it as follows ("Diseases of the Anus, Rectum, and Colon"): "This instrument is composed of a large cylinder (*f*),

into one part of the circumference of which is fitted a small metallic tube closed by a flint-glass bulb at its distal end. The electric lamp (*d*) is fitted upon a

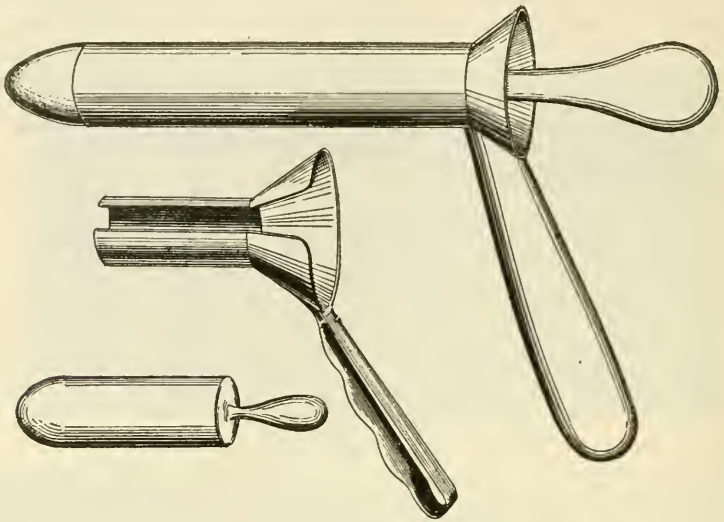

Fig. 857.—Kelly's rectal specula.

long metallic stem, and carried through the small cylinder to the end of the instrument, as shown in the illustration. The proctoscope is introduced through the anus with the obturator (*a*) in position. As soon as the internal sphincter is passed this obturator is withdrawn and the bayonet-fitting plug (*b*), which contains either a plain glass window or a lens focused to the length of the instrument to be used, is inserted in the proximal end of the instrument. This plug is ground to fit air-tight and thus closes the instrument perfectly. The plug being inserted in the tube, a very slight pressure upon the hand-bulb will cause inflation of the rectal ampulla to such an extent that the whole rectum can be observed and the instrument can be carried up to the promontory of the sacrum without coming in contact with the rectal wall. Further dilatation will show the direction of the canal leading into the sigmoid, and, by a little care in manipulating the instrument and keeping the gut well dilated in advance, it can be carried up into this portion of the intestine without the least traumatism of the parts. If any fecal matter obscures the light by being massed or smeared over the glass bulb, the plug can be removed, and a

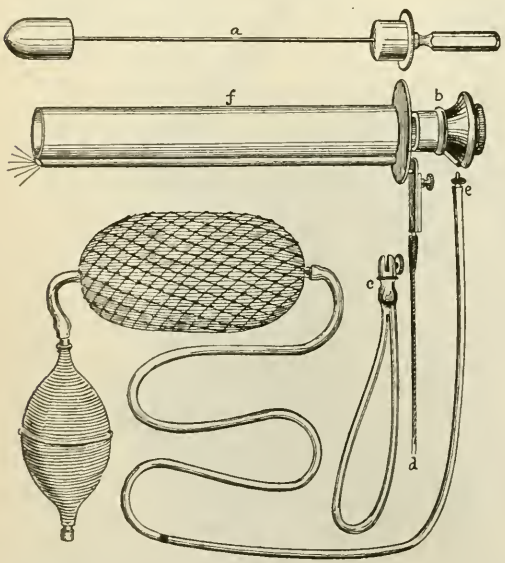

Fig. 858.—Tuttle's pneumatic proctoscope: *a*, Obturator; *b*, plug with glass window closing end of tube; *c*, handle; *d*, cords connecting instrument with battery; *e*, inflating apparatus; *f*, main tube of proctoscope.

pledget of cotton, introduced with a long dressing forceps, will wipe this off, so that the plug can be reintroduced and the examination continued with very slight delay or inconvenience. The adjustable handle (*c*) fits on the rim of the instrument and thus converts it into a Kelly tube. This instrument is operated with an ordinary dry battery of four cells. It is better, however, to have a battery with six cells, as it will not require being recharged so frequently." All the air must be allowed to escape before the instrument is withdrawn, otherwise colic may develop.

If an anesthetized patient is placed in the knee-chest position, the sphincter can be stretched by the fingers, and the rectum will distend with air and can be easily examined. The fingers are introduced as suggested by Martin (Fig. 859) and the rectum becomes visible when they are separated (Fig. 860).

Passage of Rectal Tubes.—Some have asserted that soft tubes can be passed from the anus through the sigmoid. I do not believe this can be done in a normal rectum, it matters not in what position the patient is placed, and whether or not fluid flows from the tube during its introduction. A soft tube

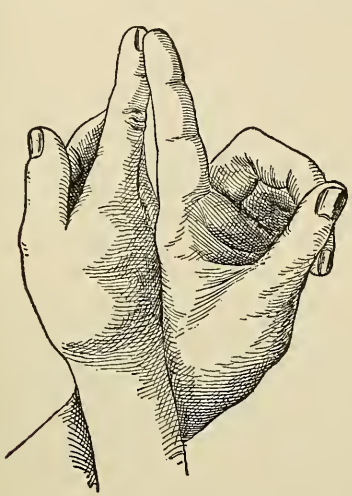

Fig. 859.

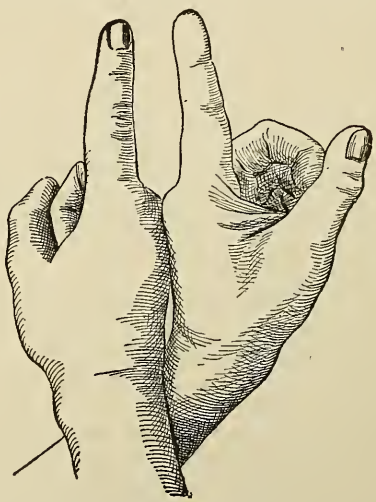

Fig. 860.

Figs. 859, 860.—A new and simple method of proctoscopy (Thomas C. Martin).

always coils up after it has ascended 6 or 7 inches. In a number of laparotomies, desiring to locate the rectum, I have had an assistant pass a rubber tube. It would never ascend above the rectal dome unless I aided it with a hand in the belly, when it could be passed through the sigmoid. Fortunately it is not necessary to give high enemas, as fluid introduced into the rectum is carried back to the sigmoid. If we wish fluid retained, attempts to pass the tube high up will cause irritation, and irritation will lead to expulsion.

Foreign Bodies in the Rectum.—It is not at all unusual for hard, undigested articles taken with the food to lodge in the rectum. They can usually be removed through a speculum by means of forceps. In some cases ether must be given and the sphincter stretched; in others, the sphincter must be divided. Sometimes large bodies are voluntarily inserted and the individual is unable to remove them. Lewis H. Adler ("Am. Med.," July 20, 1901) removed the valve of a steam radiator pipe from the rectum. The small end was 1½ inches in diameter; the large end was 2½ inches in diameter. The patient had been in the habit of introducing it frequently and removing it with a hook of galvanized iron wire. A. Marmaduke Sheild ("Lancet," Oct. 12, 1901) reports the case of a man sixty years of age who forced a gallipot into

the rectum. The pot was 2½ inches in diameter and 2¾ inches in height. The patient broke it trying to get it out. Sheild incised the sphincter from behind and removed the article by means of obstetric forceps.

If the foreign body be soft, as an apple or a potato, a hole should be bored through to allow the air to pass and thus relieve the suction. It can then be lifted out. If the body be of wood, screw in a gimlet; if of metal, cut with strong forceps; if of glass, remove as Sheild did the gallipot. If the article be rough or has sharp edges, pack gauze all around it as a first step to protect the rectal walls. In a case in which a boar's tail had been introduced, large end first, the holding back of the bristles was overcome by sliding over it a large-sized rubber catheter.

Foreign bodies may escape into the sigmoid and necessitate a laparotomy. They may also cause periproctic inflammation.

A remarkable series of cases of foreign bodies in the rectum may be found in "Anomalies and Curiosities of Medicine," by George M. Gould and Walter L. Pyle.

Wounds and Injuries of the Rectum.—These accidents may result from fractures of the pelvis, most often from fractures of the sacrum, from the improper use of enema syringe nozzles or tips, from gunshot-wounds, stab-wounds, foreign bodies introduced by the patient, and, rarely, from digital examinations. The important points to consider in these wounds are whether or not there is penetration of the entire rectal wall, involvement of the perirectal tissues, or peritoneum. Slight wounds involving the mucous membrane only are frequently very grave from the fact that the hemorrhage is constant into the rectum, filling back into the sigmoid and often followed by collapse before or when the blood is voided. The investigations in these cases should always be thorough and by both digital and visual examination, for exact diagnosis is of the utmost importance.

If the peritoneum has been lacerated, laparotomy should be performed at once, the wound in the bowel repaired, the peritoneal cavity cleansed and drained, and the Murphy treatment for general peritonitis instituted (see page 1162). If the laceration involves the perirectal tissues but not the peritoneum, cut down on the side of the bowel that is injured and make free drainage. In the event of very extensive injuries to the perirectal tissues the question of inguinal colostomy should be considered. If the wound involves only the mucous or submucous coats, dilate the sphincter, arrest hemorrhage by suture or ligature, and follow by irrigation.

Inflammation of the Rectum and Sigmoid (Proctitis and Sigmoiditis).—These conditions may be acute or chronic, simple or specific. The simple forms are acute catarrhal, atrophic catarrhal, and hypertrophic catarrhal. The specific forms are gonorrheal catarrhal, diphtheritic catarrhal, erysipelatous catarrhal, dysenteric catarrhal, and syphilitic catarrhal (Tuttle, "Diseases of the Anus, Rectum, and Colon").

Acute Inflammation.—Acute catarrhal inflammation may be caused by that class of incidents which are apt to be followed by ordinary catarrh of the respiratory passages and, in addition, errors of diet or sudden change or temperature, as sitting on a cold seat when overheated. The onset is sudden, with chill, general malaise, pain and discomfort locally, and slight fever. There is a sense of fulness and weight, with often a burning sensation referred to the rectum, and at times tenesmus with frequent desire to go to stool. Pain radiates to adjacent parts and there is bladder irritability. Patients usually prefer to be in the recumbent posture.

There will be at first a thin fecal discharge followed by mucus tinged with blood. Ulceration soon supervenes. The parts are hot, dry, and swollen in the first stages and digital examination is very painful. Later the parts are slimy and the mucous membrane is covered with tenacious mucus and pus.

Treatment.—First remove irritating intestinal contents and reduce en-

gorgement by lavage and saline cathartics, followed, if early in the case, by irrigations of cold water; if later, by hot water. A useful medicated irrigation is a 5 to 10 per cent. solution of the aqueous extract of krameria.

Chronic Inflammation.—In chronic proctitis and sigmoiditis the symptoms are similar to those present in the acute forms of the inflammation, but less severe in character. In addition there is increased secretion of mucus, flatulence, and marked general intestinal disturbance.

The mucous membrane is soft, doughy, and thickened, and this condition of the mucous membrane palpably reduces the caliber of the gut. Through the speculum the membrane is seen to be edematous, pale, and covered with secretion. It bulges into the aperture of the speculum and does not bleed easily.

Treatment is hygienic and dietetic, with antiseptic and astringent irrigations.

Atrophic Inflammation.—The atrophic variety of inflammation is characterized by long-continued constipation, dry stools covered with blood and mucus. There is such pain on expulsion of feces as to simulate in many cases fissure of the anus. The mucous membrane of the anus ruptures easily when stretched during examination. It is bright red and shiny, does not fill the aperture of the speculum, and bleeds readily. Ulceration is common and hemorrhoids are a frequent complication.

Treatment is local and general. Locally, use a dilute solution of nitrate of silver (1 : 2000), hydrastis (2 per cent. solution), or ichthyol, applied after the rectum is emptied. General treatment is hygienic and dietetic.

Peri-anal and Perirectal Inflammations.—These are of two classes —circumscribed inflammations or abscesses and diffuse inflammations that always develop pus. The circumscribed variety may be either superficial or deep. The superficial variety again may be tegmentary, subtegmentary, or *ischiorectal*. The deep variety may be of two forms—retrorectal or superior pelvirectal. It is important to note that right-sided superior pelvirectal abscess may be confounded with appendicitis.

The diffuse perirectal inflammations are variously classified, but the particular names refer only to the degree of the inflammatory process, which may vary from ordinary suppuration to gangrene.

These inflammations travel in the line of least resistance, which is upward, and more often burst into the bowel than externally. They may follow chilling of the region or external traumatisms, may be caused by perforation of the rectum by hard fecal masses, or by the direct passage of bacteria into the fossa through a fissure, an ulcer, or an ulcerated pile. They may be either acute or tuberculous. In many cases the process is at first tuberculous, and secondary infection with pyogenic bacteria takes place.

The **symptoms** are nearly identical with those of abscess elsewhere, the swelling, however, being brawny, and it being difficult or impossible to detect fluctuation. Pain in the groins is often complained of, and there may be enlarged glands in these regions. Abscesses commonly result in fistula, and a patient should be warned of this tendency before operation is performed. Superior pelvirectal abscesses generally follow inflammation of some pelvic organ, viz.: tubes, urethra, prostate, and the symptoms are mainly those of such an inflammatory condition. The usual tendency of the pus is to burrow upward. The presence of pus is indicated by the symptoms of suppurative toxemia, which sometimes simulate typhoid fever.

The **treatment** is instant incision. The patient, after having been anesthetized, is placed in the lithotomy position. The cut should be parallel to the fibers of the external sphincter and well outside of the muscle and longer than the inflamed area. When this incision is made, the finger should be introduced to break down the necrotic septa of cellular tissue. Then an incision should be made from the middle of the first cut radiating outward and opening any pockets external to the original focus. Then the free edges of the cuts are pared away,

sacrificing all involved tissue. The wound is irrigated, the sphincter dilated, and the cavity packed with iodoform gauze. If a fistula is found opening into the rectum, it is not to be operated on until after the wound is nearly healed, only a small fistulous tract remaining.

In cases of superior pelvirectal abscess the incision should be made at right angles to the fibers of the levator ani muscle to facilitate drainage. In these cases tubal drainage is used.

Imperforate Anus.—There are two forms of this condition. In one form the rectum empties into the bladder, vagina, or urethra. In the other form there is no rectal opening either upon the surface of the body or in the genito-urinary organs. The diagnosis is usually at once apparent, except in cases in which the anus looks normal, when the diagnosis will often not be made until symptoms of obstruction arise.

Treatment.—If the rectum bulges when the child cries, open into it with a knife and keep the opening patent by inserting a plug of iodoform gauze. In cases in which the rectum is more deeply seated, a catheter is introduced into the bladder, an incision is made from the anus to the coccyx, the rectum is sought for, and when found is sewed to the anus and is incised. Keen, the author, and others have performed Kraske's sacral resection, pulling down the rectum to the anal margin, sewing it there, and incising the occluded anus. If the rectum cannot be found or cannot be pulled down, an artificial anus must be made.

Fistula in ano is the track of an unhealed abscess. An abscess in the anal region is apt to refuse to heal because of the constant movement of the parts (produced by respiration, coughing, the passage of gas, defecation, etc.). The passage of feces along the tract will keep a fistula open. If a tuberculous

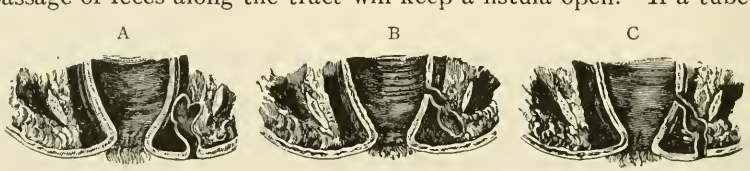

Fig. 861.—Fistula in ano: A, Blind external; B, blind internal; C, complete (Esmarch and Kowalzig).

ulcer perforates a tuberculous sinus forms, and a tuberculous sinus is also apt to follow a cold abscess of the ischiorectal fossa. Fistula is often associated with phthisis pulmonalis, and is not unusually linked with piles, cancer, or stricture.

There are three varieties of fistula—the blind external (Fig. 861, A), the blind internal (Fig. 861, B), and the complete (Fig. 861, C). The *external* opening is usually near the anus, but may be far away, and there may be only one pathway or there may be several sinuses and openings. In a healthy individual the external orifice is small and a mass of granulations sprout from it. In a tuberculous fistula the external orifice is large and irregular, with thin and undermined edges, shows no granulations, extrudes small quantities of sanious pus, and the skin about it is purple and congested. In a fistula following an anal abscess the *internal* opening is just above the anus, between the two sphincters. In fistula following an ischiorectal abscess the internal opening is usually near the anus, but may in rare cases be above the internal sphincter. A sinus may run up under the mucous membrane from the internal opening. In a *horseshoe fistula* the internal opening is usually upon the posterior wall of the bowel, "and from this a tract leads into the ischiorectal fossa, not on one side only, but upon both. Therefore we have one opening into the bowel and one through the skin on either side."[1] In some cases of horseshoe fistula there is no internal opening; in other cases there are two openings. In

[1] "Diseases of the Rectum, Anus, and Sigmoid Flexure," by Joseph M. Mathews.

an old fistula the track becomes fibrous and cannot collapse. Two or more fistulæ may exist in the same patient. In dealing with a fistula always determine if the condition is stationary or progressive.

The **symptoms** of a complete fistula are the passage of feces and gas through the opening and the flow of a discharge which stains the clothing. In a complete fistula a probe can be carried from the external opening into the bowel. After a time incontinence of feces is apt to come on, repeated attacks of inflammation thickening the rectum and destroying its sensibility. From time to time the opening will block and new abscesses form. In examining a fistula use Brodie's probe, as its flat handle enables one to locate the direction the bent instrument has taken, and its slender shaft will find its way through a very small channel.

Treatment.—In treating a fistula cleanse the parts, as cleanly work, though it will not prevent pus, will limit suppuration. The external parts are washed with soap and water. The rectum, which must be empty, is irrigated with warm saline solution. Corrosive sublimate should not be used in the rectum because it is irritant, causes a flow of serum, and hence lessens tissue resistance, and is rendered inert as an antiseptic by being converted into sulphid of mercury. Anesthetize the patient with ether unless the fistula be tuberculous, in which case use local anesthesia, spinal anesthesia, or nitrous oxid. Ether is avoided in such cases by many surgeons for fear of the existence of a pulmonary focus. A tuberculous focus in the lung may disseminate after inhalation anesthesia. Place the patient in the lithotomy position. If operating upon a complete fistula the usual method is as follows: Pass a grooved director into the external opening, carry it through the sinus, make it enter the bowel, bring its point out externally, and lift the tissue between the sinus and the surface. If the director ascends above the internal opening, the opening must be made into the bowel from the summit of the sinus. If there is no internal opening, make one. Incise the bridge of tissue which is held up on the director (Fig. 862). Cut the sphincter at a right angle to its fibers, and do not cut it more than once at one operation. If a fistula is non-tuberculous, cut with a knife. If it is tuberculous, divide the tissues with a Paquelin cautery in order to lessen the danger of dissemination of the infection. Push the finger to the depth of the wound, to determine that the sinus does not ascend above the internal opening. Search with a small probe for branching sinuses, and if any are found, slit them open. Examine carefully to see if there is a sinus beneath the mucous membrane of the bowel, and if such a sinus is found, slit it up. Curet all sinuses, and if they are very fibrous, clip away the fibrous wall by scissors. Cut away diseased skin, irrigate the wound with salt solution, pack firmly with iodoform gauze to prevent oozing, and dress with gauze and a T-bandage. The packing is removed in twenty-four hours unless it is soiled earlier, in which case it is promptly removed. After twenty-four hours the wound is irrigated and packed lightly with gauze to its full depth. This dressing should be repeated every day and any bridging of the tissues should be broken down by a probe. If the wound becomes sluggish, it is stimulated with nitrate of silver and sodium iodid is given in small doses three times daily.

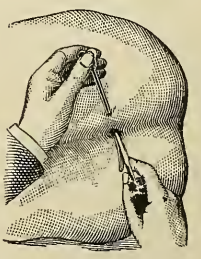

FIG. 862.—Operation for fistula in ano (Esmarch and Kowalzig).

The bowels should be moved after forty-eight hours by enema. The diet should be light and fluid for the first few days after operation, and the bowels should not be restrained by drugs. Get a tuberculous patient out of bed as soon as possible. If there are two fistulæ, cut one through, and when one wound has healed, cut the other. Some straight sinuses can be extirpated and the parts sutured, primary union occasionally resulting.

If a blind external fistula does not heal, every sinus must be incised, and thickened walls must be cut away or scraped away.

In a blind internal fistula an external incision is made to convert the case into a complete fistula, which is then treated as directed above.

In horseshoe fistula more than one operation may be necessary in order to avoid cutting the sphincter muscle twice in one operation, a proceeding which would probably lead to fecal incontinence. One side alone is operated on at one séance. Sinuses are opened and scraped, the sphincter is divided, the angles and edges of skin are trimmed away, and the wound is packed. When the wound is healed, or nearly healed, the other side should be operated upon.

Any operation will fail if it is not done thoroughly. Operative failure is common after fistula operations. The operation described above usually gives excellent results in simple fistula. It gives reasonably good results even when the internal opening is between the sphincters, although in that case it may leave distinct impairment of fecal control. If the internal opening is in and above the internal sphincter, the operation just outlined leaves as a legacy definite loss of sphincter control and great consequent discomfort (Mackenzie, "Treatment of Fistula in Ano"). For such cases, and particularly for horseshoe fistulæ, Mackenzie (Ibid.) does an operation which does not mutilate the sphincter. He dilates the sphincter; finds and dilates the internal orifice of the fistula; lifts the mucous membrane around it; pares it in the direction of the long axis of the bowel; trims the muscle in the direction of the circumference of the sphincter; sutures the muscle with catgut, the stitches passing at right angles to the fibers; sutures the mucous membrane with chromic gut; makes a flap on the side involved, the flap including the fistulous tract and all of its branches (in a horseshoe fistula he makes a flap on each side); removes all scar tissue from the rectal wall and enfolds the wall by catgut over the stitches within; removes all of the fistulous tracts from the flap, sutures the fat with buried sutures of catgut, inserts a small drain, and closes the skin.

If fecal incontinence results from an operation for fistula, remove the scar tissue and endeavor to suture the separated muscular fibers. A. W. Mayo Robson ("The Practitioner" Feb., 1903) performs the following operation for incontinence: A crescentic incision, from ½ to ¾ inch in depth and taking in about one-half of the circumference of the bowel, is made at the anterior border of the anus. The middle borders of the incision are then pulled apart until the ends of the cut approximate in the middle line, when they are stitched with deep catgut sutures and the skin is sewed with silk-worm gut, the immediate result being an incision apparently radiating from the anus. If there be a large defect in the muscles simple suture is impossible. The attempt to bring down adjacent muscles and to train them to sphincter function is futile. To constrict the intestinal tube is of no service when feces are soft. Rectopexy is useless. Plastic operations upon the sphincters have been devised (Koerble, "Arch. für klin. Chir.," 1916, cviii). Should an operation be undertaken for fistula if phthisis exists? Many of the old masters said *no*. Mathews sums up the modern view: In incipient phthisis operate; in rapidly progressive fistula operate whether cough exists or not; if much cough exists do not operate unless the fistula is rapidly progressive; in the last stages of phthisis do not operate.

Pruritus of the anus is a symptom and not a disease. It may be due to piles, fissure, seat-worms, eczema, nerve disturbance, kidney disease, gout, jaundice, constipation, inebriety, the opium-habit, torpid liver, dyspepsia, alcohol, tea-drinking, vesical calculus, tobacco-smoking, urethral stricture, uterine disease, diabetes, ovarian trouble, and mental disorder. In some cases it seems to be a pure neurosis and no special causative factor can be recognized. It is vastly more frequent in males than in females, and is especially common

in fat men who sweat profusely. It is seldom seen before the age of thirty, except in children suffering from thread worms. The itching comes on gradually and usually intermittently, but grows progressively worse and worse until it becomes torturing. In many cases it is at first noticed only when warm in bed; in other cases it exists day and night. A violent exacerbation may be excited by worry, anxiety, overwork, dietary indiscretion, a sudden change of temperature, and many other things. The itching finally becomes an unbearable agony, sleep, except in snatches, is impossible, the appetite disappears, the strength fails, and the sufferer may become a nervous wreck. In some cases of pruritus the anal folds are edematous, there are abrasions here and there from scratching, the area is white and moist and gives origin to a fine secretion; in other cases the mucous membrane is dry and fissured.

Treatment.—In every case first of all make a careful examination to find a probable or a possible cause, local, reflex, or constitutional, and endeavor to remove this supposed cause. Then undertake treatment for the pruritus. It is very important to prevent constipation. Kelsey directs that the parts be cleansed twice a day, and after each cleansing the following ointment be applied: Menthol, 1 dr.; cerat. simp., 2 oz.; oil of sweet almonds, 1 fl. oz.; acid carbolic, 1 dr.; pulvis zinc oxid, 2 oz. Mathews commends the following mixture: Chloral, 1 dr.; gum-camphor, ½ dr.; glycerin and water, each, 1 oz.[1] In this disease a "scarf skin" forms, which must be made to peel off by the application of iodin, pure carbolic acid, corrosive sublimate (4 gr. to 1 oz. of cosmolin), or calomel (2 dr. to 1 oz. of cosmolin). In obstinate cases paint the parts, night and morning, with a mixture of 60 gr. of alum, 30 gr. of calomel, and 300 gr. of glycerin; or smear with an ointment composed of ½ part of oleate of cocain, 3 parts of lanolin, 2 parts of vaselin, and 2 parts of olive oil (Morain). In very severe cases, in which the skin is dry and cracked, apply a 5 per cent. solution of eucain to the abraded portions and paint the entire surface with a concentrated solution of silver nitrate. It may be necessary to repeat this treatment several times at intervals of four or five days. Adler advised us to apply to the parts the day after the silver has been used unguentum hydrargyri nitratis in full strength, only discontinuing on the day a fresh application of silver is made, and the next day resuming the applications of ointment. If during treatment the skin becomes sore, use calomel ointment until soreness disappears. Violent attacks of itching are met by applying hot water and black wash or calomel ointment. This plan of treatment must be pursued for some months (Lewis H. Adler, Jr., "New York and Phila. Med. Jour.," July 29, 1905). I have used this plan with some satisfaction. In severe and protracted cases we may employ the *x*-rays twice a week (J. R. Pennington). I have seen their application productive of great benefit in the worst cases. In some cases we employ the Paquelin cautery, in others we resect the mucous membrane, as in Whitehead's operation for hemorrhoids. Ball divides the sensory nerves going to the implicated skin and has obtained excellent results. H. B. Stone ("Bull. Johns Hopkins Hospital," 1916, xxvii) has had success with injections of alcohol. He anesthetizes the parts by injecting a 1 per cent. solution of novocain or a 1 per cent. solution of urea hydrochlorid and quinin. A general anesthetic may be given instead of local anesthesia. The needle for the alcohol is carried through the skin vertically and is then placed horizontally under the skin. It must be found to be freely movable from side to side. Alcohol is injected beneath the area involved. The anal canal is not injected. This method is as beneficial as operation.

Fissure of the anus is an irritable ulcer at the anal orifice producing spasm of the sphincter. Pain exists because twigs of nerves are exposed upon the floor of the ulcer. Fissure is caused by constipation or traumatism. It is usually posterior.

[1] "Diseases of the Rectum."

The **symptom** is violent, burning pain, sometimes beginning during defecation, but usually at the end of the act, and lasting for some hours. Constipation exists, and often pruritus. Examination discloses a fissure, usually at the posterior margin, running up the bowel ¼ to ½ inch. Piles often exist with fissure.

Treatment.—The *palliative treatment* is to prevent constipation, to wash out the rectum with cold water, and apply an ointment made by evaporating 2 oz. of the juice of conium down to 2 dr., and adding it to 1 oz. of lanolin and 12 gr. of persulphate of iron. Pure ichthyol frequently promotes healing unless the edges are thick or the base indurated, when operation must be done. Many cases are so sensitive and painful to the touch that medication and examination are almost impossible. These may be made bearable by insufflations of orthoform.

Operative Treatment.—Anesthetize the patient. Thoroughly cleanse the parts. Some surgeons advocate operation without stretching the sphincter. It has always been my custom to stretch the sphincter for fissure. Stretching gives us room in which to work, and by thus paralyzing the muscular fibers the raw surface is put at rest and paroxysms of pain cease to occur. In order to stretch the sphincter the patient is anesthetized, the surgeon's thumbs are inserted into the rectum, and the parts are stretched slowly until the thumbs touch the ischia. After stretching the sphincter the fissure is incised through its base ¼ inch deeper than the deepest part of the ulcer, extending ¼ inch above and below the diseased tissues, so that the healthy muscular fibers at either end are divided. In cases in which the ulcer is at either the anterior or posterior commissure a V-shaped incision is made, the apex of which should begin ¼ inch above the highest point of the ulcer and the diverging line running close to the sides of the fissure, but in healthy tissue.

A search is made by a probe to be sure no pockets exist. Any pocket must be opened and scraped. The floor should be curetted and touched with the solid stick of nitrate of silver. If there are redundant edges, exuberant granulations, a sentinel pile, or a polypus, they should be curetted or excised. The wound is then packed lightly with gauze and the patient kept in bed for twenty-four hours.

Hemorrhoids, or Piles.—There are three varieties of varicose tumors of the rectum, namely: *external*, which take origin without the external sphincter; *internal*, which take origin within the external sphincter; and *mixed* hemorrhoids, which are a combination of the two.

External hemorrhoids are covered with skin. Internal hemorrhoids are covered with mucous membrane. The term "external hemorrhoids" is not strictly accurate, as hemorrhage does not occur in external piles, and all external piles are not related to the external hemorrhoidal veins. An external pile may involve the veins of the skin.

External hemorrhoids are classified as thrombotic, varicose, inflammatory, and connective-tissue external hemorrhoids (Tuttle).

Thrombotic External Hemorrhoids.—These are external hemorrhoidal veins filled with clot. When an external hemorrhoidal vein inflames the parts become itchy, painful, and swollen, and defecation increases the pain. The blood clots in the inflamed vein and sometimes the vessel ruptures.

Symptoms and Treatment.—External piles of this variety are usually, but not always, multiple. Small oval tumors appear beneath the skin or the junction of the skin and mucous membrane. They appear suddenly. The parts itch and pain, defecation increases the pain, and each pile increases rapidly in size. When the vein ruptures, a livid, soft enlargement rapidly forms. External piles of this variety may be absorbed, may become organized into a scar, or may suppurate. These piles do not bleed. In treating external hemorrhoids some surgeons merely use remedies to combat the in-

flammation. An old plan of treatment is to incise the blood-tumor, turn out the clot, and pack with a bit of iodoform gauze. Mathews freezes the part or injects cocain, catches up the blood-tumor with a volsellum, excises the tumor and the tabs of inflamed skin, dusts the part with iodoform, and dresses it with antiseptic gauze. The bowels should not be allowed to move for two days. Never inject external piles with carbolic acid; it causes great inflammation, violent pain, sloughing, and is not free from danger. If the patient declines operation, order rest, a non-stimulating diet, avoidance of tobacco (Mathews), the use of saline purgatives, injections into the rectum of cold water several times a day, sponging of the anus frequently with hot water, and the application of hot poultices. As the acute symptoms begin to disappear use extract of hamamelis locally; when they have nearly subsided, apply zinc ointment.

Varicose External Hemorrhoids.—They are varicose external hemorrhoidal veins and are visible at the anal margin when the patient strains. They rarely produce pain or discomfort, and it is seldom that operation is necessary. The bowels should be moved daily, but not with violent purgatives, and after each movement cold should be applied to the anus, while the patient is recumbent. Tuttle advocates the use at night of an ointment containing 2 dr. of suprarenal extract and 6 dr. of lanolin; this is spread on cotton-wool, which is applied to the anus and held in place by a T-bandage.

Inflammatory Piles.—By this term we mean edematous inflammation of the anal folds. The inflammation may be due to a traumatism, the presence of an ulcer or fissure, etc. There are burning, itching, and swelling of the anus, which are all greatly increased by defecation. One or more pear-shaped swellings can be seen at the anal margin.

In some cases medical treatment produces cure. This treatment consists, during the first twenty-four hours, in the use of cold and of rest in bed. After this period heat should be employed. Tuttle applies gauze soaked in a 25 per cent. solution of boroglycerid and places a hot-water bag over this. He also recommends the following ointment, to be applied two or three times a day:

℞. Morphinæ sulph. ..... gr. v–x;
Ichthyol. ..... ʒiv;
Ung. belladonnæ } ..... āā ʒj.
Ung. stramonii }
Sig.—Apply two or three times a day.

If these means fail, ether is given, the sphincter is stretched, and the tumors are cut away.

Connective-tissue External Hemorrhoids (Skin Tabs).—They are due to hypertrophy of mucocutaneous tissue at the anal margin. Usually they result from acute inflammatory external piles; sometimes they arise gradually as a result of chronic anal or rectal inflammation or irritation, and they may be due to varicose or thrombotic external piles (Tuttle). They produce no trouble when not inflamed. If they cause serious annoyance the treatment is extirpation.

Internal hemorrhoids are varicose tumors of the internal hemorrhoidal plexus, and are found internal to the external sphincter, just within the anus, and they prolapse easily. They are not simply varicosities, but new tissue has been formed, and they are, in reality, vascular tumors. They are covered with mucous membrane. *Capillary* piles are small, sessile, with a surface like a mulberry, and bleed freely. Children are not very liable to develop piles, excepting the capillary form. *Venous* piles are the most common variety. They extend from just above the anal margin for an inch or more. They are purple in color, soft, irregular in outline, and are usually multiple. They bleed when irritated by hard fecal masses, but not so easily as the

capillary piles. Each pile is composed of a varicose vein, some fibrous tissue, and a few arterial twigs. *Arterial* piles are very unusual. They are large, smooth, pedunculated, bleed easily and freely, and contain, besides a distended vein, arteries of some size.

Anything producing venous congestion in the rectum—constipation, diverticulitis of the sigmoid, diseases of the rectum, enlargement of the prostate, pregnancy, tumors of the womb, congestion of the liver, cirrhosis of the liver, certain diseases of the heart and lungs, sedentary occupations, relaxing climate, and stricture of the urethra—may cause hemorrhoids.

Symptoms and Treatment.—If there is neither bleeding nor protrusion the piles give no trouble. The first symptom is usually hemorrhage, and rectal examination by the speculum will make clear the condition. After a time, during defecation, the piles protrude; they may reduce themselves when the patient stands up, or it may be necessary to push them in. Pain does not exist in uncomplicated cases, and pain during or after protrusion means "abrasion, fissure, or ulceration" (Mathews).

Palliative Treatment.—This will not cure, but it will give great comfort. Some people only suffer at rare times when the liver is congested, and such subjects will not submit to operation. Remove, if possible, the cause (alcohol, irritating foods, want of exercise, etc.); restrict the diet; insist on regular exercise; give a course of Carlsbad salt, and follow this by the administration of bichlorid of mercury ($\frac{1}{24}$ gr. after each meal). Prevent constipation by a nightly dose of extract of cascara. After each bowel movement wash the parts with a soft sponge soaked in cold water, and syringe out the rectum with cold water and dry outwardly with a soft rag. If the hemorrhoids prolapse after restoring them and injecting cold water, insert a suppository containing 10 gr. of the extract of hamamelis and use another suppository at bedtime. A useful suppository for prolapse is that employed by Tuttle: it contains 5 gr. of ichthyol, 5 gr. of tannic acid, $\frac{1}{3}$ gr. of ext. of stramonium, $\frac{1}{3}$ gr. of ext. of belladonna, and 10 gr. of ext. of hamamelis. Bleeding may be arrested by suppositories, each containing 5 gr. of suprarenal extract. When the piles prolapse and inflame, rub Allingham's ointment on the parts (2 dr. each of ext. of conium and ext. of hyoscyamus, 1 dr. of ext. of belladonna, and 1 oz. of cosmolin). Mathews uses 12 gr. of cocain, 1 dr. of iodoform, $\frac{1}{2}$ dr. of ext. of opium, and 1 oz. of cosmolin. Grant uses an ointment containing 8 gr. of morphin, 12 gr. of calomel, and 1 oz. of vaselin. A small quantity of this is applied after bathing the part with hot water. If the piles are protruding and reduction cannot be effected, put the patient to bed, give a hypodermatic injection of morphin, and apply hot poultices. If reduction cannot soon be effected, divulsion of the sphincter must be practised or radical operation must be resorted to.

Operative Treatment.—Give a saline the morning before and an enema the evening before the operation, and wash out the rectum well the morning of the operation. In treating by *injection of carbolic acid* the sphincter should be divulsed while the patient is under the influence of nitrous oxid gas unless the pile be thrombotic. "Under gas muscular relaxation does not obtain as in the use of ether. Hence dilatation under gas can be more rapidly induced, as we have the sphincteric rigidity as a guide in knowing exactly how much force may be employed in the individual case" (Lewis H. Adler, Jr., in "Jour. Am. Med. Assoc.," Jan. 21, 1905). The surgeon must be careful not to tear the parts. The tumors are drawn out or, if gas has not been given, the patient strains them out. An injection is given by a hypodermatic syringe into the center of the pile, and as each pile is injected it is pushed into the rectum. Only one or two piles are injected at each séance, and the operation is not repeated for one week (Geo. W. Gay, in "Boston Med. and Surg. Jour.," Dec. 5, 1901). The dose for each pile is 1 or 2 min. of a 10 per cent. solution of carbolic acid. The

injections relieve the condition, but are rarely absolutely curative and are not without danger, and may produce abscess, sloughing, hemorrhage, phlebitis, pyemia, stricture, and even death (W. T. Bull-Kelsey). Dr. Collier F. Martin ("American Medicine," August 27, 1904) maintains that the method is safe and satisfactory. He injects equal parts of a French preparation of phenol and distilled water, freshly mixed and filtered. From 7 to 15 min. are injected into a pile and only one pile is injected at a séance. In from five days to one week another injection may be given. Before beginning a course of injections the sphincter is stretched while the patient is under nitrous oxid and oxygen. It is not necessary to repeat this for future injections. During injection a special speculum is used. The pile protrudes into the speculum, is cleansed with a 1 per cent. solution of creolin, and the injection is thrown into the most prominent part of the pile. The speculum is withdrawn before pulling out the needle. This maneuver prevents escape of injection and arrests bleeding. I seldom employ the injection treatment. I never use it if the patient consents to the clamp and cautery operation or to ligation. The *clamp and cautery* is, in the great majority of cases, the operation of choice. It requires but a few minutes to do it; after it is done there is little or no postoperative pain, in very many cases retention of urine does not occur, and the patient usually is about again within ten days. The patient is anesthetized and the sphincter

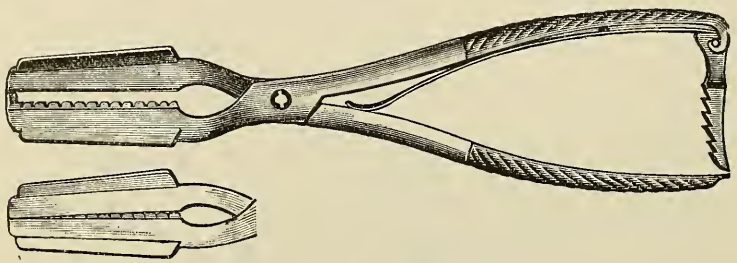

Fig. 863.—Brick's pile clamp.

is carefully and thoroughly stretched. The stretching of the sphincter is very important. It gives free access to the parts, prevents subsequent spasm and pain, and lessens the likelihood of venous bleeding after operation. The pile is caught by forceps and drawn outside of the sphincter. Many use Smith's clamp. It is applied with the ivory surface against the mucous membrane of the bowel. I use the clamp devised by Dr. J. Coles Brick (Fig. 863). From the bite of Brick's clamp the pile cannot slip, as the blades come evenly and firmly together. The pile is cut off and the stump is seared with the Paquelin cautery at a dull-red heat. Pile after pile may be thus treated, care being taken to leave some mucous membrane at each side of every pile. If this precaution be not taken, healing will be slow and stricture will result. After cauterization is complete a speculum is inserted and the blades are widely opened. Any bleeding points are at once ligated. This is a most important precaution. Packing is never inserted. I formerly used it, but have given it up. It is of no service and produces severe pain and edema. The treatment from this point is identical with that advised below after the use of the ligature. *Excision* is preferred by Allingham. He stretches the sphincter, holds it open with a retractor, catches up the pile, cuts it off, and twists the bleeding vessels. Some prefer to pass a silk or catgut suture, cut off the tumor, and tie the thread (Fig. 864). *Whitehead's operation* (Fig. 865) is only to be performed in severe cases, when the piles are extremely large and form a protruding circular mass. Primary union is rarely secured. When first introduced the operation was viewed with favor, but experience shows it is sometimes followed by disastrous conse-

quences.[1] Stricture not infrequently arises after its performance; fecal incontinence occasionally results, and anal anesthesia with inability to restrain the passage of gas is common. After this operation the anus is permanently more or less moist. The entire pile-bearing area of mucous membrane is dissected out and the cut margin of mucous membrane is pulled down and stitched to the surface. The sphincter may be dilated as a preliminary measure.

Fig. 864.—Extirpation of hemorrhoids (Esmarch and Kowalzig).

The *application of the ligature* is an easy and useful method. It is not so rapid as the cautery, is followed by more pain, healing requires a longer time, and stricture is more common. In this operation, after anesthetizing, stretch the sphincter and treat each hemorrhoid separately. Catch a pile with a pair of forceps or a volsellum, pull it down, and cut a gutter through the skin-margin if the pile is of the mixed variety; tie the small piles without transfixing, but transfix the large piles; tie with silk (coarse silk for the large piles, finer silk for the small piles); cut off each tumor beyond the thread and cut the ligatures short. Treat the other piles in the same manner. Irrigate with hot normal salt solution. Do not insert packing. Place a 2-gr. opium suppository in the rectum. Apply a gauze pad and a T-bandage over the anus. The opium locks up the bowels. The patient is kept on a light diet for three days, at the end of which time a saline may be given. Just before the bowels act remove the dressings and give an enema of warm water or of glycerin or of glycerin mixed with olive or linseed oil. After the movement wash the parts first with dilute peroxid of hydrogen and next with hot salt solution, dust with iodoform, and apply a gauze pad over the anus. Irrigate daily until healing is complete. After the tenth day examine with a speculum to see that the ligatures have come away; if any are found in place, remove them.

Prolapse of the Rectum.—If the mucous membrane be prolapsed the condition is commonly called *prolapsus ani;* if the entire thickness of the rectal wall be prolapsed, it is commonly called *prolapsus recti* (Fig. 866). The term "prolapse of the anus" is an incorrect and objectionable one, and we should designate such cases *prolapse of the rectal mucous membrane, incomplete* or *partial prolapse.* If all the coats of the bowel descend the condition should be called *complete prolapse* or *procidentia.*

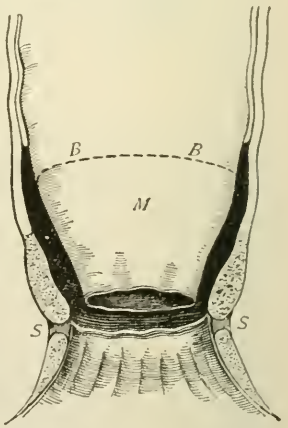

Fig. 865.—*S*, *S*, The lower circular incision along Hilton's white line; *M*, tube of mucous membrane dissected from the sphincter; *B*, *B*, dotted line showing the place for the upper circular incision (Edmund Andrews).

Incomplete Prolapse (Partial Prolapse).—In this condition the mucous membrane of the rectum protrudes from the anus. In normal conditions the membrane protrudes during defecation and at once retracts when the act of defecation terminates. In the condition under discussion the mucous membrane remains protruded because the submucous tissues, being stretched and relaxed, find it difficult or are unable to draw the mucous membrane in again. In this condition a ring of mucous membrane or only a portion of its circumference may protrude. It is particularly common in early youth and in old age. Prolapse is apt to occur from excessive straining at stool and is commonest in feeble, ill-nourished children. A polypus may be the cause. Piles and worms may lead to prolapse. Straining from phimosis, stone in the bladder, or urethral stricture may be

[1] Andrews, in "Mathew's Medical Quarterly," Oct., 1895.

causative. Its development is favored by the use of articles of food which cause frequent movements of the bowels. If an individual sits a long time on the seat of the closet or on the chamber the development of prolapse is favored. The condition comes on gradually and is at first painless. For some time it reduces itself spontaneously after defecation, but reduction becomes more and more difficult. A common custom of sufferers is to push it by the fingers above the grasp of the sphincter. Sometimes, but seldom, it becomes strangulated. A recent prolapse is pink, an older one is angry red; one which is tightly caught is purple; a strangulated one is deep purple and soon becomes black from gangrene. If the prolapse be of the entire circumference it shows radial folds of mucous membrane. It frequently bleeds. Prolapse, be it large or small, tends to recur again and again, and eventually the mucous membrane inflames, ulcerates, or sloughs. Prolapse of all the coats may ensue (see below). The condition is sometimes confused with hemorrhoids, but in

Fig. 866.—Rectal prolapse.

prolapse the protruding mass is circular and has a depression in the center, whereas hemorrhoids are distinct masses. Further, hemorrhoids are very rare in children. Hemorrhoids often exist with prolapse of the mucous membrane and frequently cause it. In prolapse of the mucous membrane there is no sulcus between the sphincter muscle and the anterior portion of the protrusion; in complete prolapse there is.

Treatment.—*Palliative* treatment forbids straining at stool and amends an improper diet. Phimosis must be corrected; stone in the bladder must be removed; stricture must be dilated; hemorrhoids and polypi are to be removed. Give an enema of cold water just before going to stool in order to hurry the emptying of the rectum. If prolapse occurs, the protrusion must be bathed with cold water and restored. Constipation must be prevented (enemata of water or glycerin may be used), and after each movement several ounces of an infusion of white oak bark (1 ounce of quercus to a pint of water) should be injected. If a prolapse is caught firmly, paint it with cocain and adrenalin, place the patient in the knee-chest position, apply

hot compresses, grease it with cosmolin, insert a finger into the rectum, and apply taxis around the finger (Mathews). If this fails, cover a finger with a handkerchief and insert the wrapped digit into the rectum; if this proves futile, invert the patient before manipulation. Do not give a general anesthetic unless it is imperatively necessary; the vomiting so often caused by ether and chloroform might reproduce the prolapse. After reduction apply a compress to the anus, direct that it be worn when at stool, and before each act of defecation give an injection of cold water containing an astringent (tannin or fluidextract of hydrastis). Most cases in children can be cured without operation. Some cases in adults and obstinate cases in children may be treated by painting the prolapse with fuming nitric acid, greasing it with olive oil, and restoring it. Some cases require excision of the mucous membrane, the divided edge of this membrane being stitched to the skin. In other cases the protrusion is stroked longitudinally with the actual cautery and restored. When the surgeon comes to operate for recurring prolapse, it will often be found to have modestly withdrawn and he may be obliged to stretch the sphincter to bring it into view.

Complete Prolapse (Procidentia).—In this condition all of the rectal coats protrude. There are said to be three degrees of this condition. In the first degree the prolapse begins at the anal margin and its outer surface is continuous with the peri-anal skin, there being no sulcus between. It is usually a consequence of prolapse of the mucous membrane. In the second degree (genuine procidentia) the prolapse begins on a level or above the level of the lower margin of the peritoneum and projects out of the anus. In the third degree the prolapse begins at the origin of the rectum or in the sigmoid, and is, in reality, a protruding intussusception. Some cases come on suddenly. The prolapse of the first degree has no furrow between it and the perianal skin, and the folds are circular instead of longitudinal. It is usually treated as is prolapse of the mucous membrane. If simple methods fail, it will be necessary to do an operation to lessen the size of the anal orifice. In prolapse of the third degree the treatment is as for intussusception. It is prolapse of the second degree that we consider here. It is more common in adults than in children. There are many theories as to its causation. Esmarch regards it as due to inflammation of the rectum, which spreads to all the coats and also to the perirectal structures. Another theory (Jeannel's) is that the small intestine is in a state of ptosis, and by falling into Douglas's culdesac presses upon and causes atrophy of the levator ani muscle. The most probable theory is that the condition is, in reality, hernia (Waldeyer, Zuckerkandl, Moschcowitz). Moschcowitz ("Surg., Gynec., and Obstet.," July, 1912) makes a powerful argument to prove that the intestine in Douglas's culdesac causes a bulge of the anterior rectal wall, that this bulging part of the wall grows larger and descends, and that finally the entire circumference of the rectum is dragged down.

Complete prolapse is usually preceded by chronic constipation, great straining being necessary to effect defecation. Chronic rectal catarrh is also a common antecedent.

A mass sticks out of the rectum and there is a purulent discharge which often contains blood. The protruding mass (which is seldom over 6 inches in length) is covered externally with mucous membrane (which may be normal, inflamed, ulcerated, or bleeding) and is lined by normal mucous membrane (Moschcowitz, Ibid.). The opening is at the apex of a canal directed backward. The anterior part of the protrusion is much larger than the posterior part, the anterior part is usually tympanitic, and the posterior part dull on percussion (Moschcowitz, Ibid.). There is a deep furrow between the anterior portion of the sulcus and the anal margin. The furrow, as a rule, is about 1 inch deep.

Early in the case the prolapse is reduced spontaneously, later it must be

reduced by the hand. It may become incarcerated or strangulated. The protrusion when strangulated becomes gangrenous.

Treatment.—In children the condition may often be cured by the methods used for prolapse of the mucous membrane. If a prolapse is caught tightly, apply hot compresses to reduce swelling, paint it with cocain and adrenalin, put the patient in the knee-chest position, and reduce as described under partial prolapse. General anesthesia is undesirable because of the probability of vomiting with consequent straining. After reduction apply a support. Electricity is used by some, injections of astringents under the mucous membrane by others. Operation is necessary for prolapse in most adults and in some children. As a preliminary, hemorrhoids, ulcerations, etc., must be cured. A multitude of operations have been recommended. Some try to constrict the anal opening (cauterization by the actual cautery, nitric acid or chlorid of zinc, removing a wedge-shaped piece from posterior rectal wall followed by suturing, twisting the rectum, injections of paraffin about the sphincter, and various other plans). Such operations are entirely inefficient. Some operate on the bowel higher up, striving to increase support. Moschcowitz also mentions "methods which pay particular attention to the fixation apparatus of the rectum." One plan is to operate through an abdominal incision, fixing the sigmoid to the abdominal wall—an unphilosophical operation "because the distal end of the sigmoid is fixed to the sacrum, and pulling can have very little, if any, effect upon the prolapse of the rectum" (Moschcowitz, Ibid.).

I have abandoned the operation of stitching the sigmoid to the abdominal wall (*colopexy*) because it is dangerous thus to anchor the gut and because, I believe, it always fails to cure. Mikulicz's operation of excision of the prolapse has elements of decided danger, but may cure the case. I apparently cured 1 case this way, but in another case the condition recurred.

Moschcowitz's operation is the most reasonable one. The abdomen is opened, the rectum is held taut, and the culdesac of Douglas is obliterated by silk or linen sutures. The pelvic fascia is included in the sutures.

Ulcers of the rectum are divided into the simple traumatic, the syphilitic, the tuberculous, the dysenteric, the gonorrheal, and the malignant. *Simple* ulceration is due to abrasion with fecal masses or a foreign body, the abraded area ulcerating. It may follow an operation for piles and also protracted labor ("Diseases of the Rectum," by Allingham), and is apt to be single. The base and edges of a simple ulcer are neither prominent nor hard and stricture rarely forms. *Syphilitic* ulceration is a tertiary lesion commonest in women. There are numerous small ulcers of the mucous coat or submucous tissue, but little indurated, with sharp-cut edges which are not undermined. These ulcers fuse and constitute one large irregular ulcer; fibrous tissue forms in the wall of the bowel, induration becomes noticeable, and stricture follows. There is profuse discharge and fistulæ are apt to form. Such ulcers may be surrounded by nodules of a bluish color. In many cases the first condition is stricture due to the formation of masses of fibrous tissue in the rectal walls, and ulceration occurs secondarily. In syphilis there may be a breaking down of a huge gummy mass or of multiple gummata. It has been proved by the microscope that tuberculous ulceration may arise in the rectum. *Tuberculous* ulceration presents a conical ulcer with overhanging edges and a pale-red base. There is some mucous discharge, some tenesmus, and a little pain. Tuberculosis is seldom *directly* responsible for stricture (see page 1325). Dysentery, catarrh, diabetes, Bright's disease, neoplasms, and foreign bodies may produce ulceration of the rectum.

Symptoms.—There may be merely uneasiness about the rectum, but sometimes there is severe burning pain on defecation, and perhaps for some time after the act. There may be constipation or diarrhea; the patient strains at stool, and the stools may contain blood, mucus, or pus. As a rule, there is

diarrhea on rising in the morning, the first movement consisting of blood and mucus, and the next movement being fecal. The history should be carefully inquired into; tuberculosis should be sought for; the question of syphilis should be investigated. A digital examination enables the surgeon to feel the ulcer, and an examination by means of an ordinary speculum or an electric proctoscope brings it into view.

Treatment.—In *simple* ulcer empty the bowel by the administration of a saline cathartic, wash out the rectum with hot water after the saline has acted, introduce a speculum, touch the ulcer with pure carbolic acid or silver nitrate (40 gr. to 1 oz.), place the patient in bed, restrict him to a liquid diet, and every day inject iodoform and olive oil (10 per cent.) or insufflate iodoform into the rectum. If this fails, give ether, stretch the sphincter, incise the ulcer through its entire thickness, and cauterize with fuming nitric acid, caring for the case subsequently as we would a patient who had had piles ligated. In *tuberculous* ulcer improve the general health, send the patient to a genial climate,

FIG. 867.—Papilloma of anus and rectum.

or at least into the sunlight and fresh air, prevent constipation, give nutritious food, especially fats, wash out the rectum every day with hot water, and insufflate iodoform or inject iodoform emulsion. Touch the ulcer once a week with silver nitrate (10 gr. to 1 oz.). In *syphilitic* ulcer give antisyphilitic treatment and treat the ulcer locally, as is done in tuberculous ulcer. *Dysenteric* ulcer requires injections of hot water, the touching of the ulcer with pure carbolic acid, insufflations of iodoform, and special treatment of the dysentery.

Benign Tumors of the Rectum and Anus.—These tumors may be of the connective, epithelial, or muscular tissue type. Of the first there are fibroma, enchondroma, lymphadenoma, lipoma, and myxoma; of the second, adenoma and papilloma; of the third, myoma and fibromyoma. Many benign tumors appear in polypoid form. A polyp is a tumor with a pedicle. A polyp may be a fibroma, myxoma, myoma, papilloma, or adenoma. Papilloma is a rare growth, usually has a broad pedicle, but may have no pedicle. It does not occur in childhood. A papilloma bleeds profusely and causes a discharge of mucus. A polyp causes no pain unless ulceration occurs. It

causes bleeding and mucous discharge. On coming from stool the patient feels as though the rectum still contains feces. A polyp may protrude during defecation. It can be detected by digital examination and can be readily seen through a proctoscope. There may be one polyp; two, several, or many polypi. Polypi are most common in children. (See Adler, in "Annals of Surgery," Dec., 1909.) The most common forms of tumor are the myxoma, hypertrophied solitary follicles, adenoma, fibroma, and lipoma. Myxoma is most common in children. Fibroma originates in the connective tissue or the submucosa and is very rare. It may arise at the upper end of a fissure. It has a long pedicle and may become very large.

Symptoms of tumor are dull, aching pain, tenesmus, frequent defecation, and sometimes ulceration of the mucous membrane. In a non-polypoid benign tumor there is absence of hemorrhages and of mucous discharges.

Treatment.—Remove the tumor after dilating the sphincter. In tying or snaring off polypi it should be borne in mind that the peritoneum may be invaginated in the pedicle and, therefore, no traction on it should be made when operating. Sessile growths are dissected out. The postoperative treatment is practically the same as for hemorrhoids.

Cryptitis (*Inflammation of the Crypts of Morgagni*).—These crypts, five to ten in number, are situated in the mucous membrane of the rectum, about 3 cm. from the anus. They occasionally become packed with mucus or feces. There is quite severe pain referred to the site, especially after defecation. In this condition the examination of the anus by the finger is extremely painful. The inflamed crypts may be detected by examination through the speculum.

Treatment.—Divide the affected crypts, curet away any granulations, and allow the parts to heal.

Non-cancerous stricture of the rectum may be congenital or acquired. There are two forms of acquired stricture: first, stricture due to external pressure; second, stricture due to primary narrowing of the rectal lumen.[1] Stricture due to external pressure is very rarely complete, and may be caused by bands of adhesions or a tumor growth. The second form may be produced by syphilitic tissue, ordinary inflammatory tissue, cicatrices after operations, sloughing, tuberculous, syphilitic, or dysenteric ulceration, rectal gonorrhea, and traumatism. The usual seat of simple stricture is from 1 inch to 1½ inches above the anus. The deposit may be limited to the submucous coat or all the coats may be involved. It is very seldom that stricture arises as a result of abrasion from fecal masses or foreign bodies. It may follow an operation for piles if considerable tissue be removed, and is an occasional sequence of Whitehead's operation. A perirectal inflammation may be responsible. Stricture due to dysentery is extremely rare, and no case has ever been reported to the United States Pension Office (Peterson). The existence of stricture as a result of rectal gonorrhea has not been positively proved. A majority of sufferers from rectal stricture have labored under syphilis, but it is not probable that the lesion is syphilitic in all or even in most of them. The stricture may be due to the formation of fibrous tissue and ulceration may or may not occur. It may be caused by the contraction and healing of a large ulcer. Along with syphilitic ulceration comes great connective tissue hyperplasia, a hyperplasia so great that the rectum becomes a thick rigid, nodular, immovable tube. Most cases of syphilitic stricture occur in women. Some maintain that tuberculous stricture does occur. Mathews dissents from this view and points out that the tendency of tuberculous matter is to break down, and before the rectum can form a stricture from tuberculosis it breaks down from ulceration. Peterson[2] says a large proportion of the victims of rectal stricture die of phthisis, and that one-third of so-called syphilitic cases are tuberculous. It may begin as an ulcer or as an infiltration of submucous tissue.

[1] Reuben Peterson, in "Jour. Am. Med. Assoc.," Feb. 3, 1900. [2] Ibid.

Although a syphilitic or a tuberculous lesion may cause rectal stricture, in most cases such lesions simply expose the tissues to infection, and benign rectal stenosis results from the infection. Tuberculosis may cause stricture, but does so indirectly rather than directly.

The symptoms of rectal stricture are constipation, pain on defecation, straining at stool, perhaps the presence of blood and mucus in the stools, an open anus, and the passage of stools flattened out into ribbons if the stricture be low down. In some cases there is fluid diarrhea, solid fecal matter being retained above the stricture. The stricture is found by the finger or by the soft-rubber bougie, used with the utmost gentleness and care. A stiff instrument or the rough use of any instrument would be dangerous and might rupture the rectum. In syphilitic cases, in tuberculous cases, and in benign cases the fibrous thickening is usually in the submucous coat, and in syphilitic and tuberculous cases the mucous membrane is apt to ulcerate. It is said that complete obstruction may arise. I have seen obstructive symptoms, but never *complete* obstruction in rectal stricture. Distention of the abdomen and colic are very usual.

The tratement of non-cancerous and primary narrowing of the rectal canal is rest, non-stimulating diet, warm-water injections, mild laxatives, and hot hip-baths. Cocain suppositories may be needed. Any existing disease is treated. Bougies are passed every other day. Use a soft-rubber bougie, warmed and oiled, and introduce it gently. If the method of gradual dilatation alone be employed the patient must, for the remainder of his life, pass a bougie from time to time. For fibrous strictures forcible dilatation (*divulsion*) by a special instrument is employed or incision is practised. Incision (*proctotomy*) may be either external or internal. In internal proctotomy one or more incisions are made from the rectum through the stricture down to healthy tissue, the first cut being in the middle line posteriorly. External proctotomy, which divides the sphincters, is apt to leave incontinence as a legacy. Electrolysis finds some advocates, but on what grounds it is difficult to see. In some cases the rectum should be removed by Kraske's resection, the sphincters being spared and the ends of the gut being united. In incurable cases perform iliac colostomy.

Cancer of the rectum is the cancer of the bowel most often met with. According to Abbe ("Keen's Surgery") rectal carcinomata constitute three-fourths of all intestinal tumors. Its growth may be primarily malignant or may arise from an adenoma. The commonest growths are composed of columnar cells, and may be either soft or scirrhous. In cases secondary to epithelioma of the anus ordinary epithelioma arises.

In most rectal carcinomata the cells present a tubular arrangement surrounded by a more or less plentiful stroma of connective tissue. In soft tumors the connective tissue is scanty; in hard tumors it is plentiful. The softer the growth the greater its malignancy and the more rapid its progress. Scirrhus is met with more frequently than encephaloid. Either form may undergo colloidal change. Scirrhus begins as a nodule in and under the mucous membrane and ulceration is late. In soft cancer ulceration is early.

Sixty-five per cent. of cases are in men. Cancer is most common after the age of forty, but it not unusually occurs before the thirty-fifth year, and is sometimes seen as early as the twenty-fourth year or even earlier. I operated upon a man of twenty-seven and upon another of thirty-one. "Of 115 cases of cancer of the rectum at the Rostock Clinic, 4 occurred in patients between fourteen and seventeen years of age" (Miles Porter, in "New York Med. Jour.," Feb. 10, 1912). Most commonly the lower margin of the growth is on a level with the internal sphincter. Extensive ulceration occurs in the growth and may also occur above the growth. If a hard ring encircles the rectum the lumen of the tube is greatly and progressively diminished. In cases of diffuse infiltration the lumen is not greatly lessened. In growths involving the

anus, the inguinal glands are involved and also the glands in the hollow of the sacrum. In growths limited to the rectum proper, the glands back of the peritoneum in the sacral hollow are involved, and the inguinal glands are involved late or not at all.

Symptoms.—In the beginning and for a considerable time after there are no symptoms. There may be none for a year or more. Symptoms begin with ulceration or constriction. The symptoms of rectal cancer are like those of non-malignant stricture, except that the pain is usually greater and the hemorrhage more severe. Constipation is apt to alternate with diarrhea. The diarrhea is usually in the morning. Unfortunately, in many cases symptoms are long trivial; in fact, pain may be absent until the disease is far advanced. Mucopurulent or bloody stools are often thought to result from dysentery or hemorrhoids, which latter condition, however, may be only an accompanying condition of rectal cancer. The above symptoms may, on the patient's say-so, have been accepted by the physician, without any local examination, as caused by hemorrhoids. The patient, again, may have only imagined the presence of hemorrhoids, since, according to his notion, the above symptoms must result from hemorrhoids, with which condition so many of his friends with like complaints are afflicted. Loss of strength, emaciation, and cachexia are generally noticeable in the late stages only of rectal cancer. Tenesmus becomes unbearable. In the very latest stages only is the characteristic odor perceptible, the patient becomes septic, and abscesses attended by gangrene may form (Ernest Jonas, in "Interstate Med. Jour.," No. 4, 1906). The finger and the speculum make the diagnosis. The finger and speculum must be inserted most gently lest perforation be caused. In many cases of cancer the anus becomes funnel-shaped because contraction shortens the rectum and much wasting of fat occurs. In rectal cancer metastasis occurs late. The most favorable cases for operation are those in which the growth is small and movable. Accurately define the extent of the growth, and endeavor to make out if it has invaded the cellular tissue outside of the rectum, the prostate, the bladder, the sacrum, the uterus etc. Invasion of the bladder or prostate soon causes very distressing symptoms. Sooner or later metastasis occurs to the liver. If unoperated upon cancer of the rectum gives a prospect of life of from one to five years. I have seen nodules in the liver three months after the first symptoms of rectal cancer were observed and I have seen a man alive six years after symptoms appeared.

Treatment.—In every case of cancer of the rectum the following questions must be considered: Shall we perform a radical operation in hope of producing cure or at least greatly prolonging life? In what cases should a radical operation be attempted? It is the proper procedure if there are no metastatic deposits, if the patient is in fair general condition and free from serious organic disease, and if the cancerous bowel is movable and not fixed by dissemination to adjacent structures. As W. Watson Cheyne ("Brit. Med. Jour.," June 13, 1903) says, a slight adhesion to the vagina is not a contra-indication, because this portion of the vagina can be readily removed with the diseased rectum. Some surgeons will not attempt radical operation if they cannot pass a finger through the growth. I do not regard high position as forbidding operation, although, of course, it makes it more dangerous to life and less promising as to cure. Cheyne is of the same opinion. When the surgeon is first called to a case of cancer of the rectum it is usually found to be so far advanced as to be inoperable. In at least 75 per cent. of my cases radical extirpation was impossible when I first saw the case.

If a radical operation be determined on, the next question to answer is, Shall we, or shall we not, perform *preliminary colostomy*? If the cancer is very low down, involves the anal canal, and is to be removed from the perineum, preliminary colostomy is rejected by many. I believe that even in such cases it should be done. If the cancer be high up and we propose to attack it by

Weir's method or the Quénu-Mayo method, preliminary colostomy should not be done. If Kraske's operation is to be performed, I believe preliminary colostomy is usually indicated. It enables us to cleanse the area upon which operation is to be performed, and to keep the wound clean, and gives us a much better chance of obtaining primary union. In cases in which the sphincter is retained and it is possible to anastomose the divided ends of the gut together, colostomy is not necessary; and if an artificial anus has been made in such a case, another operation will be required to close it. As a matter of fact, I have found it always difficult and usually impossible to suture the divided ends of the gut together after Kraske's operation, and I now follow the advice of Keen, and always precede Kraske's operation by colostomy. The abdominal incision necessary to reach the bowel to do colostomy may be used to permit of exploration, but it is wiser to have a median incision for this purpose. I consider exploration of the first importance. It enables the surgeon to examine the outer surface of the rectum, to detect glandular involvement, to find out if there has been metastasis to the liver, and to determine with certainty whether or not the cancer is operable. Several times in cases of small and apparently operable cancer of the rectum I have found on opening the abdomen extensive glandular involvement or unsuspected metastasis to the liver, and once I found another cancer 4 inches above the one to which attention had been directed. It is my custom to make a median incision for exploration and then a small incision through which to bring out the gut for colostomy. A large abdominal incision for colostomy is objectionable. I strongly object to operating at all on rectal cancer without a preliminary exploratory operation. If radical operation be rejected (and about three-fourths of the cases, when first seen by the surgeon, are obviously beyond such aid), palliative treatment is desirable. The best palliative treatment is the operation of inguinal colostomy. If this be refused, what shall be done? One plan is to introduce a tube through the stricture daily, wash out the rectum with warm water, and after washing inject emulsion of iodoform (10 gr. to 1 oz. of sweet oil). Injections of chlorid of zinc (1 gr. to 1 oz. of water) lessen the foulness of the discharge. The bowels are opened regularly by laxatives, and if the growth causes obstructive symptoms it is scraped away with a sharp spoon. Opium is given to relieve pain. The advantage of this plan is that the patient does not suffer from the unpleasantness of an artificial anus. Sooner or later, however, the growth gets outside of the bowel, and terrible pain will arise from involvement of the sacral plexus. W. Watson Cheyne ("Brit. Med. Jour.," June 13, 1903) would restrict palliative treatment of this character to cases in which fungating masses grow from one side of the bowel.

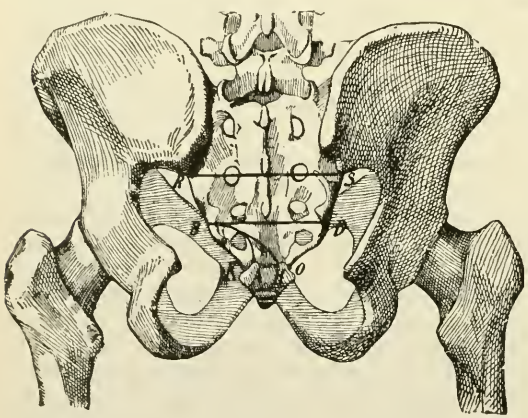

FIG. 868.—Different levels of resection of the sacrum: *K–O*, Kocher's line; *B–O*, Kraske's; *B–H*, Hochenegg's; *B–D*, Bardenheuer's; *R–S*, Rose's (Mass.).

If a growth encircles the bowel and produces symptoms of obstruction, *palliative colostomy* should be performed. This operation gives great comfort to the patient and allays pain by intercepting the feces before they reach the cancer. I am not convinced that it distinctly retards the growth of the cancer or notably

prolongs life. Unfortunately, colostomy does not do away with pain if the sacral plexus be involved. I have had no experience with radium in inoperable cancer of the rectum and have never seen the *x*-rays produce any marked or lasting improvement. *Operative treatment* includes one of several procedures. Excision of the rectum from below (*Cripps's operation*) is practised by some if not more than 3 inches require removal, if the peritoneum is not invaded, and if the adjacent organs are free from disease. The peritoneum must not be opened in Cripps's operation. After the growth is removed the divided rectum is pulled down and sutured to the skin. As the sphincter is sacrificed the condition would be dreadful without an artificial anus. A perineal anus without a sphincter is vastly more distressing than an inguinal anus. I seldom do perineal excision (it does not permit any considerable removal of lymph-glands). When of recent years I have done it I have preceded it by exploratory laparotomy and the formation of an inguinal anus. In some cases in women it may be possible to remove a low growth without damage to the sphincter through an incision in the posterior vaginal wall. Excision of the rectum after excision of the coccyx and a portion of the sacrum (*Kraske's operation*, that is, excision of the rectum after sacral resection, Fig. 868, *B–O*) is a procedure which permits removal of the entire tube, portions of the colon, and even of adjacent parts. The peritoneum is opened deliberately in this operation, and is subsequently closed with sutures before the gut is opened. The glands in the mesocolon are always

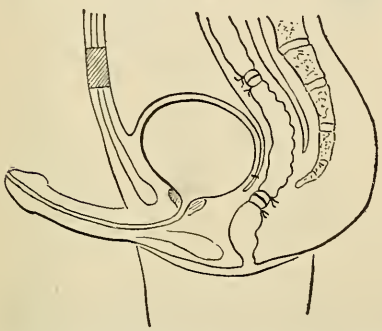

Fig. 869.—Tying off the tumor through an abdominal incision after separating peritoneum from sacrum and bladder (Weir).

Fig. 870.—Lower end of rectum everted through the anus and the upper end of bowel drawn out of the abdominal cavity (Weir).

removed. The lower end of the upper segment of bowel is fastened in the wound, or, if colostomy has been previously performed, may be closed. In some few cases in which it is not necessary to remove the lower end of the rectum, the two portions may be anastomosed after resection of a part of the tube. Kraske's operation may be done by an osteoplastic method, the bone not being removed. It is well to precede a Kraske operation two weeks by an inguinal colostomy, which permits of cleansing the lower bowel of feces and lessens the chance of severe wound infection and delayed healing after the removal of the rectum. Preliminary colostomy may make the operation of extirpation more difficult by fixing the intestine, and thus interfering with the necessary drawing down of the gut ("Operative Surgery" by E. H. Taylor). If the growth is extensive and the mesocolon short, it may be best to perform right inguinal colostomy, but in most cases left inguinal colostomy is preferred (Gerster). The colostomy remains open during the patient's life, except in those rare cases of Kraske's operation in which the continuity of the rectum can be reëstablished after excision of the growth. In such cases the artificial anus may be closed some time after resection of the rectum.

Robt. F. Weir ("Med. News," July 27, 1901) has been so much impressed with the difficulties and dangers of Kraske's operation in a case of high car-

cinoma that he now employs it solely in cases in which there is freedom from disease for 2 inches immediately above the anus and in which the cancer does not extend more than 5 inches above the anus. In high cases he does the following operation: Open the abdomen above the pubes, separate the peritoneum so that the bowel and "contents of the sacral curve" are liberated behind nearly "to the tip of the coccyx and in front of the edge of the prostate." The tumor is then tied off with tapes (Fig. 869). The portion of the rectum bearing the tumor is removed, the lower end of the bowel is everted through the anus, and the upper end is drawn out of the abdominal incision (Fig. 870). The upper end is then caught with forceps and drawn through the everted lower end of the rectum (Fig. 871, *a*). The ends of the two everted portions (Fig. 871, *b*) are sewn together, the everted bowel is replaced, the divided peritoneum is sutured to shut off the peritoneal cavity, and posterior drainage is inserted (Fig. 872). In the Quénu-Mayo operation the object is to remove all of the diseased glands as well as the cancer (Wm. J. Mayo, in "St. Paul Med. Jour.," April, 1906). The patient is placed in an exaggerated Trendelenburg position and the belly is opened by a median incision. The growth is studied to see if it is removable, and a search is made for enlarged glands which might cause us,

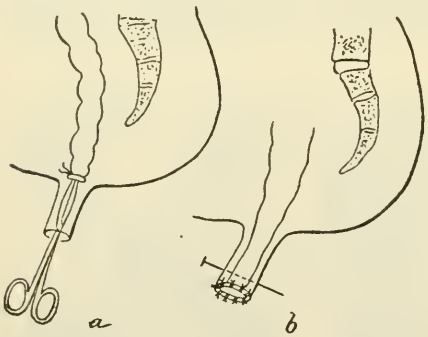

FIG. 871.—*a*, The upper bowel drawn out through the everted lower end of rectum; *b*, the ends of the two portions of the rectum sewn together (Weir).

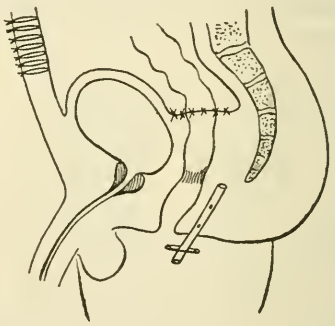

FIG. 872.—The united bowel replaced with posterior drainage and the divided peritoneum so sewn together as to shut off the general peritoneal cavity from the pelvis (Weir).

and for secondary growths which would cause us, to abandon the operation. If we conclude to attack the growth, pack away all the intestine except the sigmoid, catch two clamps across the sigmoid, one of them being on the level of the sacral promontory. Divide the gut between them. Free the mesosigmoid by lateral cuts and bring the proximal stump out of the belly, ligate it, and apply a purse-string suture to invert it. A gridiron incision is then made on the left side and the proximal stump is pulled through it and is sutured there. Incisions are now made in the sides and in front to liberate the rectum, the inferior mesenteric artery is tied above and to the left of the promontory, the fat and glands are thoroughly removed from the sacral hollow, vessels being tied as cut, except the middle sacral and middle hemorrhoidal vessels, which are tied before division. The area is now packed with gauze and the patient is put in the lithotomy position. The rectum is packed with gauze, the anus is sutured, and the rectum is separated from the prostate and urethra or from the vagina from below upward to just above the levator ani muscle. An assistant presses the cancer-bearing fragment with its glands down from the abdomen and the surgeon removes it from the perineum. The peritoneum is sutured within the abdomen, room being left for a small drain which protrudes from the perineum. The perineal wound is narrowed by sutures and the wound

in the belly is closed. In twenty-four hours the protruding end of the sigmoid is opened and an artificial anus is thus made.

(See Joseph A. Blake's views as to "The Operation of Choice in Carcinoma of the Rectum," "New York Med. Jour.," July 1, 1911.)

The mortality of Kraske's operation is from 12 to 15 per cent. Twenty-eight per cent. of Kocher's cases of extirpation of cancer of the rectum remain well from three to sixteen years after operation (W. W. Cheyne, "Brit. Med. Jour.," June 13, 1903). Charles H. Mayo ("Annals of Surgery," Feb., 1917) reports 753 cases of cancer of the rectum. Four hundred and thirty radical operations were performed with a mortality of 15.5 per cent. Before 1913 the mortality was 17.7 per cent. During 1915 it was reduced to 12.5 per cent.

XXX. ANESTHESIA AND ANESTHETICS

Anesthesia is a condition of insensibility or loss of feeling artificially produced. An **anesthetic** is an agent which produces insensibility or loss of feeling. Anesthetics are divided into—(1) *general anesthetics*, as amylene, chloroform, chlorid of ethyl, ether, bromid of ethyl, nitrous oxid, and bichlorid of methylene; (2) *local anesthetics*, as alcohol, bisulphid of carbon, carbolic acid, ether spray, cocain, eucain, stovain, ice and salt, rhigolene spray, and ethyl chlorid spray.

Anesthesia may be induced by a general anesthetic to abolish the usual pain of labor and of surgical procedures; to produce muscular relaxation in tetanus, herniæ, dislocations, and fractures; and to aid in diagnosticating abdominal tumors, joint diseases, fractures, and malingering.

Ether was first used as a surgical anesthetic by Crawford W. Long, of Georgia, in 1842, but he did not publish his cases until after William T. G. Morton, of Hartford, had given ether in public in 1846. The ether was given to a patient of Dr. Warren. Dr. W. W. Keen says ("Ether Day Address," 1915) "We, who are accustomed to anesthesia, can hardly appreciate the courage of Warren and Morton on that memorable sixteenth of October, 1846. Surely also the bravery of the patient himself should not be overlooked. The name of Gilbert Abbott should always be held in remembrance." Horace Wells gave nitrous oxid in 1844. Sir James Y. Simpson introduced chloroform in 1847.

Death-rate from Anesthetic Agents.—Sir Frederic W. Hewitt ("Anesthetics and Their Administration") combines the statistics of Julliard and Ormsby, with the following result:

Anesthetic	Total number of administrations	Total number of deaths	Death-rate
Chloroform	676,767	214	1 in 3,162
Ether	407,553	25	1 in 16,302

Hewitt regards the St. Bartholomew Hospital records as furnishing the most reliable statistics accessible. He takes them from 1875–1900. The fatality from chloroform was 1 in 1300; from ether (and gas and ether), 1 in 9319. It is to be noted that statistics covering many countries would indicate that chloroform becomes relatively safer in warm regions. In temperate regions it is relatively safer (compared with ether) in summer than in winter. Hewitt is of the opinion that ether is six times as safe as chloroform. Gwathmey ("Jour. Am. Med. Assoc.," Nov. 23, 1912) collects statistics from American sources. In 157,453 administrations of ether there were 28 deaths (about 1

death in 5623 administrations). In 16,390 administrations of chloroform there were 8 deaths (about 1 death in 2049 administrations).

Hewitt finds that during the last forty years only 30 fatalities are recorded as produced by nitrous oxid, and he thinks several of these should be excluded. It is practically certain, however, that many deaths, or at least some deaths, have not been recorded.

Seitz collected 16,000 instances of anesthesia by chlorid of ethyl, with 1 death. During a hospital experience of twenty-eight years I have seen anesthetics (particularly ether) given many thousand times. For five years I gave ether and chloroform for Prof. Keen. I have witnessed 3 deaths, each of which at the time was thought to be directly due to the anesthetic, and 1 of them was so caused. One death resulted from pouring a quantity of chloroform upon an Allis inhaler, the bandage of which had been saturated with ether. At the time the chloroform was poured in the inhaler the patient had just been struggling and consequently was breathing deeply. One death resulted from giving ether on a thick cone made of several towels with paper between the folds. The towels were saturated with ether, the patient got no air at all, and was asphyxiated, as she might have been had the cone been wet with water only. The third case was a man who had an impacted hip fracture. He became cyanotic under ether while the impaction was being pulled apart and died. The death was supposed to be due to ether, but necropsy discovered fat emboli in the brain and lungs. I believe that for a huge majority of surgical cases ether is the best and safest general anesthetic and that other general anesthetics are to be used exceptionally and for well-defined reasons.

Preparation of the Patient.—Whenever possible prepare a patient before administering a general anesthetic, and prepare him, if the case admits of it, during two or more days. Heart disease is not a positive contra-indication to surgical anesthesia. It is quite true that anesthetics are dangerous to people with fatty hearts, but shock is also dangerous, and the surgeon stands between the Scylla of anesthesia and the Charybdis of shock. Gallant truly says that not enough attention is paid to the "character of the pulse and action of the heart before operation, by which to compare its work during anesthesia, and after the operation is over, and this neglect leads to unnecessary stimulation and overdriving a heart which is doing its average best."[1] Always examine the urine if the nature of the case allows time. If albumin be found, operation is not contra-indicated, but the peril of anesthesia is greater, and certain dangers are to be watched for and guarded against. If much albumin is present, postpone operation except in emergency cases. If sugar be found, the danger is considerable, as diabetic coma occasionally develops. The percentage of sugar does not determine the amount of danger. Coma may arise when only a little sugar is present, and may not arise when there is a considerable amount. The presence of aceto-acetic acid is more ominous than is the presence of sugar. Empty the intestinal canal by purgation a number of hours before anesthetization. It is well to give the bowel six to twelve hours' rest before operation. The usual custom is to give a saline cathartic the evening before operation and an enema early on the morning of the operation. Frequently the nature of the case or the necessity for haste does not permit of preliminary emptying of the intestine by the administration of cathartics. During the twenty-four hours preceding operation food should be taken in small amounts and in forms easily digestible. During a day or so before operation there is usually impaired digestion, and no undue strain should be put upon the stomach. In the morning allow no breakfast if the operation is to be performed at an early hour, but if the patient be very weak, order a little brandy and beef-tea. If the operation is to be about noon, give a breakfast of beef-tea and toast or a little consommé; *never* give any food

[1] "Medical Record," Feb. 2, 1899.

within three hours of the operation, but brandy is admissible if stimulation be required. If the stomach is not empty at the time of operation, vomiting is almost inevitable, and portions of food may enter the windpipe; if the stomach contains no food, vomiting is far less likely to happen; and even if it occurs and vomited matter should enter the windpipe, it may do little harm, as it consists chiefly of liquid mucus. In cases of intestinal obstruction in which there has been stercoraceous vomiting there is much danger that vomiting will occur during anesthetization. In some cases of intestinal obstruction, during the administration of the anesthetic and during the anesthetic state, a stream of stinking brown fluid may flow without effort from the mouth. Vomiting or regurgitation of stercoraceous material is profuse, sudden, and dangerous. It may flood the bronchial tubes during inspiration and cause death by suffocation. In a case in which stercoraceous vomiting has occurred wash out the stomach before administering the anesthetic. If a patient with intestinal obstruction is too weak to permit lavage, a local anesthetic should be used instead of a general anesthetic. Vomiting while the patient is under the influence of an anesthetic is dangerous in any case, because of the great cardiac weakness which precedes and follows it. If a patient sleeps well the night before an operation, he will probably take the anesthetic better than if he sleeps poorly. Effort should be made to obtain a night's sleep. An excellent expedient is a hot ammonia bath, followed by a rub-down with weak alcohol.[1] It may be necessary to administer trional or bromid. About fifteen minutes before giving the anesthetic let the patient drink a glass of hot water. Water protects the stomach from the irritant effects of any anesthetic which may be swallowed. Before giving the anesthetic see that artificial teeth are removed and that the patient does not have a piece of candy or a chew of tobacco in the mouth. Always have a third party present as a witness, because in an anesthetic sleep vivid dreams occur, and erotic dreams in women may lead to damaging accusations against the surgeon. Place the patient recumbent. The effort should be to place him in as comfortable a position as possible if this position be consistent with operative necessities. Put a small pillow under him, so as to support the normal lumbar curve and prevent postoperative backache. See that the clothing is loose, particularly that there is no constriction about the neck and abdomen. Do not have the head high unless this position is demanded by the exigencies of the operation. The anesthetist must have a mouth-gag and a pair of tongue forceps at hand. It is very wrong to say that a mouth-gag and tongue forceps are never necessary. It is quite true they are often used when not needed, but this does not justify us in being without them when they are needed, and they may be needed very badly. The anesthetist should also have a pair of artery forceps and some small gauze sponges with which to swab out the mouth and throat. A hypodermatic syringe in *working* order, and solutions of strychnin, atropin, and brandy are to be in an accessible place, oxygen must be ready for administration, and it is well to have an electric battery adjacent. Accidents, it is true, are rare, but they may happen at any time, and hence the surgeon should always be prepared for them. Any danger which arises must be met promptly and decisively, or action will be of no avail. As Professor Keen says: "Every case of anesthesia irrespective of the method employed requires unremitting watchfulness from first to last" (Ether Day Address at Massachusetts General Hospital Oct. 16, 1915). Many surgeons give a hypodermatic injection of morphin a short time before operation to steady the heart, to prevent vomiting during anesthetization, to shorten the stage of excitement, to prevent rigidity, and to aid the bringing about of insensibility with very little of the anesthetic. The method has been tried by many during the last forty odd years. It is used in drunkards (as their muscles tend to remain rigid in the anesthetic state), in those whom it is

[1] A. Ernest Gallant, "Med. Record," Dec. 30, 1899.

difficult to make completely unconscious, in neurotic individuals, and in badly frightened subjects. Epileptics are very apt to clinch the jaws, become cyanotic and get convulsions when anesthetized. A preliminary injection of morphia lessens their liability to such disorders. Its greatest use has been in operations about the mouth and face, for in these procedures an anesthetic has been given on a towel or inhaler, has been of necessity given intermittently, and a preliminary dose of morphin has been found to keep the patients from rousing during the intervals. At present intratracheal anesthesia does away with the need of morphin in operations about the mouth and face. There are objections to giving morphin before anesthesia, and its use should be the exception and not the rule. It should not be used in children, in cases of stupor, or in cases in which the respiratory center is disordered. It depresses respiration, lowers temperature, and thus perhaps increases operative shock, interferes with the pupillary phenomena of anesthesia, delays awakening from the anesthetic sleep, adds to subsequent abdominal distention and headache, and actually favors postanesthetic vomiting. Hewitt ("Anesthetics and Their Administration") says that several recorded fatalities were due to the combination. If the surgeon determines to give morphin, he gives $\frac{1}{6}$ to $\frac{1}{4}$ gr. twenty minutes before the anesthetist begins to give the anesthetic. Hewitt (Ibid.) says: "The anesthetic should be given until the usual signs of anesthesia commence to appear. It should then be discontinued for a few moments and only reapplied as occasion may require. As little as possible of the ether or chloroform should be subsequently administered; the conjunctival reflex should be retained." In the clinic of the Jefferson Hospital the elder Gross long used as a routine the preliminary administration of opium, but during his later years he used it exceptionally. His successor, the younger Gross, used morphin hypodermatically exceptionally. In some cases we may anticipate trouble from the anesthetic. Cyanosis may occur in drunkards; in fat, thick-necked individuals of the Major Bagstock type, who are short of breath and congested in appearance; in individuals with some disease of the lungs, bronchi, pharynx, larynx, or trachea (empyema, emphysema, chronic bronchitis, croup, cancer of the larynx, etc.); in individuals suffering from fatty heart or valvular incompetence. Buxton points out that an individual without teeth and with stenosis of the nares is apt to become cyanotic under an anesthetic, because the lips and pillars of the fauces are drawn in like valves during inspiration.

Ether and Chloroform.—The two favorite anesthetics are ether and chloroform. Only the very best ether or chloroform should be used. It is a good plan, in order to lessen bronchitis, to mix with ether turpentine of Pinus pumilio in the proportion of 20 drops to 6 $\frac{1}{2}$ oz. (Becker, in "Centralbl. f. Chir.," June 1, 1901). Chloroform is more dangerous than ether in general cases, though it is more agreeable, less irritant to the lungs and kidneys, and quicker in its action. Chloroform, compared to ether, is relatively safer in warm than in cold countries. In fact, in the tropics it is a matter of considerable difficulty to use ether because of its great volatility. It should, however, be noted that Squire used ether successfully when the temperature was 120°F. in the shade ("Lancet," vol. i, 1913). Chloroform is preferred in campaigns, because less is required and transportation is easier. Recovery from chloroform is quicker and quieter than that from ether, but chloroform vomiting lasts longer than ether vomiting. Chloroform may induce sudden and even fatal syncope. Hare's experiments on animals indicate that chloroform may kill by respiratory failure occurring secondarily to failure of the vasomotor center; but certain it is that clinically a danger of chloroform is paralysis of the heart, and this condition may come on so rapidly that death may occur almost before an attempt can be made to save life. Heart flutter may be the cause of sudden death. Leonard Hill has proved that most chloroform deaths that take place after a considerable amount of the anesthetic has been taken

arise from paralytic distention of the heart. Sudden death, when inhalations of chloroform have just commenced, may be due to the irritant vapor acting on the nasal mucous membrane, exciting a nasal reflex, and powerfully stimulating cardiac inhibition. If ether produces danger it does so usually through the respiration, and not the heart, and there is generally time to undertake resuscitation, which is apt to be successful. Chloroform is preferred to ether by many surgeons for children under ten years of age, in whom ether causes a great outflow of bronchial mucus, which may asphyxiate; for people over sixty, entirely free from myocardial disease, at which age most persons have some bronchitis, and ether chokes them up with mucus. Ether also irritates the kidneys, which at the latter age are apt to be weak or diseased. Personally, I give ether even to infants (if they are free from bronchitis) and to old subjects without marked respiratory trouble. Chloroform is given if the actual cautery is to be used about the face, neck, or mouth, because ether vapor may take fire and chloroform vapor will not. Chloroform is preferred for labor cases, when moderate anesthesia only is required, and was preferred for operations on the mouth and nose before the advent of intratracheal anesthesia. In cleft-palate operations chloroform is usually preferred, because it causes but little cough and salivary flow. In ligation of a large artery which is overlaid by a vein ether greatly enlarges the vein, but this is no real embarrassment to an experienced surgeon. In goiter operations ether will decidedly enlarge the veins. Most goiters may be, and many should be, removed with the aid of local anesthesia only. Chloroform is particularly dangerous when there is myocardial disease, and is apt to produce cyanosis and embarrassed respiration. In valvular heart disease chloroform is more dangerous than ether, and even in functional heart trouble it is an undesirable anesthetic. It should not be used in those who smoke or chew tobacco to excess, or who overindulge in coffee or alcohol. Chloroform is more dangerous in shock than ether. A patient in dangerous shock requiring operation should, if possible, have the nerves coming from the part injected with cocain so as to cause the "physiological block" of Crile (see page 289). Chloroform is preferred for patients with difficult respiration from any cause other than heart disease (in emphysema, bronchitis, or pulmonary tuberculosis), and for patients with kidney disease. I am convinced that etherization is sometimes responsible for a latent area of pulmonary tuberculosis becoming active. Some surgeons do not use ether in abdominal operations because they believe it may cause persistent oozing of blood, but this view is not in accord with the author's experience. Ether is the best and safest anesthetic for general use. It is much safer than chloroform in valvular disease and functional heart trouble. It is dangerous in myocardial disease, but not nearly so dangerous as chloroform. In valvular disease without heightened arterial tension it is reasonably safe, but in valvular disease with heightened arterial tension it is dangerous. Ether is dangerous when atheroma exists. Both ether and chloroform may induce changes in the blood.[1] In practically all cases they produce a diminution of hemoglobin and leukocytosis. In some cases they produce alteration in the shape of the corpuscles. These changes are especially marked in anemic blood. Ether produces distinct leukocytosis, probably toxic in origin. Both ether and chloroform seem to lessen the phagocytic activity of leukocytes and hence to lower vital resistance (Ferguson, in "New York Med. Jour.," May 11, 1912). These blood changes indicate that prolonged anesthesia must militate against recovery from a severe operation. If a patient's hemoglobin be below 30 per cent., a general anesthetic should not be given. During the state of anesthesia the temperature drops from 1 to 3 degrees or more, hence the patient should be

[1] See the author on the "Blood-alterations of Ether-anesthesia," "Medical News," March 2, 1895, and also the author and Kalteyer in "The Proceedings of the American Surgical Association for 1901."

carefully covered during the operation. The question as to the effect of ether on the kidneys is much disputed. Most surgeons believe that it tends to cause albuminuria or increase existing albuminuria. Nitrous oxid is very dangerous when there is vascular degeneration, and it may induce apoplexy. It is dangerous if the air-passages are narrowed as by a goiter. Ether and chloroform lower temperature and so do other general anesthetics. The patient responds to external heat and cold like a cold-blooded animal (Pembrey and Shipway, in "Proc. Roy. Soc. Med.," 1916). This dissipation of body heat is a danger and calls for the protection of the patient against chilling during an operation. In giving ether or chloroform the administrator must devote his undivided attention to the task. He must note every symptom, must order or carry out proper treatment for complications, and must keep the operator informed as to the necessity for haste. The anesthetist must be a man who has a wholesome respect for ether and chloroform, although not afraid of them.

Can an anesthetic be administered to a sleeping person without waking him? I know that chloroform can be so given, for I have succeeded in giving it to a child without breaking the slumber. Probably, in most cases, an attempt will fail, but in some it will succeed. Stone ("Cleveland Med. Jour.," Jan., 1902) reports successful administration to sleeping children and also the chloroforming of a resident physician while asleep. Paugh ("Jour. Am. Med. Assoc.," May 18, 1901) reports three successes with children. Ether, because of the irritant nature of its vapor, would be more apt to arouse a sleeper than chloroform.

Administration of Chloroform.—Chloroform should be given by a highly trained man only. In fact, safety in giving chloroform is dependent upon skill and experience more than in giving ether. No one should think of allowing anyone but a physician to give chloroform. The most dangerous period is when the patient is incompletely anesthetized, but is going under. Most

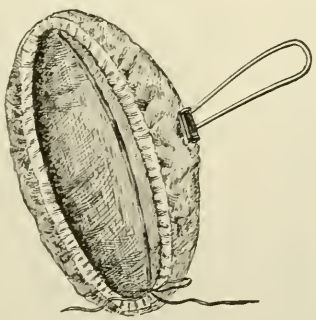

Fig. 873.—Skinner's mask.

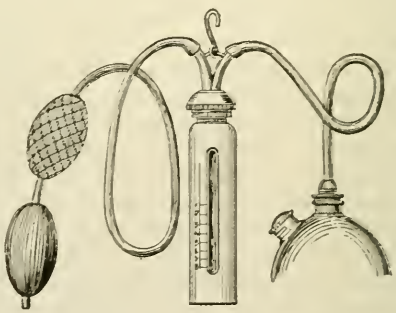

Fig. 874.—Junker's inhaler.

deaths happen at this time. In administering chloroform have at hand a mouth-gag, tongue forceps, artery forceps, small gauze sponges, a clean towel, hypodermatic syringes loaded with solutions of strychnin, atropin and brandy, an electric battery, and a can of oxygen. Use *pure* chloroform only. The patient should be recumbent. The erect or semi-erect positions are dangerous in chloroform anesthesia. The Trendelenburg position is admissible (see page 1205). No special inhaler is required, but the drug may be given upon a thin towel, a napkin, or a piece of lint. The mask of Skinner (Fig. 873) is very useful. Junker's inhaler (Fig. 874) is used by many anesthetists. In operations about the face Souchon's instrument is serviceable. Souchon's apparatus is so arranged that chloroform may be given through a tube which is introduced through the nose, the instrument being well out of the way of the operator. Some surgeons cocainize the nares before giving chloroform, so as

to prevent the supposedly dangerous nasal reflex (Rosenberg). It is advisable to smear the lips and face (including the eyelids) with white vaselin to prevent blistering. The chloroform vapor must be well mixed with air. The chloroform is sprinkled on the fabric from a drop-bottle. Raise the napkin well above the mouth, add 5 drops of chloroform, and tell the patient to take deep and regular breaths, but do not tell him to breathe forcibly. Forcible respiration may lead to cessation of respiration. Add a few more drops of chloroform, and when the patient grows so accustomed to it that he or she does not choke, turn the wet part of the fabric toward the face and place it near the mouth; do not touch the mouth with the wet lint, because it will blister. If the drug be given *gradually*, struggling is not usually violent or prolonged. Never pour on a large amount at one time. Keep the lower jaw pushed forward during the time the chloroform is being given. Cough and vomiting at this time mean that the vapor is too strong. During the stage of excitement do not suspend the administration of chloroform unless respiration becomes difficult, in which case suspend it until the patient takes one or two respirations. If the patient struggles, do not hold him, and push the administration of the drug. He holds his breath while struggling, and as struggling ceases takes full, deep breaths. If the inhaler be saturated with chloroform, he may inhale a dangerous amount during the deep respiration after struggling. Chloroform given in considerable amount when the patient is breathing deeply from the effects of ether is unsafe. If chloroform is given subsequent to anesthetization by ether, it should be given gradually and well mixed with air. When the patient becomes anesthetized, give just enough of the drug to keep him so. While a patient is taking chloroform hiccup usually means that vomiting is about to occur. If vomiting occurs at this time more chloroform must be given to abolish the reflexes. Deep and sighing respiration and repeated swallowing indicate that more of the anesthetic is required. Stop the administration or give very little when shock becomes evident or when there is profuse hemorrhage. Chloroform vapor is not inflammable, hence it is safer than ether when a hot iron is to be used about the face and when there is a lighted lamp or a stove in a small room; but the presence of a naked gas-flame decomposes chloroform into irritant products of chlorin ($COCl_3$), which cause the patient and the surgeon to cough.

Chloroform and Oxygen.—The use of this mixture was suggested by Neudorfer. Some anesthetists advocate the mixture of chloroform and oxygen, asserting that it does not produce spasm of the glottis or muscles of respiration, that it does not produce cyanosis or weakness of circulation, that it does not irritate the kidneys, is safer to life than pure chloroform, and is less often productive of severe and prolonged vomiting. These alleged advantages are probably stated with rather undue emphasis, although I do believe the mixture has less tendency to produce cyanosis than has the pure drug, does not so often induce vomiting, and is somewhat safer. Hewitt does not think that the method offers any "special advantages" ("Anesthetics and Their Administration," by Sir Frederic W. Hewitt). If this method be used, a bag containing oxygen is attached to the hand-bellows attachment of a Junker inhaler, and oxygen is forced through the chloroform and flows to the face-piece.

Administration of Ether.—The administration should not be intrusted to a novice. The anesthetist should be one of your most trusted men. I do not believe in allowing a nurse to give ether. She cannot have sufficient knowledge to observe incipient trouble, to anticipate untoward effects, and to at once do the correct thing when difficulty arises or calamity impends. The moral responsibility and the legal responsibility demand that a physician give the ether. Usually the patient is recumbent but if necessary he can be placed on the side, prone, semi-erect or in the Trendelenburg position (see page 1205). Some anesthetists precede the administration of the ether by causing the patient to breathe the vapor of oil of orange. The patient finds it pleasant and loses

some of his apprehension, and the oil so dulls the reflexes of the air passages that when ether is substituted for the orange it is "taken" more easily than otherwise would be the case. Ether is best given from a partially open inhaler. The most satisfactory appliance is Allis's inhaler (Fig. 875). This inhaler secures a plentiful supply of air. Before being used the metal frame is scalded, dried, and threaded with a clean gauze bandage. The end of the frame which is to be toward the mouth is covered with one layer of gauze. The frame is then inserted in a clean metal case and the case is wrapped in a clean towel. The drug is given drop by drop, the drops following each other in regular sequence. This is known as the *drop method*. The drop method is the safest plan and the most comfortable to the patient. Instead of Allis's inhaler a piece of gauze or an Esmarch inhaler may be used. Some surgeons prefer closed inhalers. The Clover inhaler (Fig. 876) is popular in England. *F* is the face-piece; *C*, a reservoir of ether through which the air-current passes; *B* is an India-rubber bag. In this apparatus there is no provision for the entrance of fresh air. By turning the

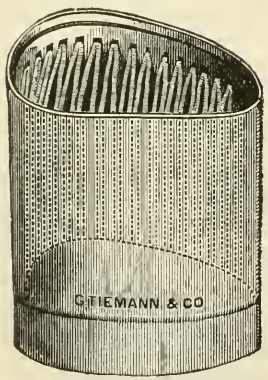

Fig. 875.—Allis's ether inhaler.

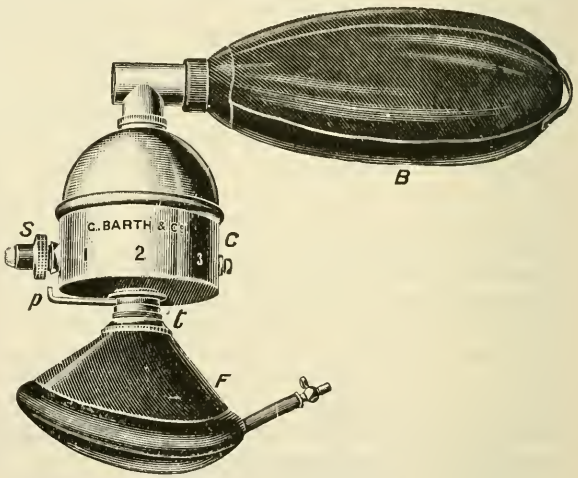

Fig. 876.—Clover's portable regulating ether inhaler.

reservoir *C* on the tube *t* the amount of current passing over the ether can be regulated. When this apparatus is used, the ether vapor breathed into the lungs is expired into the bag and is rebreathed. The inhaler, if used by a skilful man, is very useful; but any lack of watchfulness or skill will permit of cyanosis, and the very young, the senile, the anemic, and feeble are best anesthetized by the drop method described above.

An admirable detailed account of anesthetization by the closed method will be found in Sir Frederic W. Hewitt's treatise on "Anesthetics and Their Administration," and in Mr. Dudley W. Buxton's treatise on "Anesthetics, Their Uses and Administration." When giving ether, have at hand the same drugs and appliances as when chloroform is given, and keep the lower jaw pushed forward during the administration. When using Allis's inhaler, take every care that none of the ether runs through on to the face and into the eyes. If it does it will irritate and perhaps blister. Even the vapor irritates the eyes, and boric acid solution should be used now and then during the administration to flush out the conjunctival sacs. It is wise to grease the face and lips with vaselin. Place the dry inhaler over the mouth and nose, let the patient take several breaths, that he may gain confidence, begin to drop ether into the inhaler, let the patient take several more breaths, and so on, gradually increasing the rapidity with which the drops of ether are given. If he tends to struggle, diminish the amount of ether for a time, but do not hold him. Do not

tell him to breathe forcibly. Forcible breathing is liable to cause a cessation of respiration. Never suddenly add a large amount of the anesthetic: it causes coughing and often vomiting. When the patient becomes thoroughly anesthetized, give a very little ether as often as is required to maintain unconsciousness. When bleeding is profuse or shock is marked, suspend the administration of ether or give very little of it. If he rolls his eyes from side to side, if the respirations are deep and sighing, if there are repeated movements of swallowing, more anesthetic should be given (Tarnowsky). Hiccup is often preliminary to vomiting, and always means that the reflexes are returning. If a hot iron is to be used about the face, remove the inhaler and fan away the ether before bringing the cautery near. Have any light set high up, as ether vapor is heavier than air, and no explosion is possible until it reaches the level of the flame. If the vapor takes fire, cover the patient's mouth and nose with a towel.

The patient should be kept in a condition in which he feels no pain, makes no movement, and is not rigid. In this condition the cutaneous reflexes are abolished, the breathing is regular and quiet, the color is good, and the pupils react to light, though slowly. Just enough anesthetic must be given to cause the patient to pass into this condition and remain in it. To give any more is to poison him. The amount necessary varies with the individual and the operation, and requires skill, experience, and attention on the part of the anesthetist.

The old idea that we must poison a man into dangerous coma has been abandoned. When the breathing becomes louder, more rapid, or spasmodic, it means that reflexes are returning, and a little more anesthetic should be given.

The Cotton Process Ether.—Dr. James H. Cotton of McGill University, after many careful experiments and observations has published some novel views upon ether ("Jour. Canadian Med. Assoc.," Sept., 1917). The aim of the manufacturer has been to make ether as nearly pure as possible. The process of to-day makes purer ether than that made years ago, yet surgeons often feel that patients cannot be anesthetized as rapidly as in former days and that primary anesthesia is more difficult to obtain. Cotton believes that just as ether approaches to purity it loses more and more of its anesthetic power, that by removing impurities we remove a valuable element and that perfectly pure ether is not an anesthetic at all but only serves to make a man drunk.

The impurity which produces anesthesia is, Cotton believes, a gas like ethylene. Another impurity contains an unidentified gas which produces the ordinary unpleasant symptoms which so commonly follow anesthesia (vomiting, headache, etc.)

Cotton makes a chemically pure ether and charges it with the desirable anesthetic gas.

Dr. W. G. Huson, Medical Director of the Dupont Powder Works, says ("Med. Record," March 16, 1918): "Dr. Cotton believes that perfectly pure ether, for the manufacture of which an entirely new process had to be devised, is not an anesthetic at all, but produces, upon inhalation, merely a transitory stimulation similar to that from alcohol. Commercial anesthesia ether is by no means pure, but contains two sets of impurities, one of which produces the anesthesia, which we have been attributing to the ether itself, and the other the undesirable after-effects, which have been so great a drawback to the administration of ether. He then proceeded to charge his chemically pure ether with only the desirable impurities, going beyond the proportions in which they exist in ordinary anesthesia ether. When this was done, not only were the undesirable after-effects eliminated, but it was found possible to produce an entirely new type of anesthesia, during which the patient can be maintained in a condition in which all sensation is abolished, but in which he is perfectly conscious, can carry on a conversation intelligently

and can even walk about, although rather unsteadily. If the amount administered is reduced, sensation begins to return, while if it is pushed, the condition passes over into the ordinary surgical anesthesia, with loss of consciousness but without any intervening stage of excitement."

We are at present testing out the Cotton ether in Jefferson College Hospital and feel encouraged to hope that an important discovery has been made but it is too early to speak with confidence.

Ether and Oxygen.—This mixture is useful in certain cases in which respiratory difficulty exists, particularly in empyema. If during the administration of ether cyanosis tends to occur, it is often advantageous to give oxygen with the ether. The process of anesthetization by ether and oxygen is somewhat slower than by ether vapor mixed with air. It can be given by inserting beneath the Allis inhaler or pushing deep down into it, from above, a tube attached to a reservoir of oxygen and from which a stream of oxygen emerges.

Endotracheal Insufflation Anesthesia (Intratracheal Anesthesia) (Method of Meltzer and Auer).—A flexible elastic tube much smaller in diameter than the trachea is carried down almost to the tracheal bifurcation. When air is forced in, it emerges between the tube and the trachea. The addition of ether vapor to the air makes the maintenance of anesthesia easy. Ether can thus be administered by means of a tracheal tube, a Wolff bottle to contain the ether, and a foot-bellows. I have had it given in this way a number of times. Elsberg's apparatus (see Fig. 656) permits of the most desirable method.

The patient is first anesthetized by the ordinary method. When unconscious the head is dropped back over the end of the table, and the tube is passed into the trachea "under the guidance of the eye by means of a Jackson direct laryngoscope" (see Fig. 630). (See Brewer, in "Keen's Surgery," vol. vi). In this form of anesthesia the stream of air carries off ether vapor and prevents accumulation in the tubes.

A degree of anesthesia necessary to maintain muscular relaxation will not apparently cause dangerous symptoms. If the ether is given for a long time in unnecessarily large amounts danger may be reached, but it is attained gradually and not suddenly and gives warning. If there should be an ominous fall in blood-pressure and respiratory failure, cut out the ether vapor and use the apparatus for artificial respiration. A patient remains very still under this method of anesthesia, awakes rapidly from it, and suffers little from shock and postoperative vomiting. Nitrous oxid and oxygen have been given by this method. Meltzer is studying chloroform so used ("Keen's Surgery," vol. vi). In operations about the head, mouth, and neck insufflation anesthesia keeps the anesthetist out of the operator's way. In operations about the mouth the method prevents the inhalation of blood or vomit. In goiter operations it is a safeguard against sudden suffocation. It is useful in brain operations especially cerebellar operations. In intrathoracic operations it serves to prevent collapse of the lung. After the operation all ether vapor is driven out of the lungs by a stream of fresh air. Peck ("Annals of Surgery," July, 1912) maintains that the insufflation method is safe if certain rules are carefully followed. These rules are to avoid excessive pressure (which might rupture air-cells), to be sure not to spray liquid ether into the tracheal tube, not to carry the tube into the gullet, or beyond the tracheal bifurcation, and not to damage by rough introduction.

I use the method frequently, find it extremely useful and regard it as safe. Meltzer has only been able to learn of 4 or 5 deaths during the application of the method and he does not think one of them was due to the method. One was due to liquid ether being allowed to run into the tube; another to rupture of the lung brought about by the tube being pushed down too far; another death was due to the tube having been passed into the gullet; in another case the tube was forced, producing cyanosis, emphysema and death. A tube with a safety-valve and scrupulous care would probably have saved these lives. (Abstract in

"Surgery, Gynecology, and Obstetrics," Jan., 1915, from "Berlin klin. Wochen.," 1914, ii.)

Rectal Etherization.—Pirogoff suggested this method in 1847 and Roux employed it the same year. The method is recommended by some for operations upon the face, tongue, nasopharynx, pharynx, mouth, larynx, trachea, thyroid, or chest; in other words, in cases in which, were the ether given by inhalation, the operator and anesthetist would interfere with each other. It is useful if a patient must assume a prone position (as in laminectomy, in head operations, if bronchitis exists and in the aged). It is especially useful in fat alcoholics. It does not cause a sense of suffocation, the stage of excitement is brief and struggling is absent or trivial. Rectal anesthesia causes much less mucus to flow into the air-passages than does inhalation anesthesia. Postoperative nausea and vomiting are less common than after inhalation anesthesia. A badly frightened patient can by this method be anesthetized without his knowledge. It is contra-indicated in pelvic operations, if there is irritation or inflammation of the intestines and in laparotomy because gaseous distention of the gut interferes with work and necessitates much handling. Until recently the following rules were laid down for the administration. The rectum should be emptied by a purgative enema the day before the operation, and again the morning of the operation, and a short time before giving the ether the rectum should be irrigated with warm salt solution. A dose of laudanum is given a few hours before, or an injection of morphin and atropin twenty minutes before the administration of the ether. We should employ an apparatus of the type of Buxton's, which prevents liquid ether from passing into the rectum.

A tube containing ether is set in a vessel containing water at a temperature of 122°F. The ether tube is joined by a glass tube and rubber pipe to a glass globe, and the globe is connected by a rubber pipe to the tip, which is inserted into the rectum. If ether vapor condenses into liquid in the glass globe the globe should be at once emptied. During the administration abdominal distention occurs from unabsorbed ether, and from time to time the administration should be suspended temporarily to permit the gas to escape, otherwise too much will be given and prolonged stupor and postoperative colic may result. It takes much longer to obtain unconsciousness by rectal administration than by inhalation. This method never came into general use. It was found to irritate the large intestine, to produce colic in many cases, and sometimes to lead to protracted stupor ("Anesthetics and Their Administration," by Sir Frederic W. Hewitt). After one of Baum's cases intestinal hemorrhage occurred; in another, gangrene and perforation ("Zentral. für Chir.," March 13, 1909). Dudley W. Buxton, however, employed it in many operations about the face, mouth, and larynx, and in some operations for empyema, and commended it. James T. Gwathmey ("N. Y. Med. Jour.," 1913, xcviii—1914, xcix) improved the method greatly. He calls the new method Oil-ether Anesthesia by the rectum. The mixture used consists of 4 ounces of olive oil and 2 ounces of ether. One ounce is given for each 20 pounds of the patient's body weight but not more than 8 ounces are to be given. The night before the operation compound licorice powder or castor oil is given. A couple of hours before the injection the rectum is washed out. Forty minutes before operation a hypodermatic injection is given. It contains gr. $\frac{1}{4}$ of morphin and gr. $\frac{1}{100}$ of atropin. At this time anesthetize the rectum by injecting into it gr. v to gr. x of chloretone in ether and olive oil. Twenty minutes before operation the patient is placed in the Sims position and the mixture of oil and ether (which has been well shaken in a bottle is introduced slowly into the rectum by means of a funnel and a rubber catheter. It is given at the rate of an ounce a minute. In 5 or 6 minutes the patient should be unconscious and in 20 minutes from beginning the injection anesthesia should be complete. In some cases anesthesia is not complete for 30 or 40 minutes. The ocular reflexes must not be abolished and stertorous respira-

tion is a danger sign (W. M. Johnson in "N. Y. Med. Jour.," 1916, civ). Gwathmey insists that respiration should be smooth and easy, without stertor and with the retention of eyelid reflex. If danger signals arise some or all of the mixture is withdrawn by lowering the tube. At the termination of the operation the mixture is withdrawn from the rectum, the rectum is well washed out with cold water containing soap and a pint of cold water is left in the rectum (Gwathmey, "N. Y. Med. Jour.," 1914, xcix). Sometimes the unconsciousness is inordinately prolonged. In some persons resistant to ether it is necessary to supplement rectal administration by inhalations of ether. I see no reason to doubt that rectal anesthesia is as dangerous as inhalation anesthesia. It is certainly less controllable. It is useful in certain cases but will not displace the inhalation method. Intratracheal insufflation anesthesia seems to have nearly done away with all need for rectal anesthesia.

Intravenous Etherization (Infusion Anesthesia).—This method was devised by Burkhardt, of Würzburg, and is still on trial. A 7½ per cent. solution of ether in normal salt solution is employed by Rood ("Lancet," March 23, 1912). He found that a 10 per cent. solution causes hemolysis and a 5 per cent. solution is inadequate. About three-quarters of an hour before operation he gives a hypodermatic injection of ⅙ gr. of morphin, 1/100 gr. of scopolamin and 1/100 gr. of atropin. When ready to operate, a vein is selected, exposed and opened, and the cannula is introduced. The solution is warm. From ½ to 1 pint of the fluid is run in and anesthesia should be secured in from three to five minutes. Anesthesia is maintained by running in a constant succession of drops. If anesthesia becomes too deep the rate of flow is lessened, and vice versâ. This method of anesthesia keeps the anesthetist out of the way in operations on the head, neck, and mouth. It is claimed that it enables us to measure the dose of anesthetic much more accurately than does the respiratory plan, and that by it we avoid irritation of the mucous membrane of the respiratory tract. The respiration must be watched just as carefully as in respiratory anesthesia. Rood ("Brit. Med. Jour.," Oct. 21, 1911) has had 136 cases and no bad results. It would seem however, that there must be elements of danger, ecchymoses may appear on the back and buttocks and it has been stated that there is a tendency to pulmonary edema ("The Art of Anesthesia" by P. J. Flagg).

Hedonal has been used for infusion anesthesia. It was suggested by Federoff, of St. Petersburg. Mr. Page, of London, has reported 75 cases ("Lancet," March 23, 1912). He uses a 0.75 per cent. solution in normal salt solution and gives it continuously. Ward ("Lancet," March 23, 1912) has reported a death from it.

Anesthetic State from Ether or Chloroform.—The inhalation of an anesthetic produces irritation of the fauces, often some cough, a profuse secretion of mucus, acts of swallowing, dilatation of the pupils, flushed face, and sometimes struggling (especially in children and in drunkards). If at the start the vapor is given in concentrated form, cough will be violent and will cause cyanosis. If the anesthetic is given gradually the cough soon ceases, the respirations become rapid and often convulsive, the pulse becomes frequent, and the patient passes into a condition of active intoxication with preservation of sight and touch, loss of hearing and smell, diminution of pain and sensibility, and often with illusions or hallucinations. In this stage the patient may struggle, and while efforts are being made to hold him, cyanosis may occur. From the stage of excitement just alluded to, many subjects (strong men and drunkards) pass into a stage of rigidity in which the muscles become firmly fixed, the breathing is impeded, the respirations are stertorous and the face is bluish and congested. Too rapid forcing of the anesthetic tends to cause rigidity, and a skilled anesthetist endeavors to avoid its production, because it is dangerous. The next stage is one of insensibility; the pupils

are contracted and react sluggishly to light. If anesthesia is deep the contracted pupils will not react to light; if anesthesia is profound the pupils dilate, but will not react to light. The conjunctival reflex is gone; the lids are closed; if the arm is lifted and allowed to fall, it drops as a dead weight; the skin is cool and moist and often wet with sweat; the respirations are easy and shallow; the pulse is slow, and there is complete unconsciousness to pain. The loss of conjunctival reflex is the usually accepted sign that the patient is unconscious. In a young child this reflex is soon exhausted by touching the eye, and the sign is unreliable. If a baby is to be anesthetized, the administrator places his finger in the infant's hand. The child grasps the finger, and relaxes its grasp when unconscious.

Always bear in mind that dilated pupils reacting to light and associated with preserved conjunctival reflex mean that anesthesia is not complete; that contracted pupils reacting to light and without conjunctival reflex mean moderate anesthesia; that contracted pupils not reacting to light and without conjunctival reflex mean deep anesthesia; that dilated pupils not reacting to light and associated with lost conjunctival reflex mean dangerously profound anesthesia. Sudden dilatation with fixation is always very ominous. The pupillary phenomena are very valuable when present, but unfortunately they are absent at some stage of the anesthesia in many cases. Inequality of the pupils is not unusual and fixation of one pupil or of both may occur. A preliminary dose of morphin or atropin interferes with the pupillary phenomena. Weak pulse and pallor may be due to nausea, but always require instant attention. Vomiting may be due to forcing strong vapor upon the patient, but may also be due to his partially emerging from a state of insensibility.

Watch the pulse carefully to see if it becomes very weak, irregular, abnormally slow, abnormally fast, or if it suggests a fall of blood-pressure. Syncope may be due to nausea, shock, hemorrhage, or the giving of too much of the drug. Watch the respiration, and do not forget that the chest walls and belly may move when no air is entering the lungs; hence always *listen* to the breathing. *Cyanosis* is a dusky or bluish discoloration of the skin. This condition indicates want of oxygen in the blood. The individual may have been cyanotic or predisposed to cyanosis from the beginning; cyanosis may be due to pressure; to cough early in the administration; to struggling during the stage of excitement; to the gathering of mucus in the respiration tract; or to rigid fixation of the respiratory muscles. It may also be due to obstruction of the air-passages by some foreign matter, as blood or vomit, lodging in the bronchial tubes, windpipe, larynx, or pharynx; falling back of the tongue (*swallowing of the tongue*); closure of the epiglottis; or to the glottis being pushed against the pharyngeal wall by bending the head forward. Some patients with occluded nostrils may fail to get enough air because of closure of the lips. A patient may, while taking an anesthetic, lie perfectly quiet and appear to "forget to breathe. Ether and chloroform mitigate the causal mental phases of shock, but neither drug keeps nerves from conveying stimuli and each produces a fall of blood-pressure, chloroform directly by its action on the vasomotor center, ether by overstimulation of the vasomotor center (Buxton, in "Proceedings of the Royal Soc. of Med.," April, 1909). Each produces a fall of temperature. Buxton heartily condemns the once common belief "that evidences of shock during a surgical operation are a proof that an insufficient quantity of the anesthetic has been given and that the symptoms of shock can be abrogated by increasing the depth of the narcosis" (Ibid.). Heavy anesthesia by ether or chloroform produces or adds to shock. Shock is manifested by deathly pallor, weak, rapid, and irregular pulse, slow respiration, cold extremities, and a drenching sweat. Edema of the lungs occasionally arises during or after anesthesia.

Treatment of Complications.—*Vomiting* due to too much anesthetic is corrected by giving a few breaths of air; vomiting due to incomplete anesthesia is

amended by giving more of the vapor. While the patient vomits hold the head over the edge of the bed or table, and when vomiting ceases separate the jaws with the gag, and wipe out the vomited matter, mucus, and saliva. *Shock* is treated by diminishing the amount of the anesthetic that is being given, by the hypodermatic injection of atropin (atropin is particularly useful when there is a profuse sweat), by the administration of hot saline fluid by the rectum, by surrounding the patient with hot-water bottles, or by wrapping him in hot blankets, and by lowering the head, of the bed. Syncope is sudden cerebral anemia and is usually due to a reflex cause. A tendency to *syncope* requires lowering of the head, suspension of the anesthetic, and hypodermatic injection of strychnin. In *extreme syncope*, which is most apt to occur from chloroform, do not wait for breathing to cease, but suspend the anesthetic, lower the head of the bed, open the mouth with the gag, catch the tongue, and make rhythmical traction while an assistant is making *slow* artificial respiration. If the patient does not *at once* improve, invert him completely, holding him by the legs and continuing artificial respiration by compressing the sternum (Nélaton). By continuing artificial respiration the blood is urged on through the heart. Give hypodermatic injections of atropin, ether, or even of ammonia. Put mustard over the heart and spine. Employ faradism to the phrenic nerve (one pole to the epigastric region, the other to the right side of the root of the neck). Let fresh air into the room, put hot-water bottles around the legs, apply friction to the extremities, wrap the patient in hot blankets, give an enema of hot salt solution, and hold ammonia to the nose. In some cases of anesthetic poisoning *direct heart massage* has been successfully employed. The method was suggested by Schliff in 1874. Frazier was operating for hydrocele when the patient's respiration ceased and his pulse disappeared. Frazier at once opened the abdomen and, with one hand on the chest wall and the other against the diaphragm, "massaged the heart at the rate of 15 to 20 movements a minute." In about two minutes cardiac contractions were perceptible. In about eight minutes resuscitation was complete ("Jour. Am. Med. Assoc.," May 20, 1911). In Conkling's case there was a chest wound exposing the lung. The heart ceased to beat. The surgeon grasped the heart between the fingers and made compressions. In less than a minute he detected a thrill, and in a few seconds more regular pulsation began ("New York Med. Jour.," Sept. 2, 1905). In Sencert's successful case an operation was being done for gall-stones when collapse occurred, and the surgeon stroked and kneaded the heart through the diaphragm. In a case recorded in the "Brit. Med. Jour.," Nov. 18, 1905, respiration and pulse had ceased three minutes when the abdomen was opened and the heart was kneaded. Recovery ensued. Müller, of Hamburg, advocates exposing and opening the pericardium to perform massage, introducing oxygenated salt solution into a vein, opening the trachea, and performing artificial respiration. Frazier ("Progressive Medicine," March, 1911) publishes statistics of 50 collected cases. These figures indicate that the subdiaphragmatic method is more successful than either the direct method or the transdiaphragmatic method. The table is as follows:

	Successful	Partially successful	Failures	Total
Direct	2	8	18	28
Transdiaphragmatic	0	1	2	3
Subdiaphragmatic	8	5	6	19
	10	14	26	50

Leonard Hill holds that in the failure which arises *soon after administration of chloroform is begun* the trouble is due to vasomotor paralysis with starvation of the nerve-centers. In such a case he applies abdominal compression and inverts the patient, making artificial respiration at the same time. In the

failure which occurs after *considerable chloroform has been taken* there are paralytic distention of the heart, fulness of the venous system, and loss of the compensations for the hydrostatic effects of gravity. In such a condition empty the distended heart of venous blood by raising the patient into an erect position, and after a moment place him recumbent and make artificial respiration.

Forgetting to breathe is met by removing the inhaler and waiting a moment; a breath will usually be taken soon; but if it is not taken, somewhat forcibly knead the structures in the arm-pit. If this fails, open the mouth and pull forward the tongue; this causes a reflex inspiration. Cyanosis is practically not encountered when oxygen is given with ether or chloroform. *Cyanosis*, if slight and due to cough or struggling, is met by removing the inhaler while the patient takes a breath or two of air. If position is responsible for cyanosis, correct it. In empyema, lying upon the sound side may produce it. Obstruction to breathing may be due to bending down the head. If due to stenosis of the nares in a person without teeth, hold the lips apart with a finger. If due to collection of mucus, wipe the mucus out of the mouth by means of bits of gauze firmly clamped in forceps; raise the shoulders, extend the head and place it on its side in order that mucus may run out of the angle of the mouth; and give a dose of atropin hypodermatically. If the amount of mucus is large and the secretion is persistent, it may be necessary, especially in children, to empty the respiratory passages by inverting the patient. In cases of excessive bronchial secretion we fear the development of pulmonary edema or postoperative bronchopneumonia.

Dudley W. Buxton points out that duskiness will often pass away if ether is removed, one or two inhalations of chloroform given, and ether then continued. If in any case cyanosis is severe or grows worse, suspend the drug, dash cold water in the face, force open the jaws, pull forward the tongue, make artificial respiration until a breath is taken, and then give oxygen for a time. If these means fail, stretch the sphincter ani and bleed from the external jugular vein. If a breath is not now taken, do tracheotomy. In respiratory or heart failure forced artificial respiration by Fell's method is of great value (see page 1021). The pulmotor or lungmotor, if at hand, enables the surgeon to maintain regular artificial respiration for an indefinite time (see page 977). *Swallowing the tongue* is corrected by pulling the tongue forward. If it tends to recur, lay the head upon its side or keep the tongue anchored with forceps. *Closure of the epiglottis* is corrected by pulling the patient's head over the edge of the table and pushing strongly back upon his forehead. This maneuver lifts the hyoid bone, and with it the epiglottis. The epiglottis can be lifted by passing a spoon-handle or the index-finger over the dorsum to the base of the tongue and pressing forward. If, in obstruction to respiration, the above means fail, make artificial respiration at once (see page 974); if obstruction continues, perform tracheotomy).

Edema of the lungs is treated by instant venesection, the inhalation of nitrite of amyl, and the administration of stimulants and nitroglycerin hypodermatically. Sometimes during the anesthetic state the muscles of the belly become very *rigid*, a condition which greatly interferes with an abdominal operation. It may arise during cyanosis, and if so caused is amended, as cyanosis abates under proper treatment. In some cases it is due to the fact that sufficient anesthetic has not been given. If the air-passages are obstructed before operation, abdominal rigidity is apt to arise. In some cases it seems impossible to overcome it with ether. In such a case, if the anesthetist is a trusted man, anesthetize the patient with gas and ether and then give chloroform (Blumfield in "Lancet," May 31, 1902).

The Reaction from Anesthesia.—When ether or chloroform is given, a considerable quantity is swallowed and either drug irritates the stomach

and creates nausea and often vomiting. The longer the operation, the more of the anesthetic enters the stomach, and the greater the liability to subsequent vomiting. At the termination of a prolonged operation upon an adult, if the patient's condition admits of it, and if the nature of the operation does not forbid it, I like to have a stomach-tube passed and the stomach well washed out with warm water. The washings smell strongly of the anesthetic, and the procedure greatly lessens the severity and frequency of postoperative vomiting (Geo. S. Brown, in "Surg., Gynec., and Obstet.," August, 1905). After the administration of the anesthetic has been suspended and the operation has been completed the temperature is usually subnormal. The patient must be watched until consciousness returns. If he is left alone, a change of posture may lead to arrest of feeble respiration, the assumption of the erect position may cause fatal syncope, and mucus or vomited matter may block the air-passages and cause suffocation. The best position to place him in is the recumbent, the head being level with the body or somewhat lower and the side of the face resting on the pillow. Shock is treated by ordinary methods (see page 290). The inhalation of oxygen is of great value in rousing a patient from the state of anesthesia, and will often prevent vomiting. If vomiting occurs, the head should be upon its side or should be held over the edge of the bed, and after the spell of vomiting the mouth must be wiped clean. The face should be washed with cold water and be fanned rather actively. It is the routine practice of some surgeons to administer vinegar by inhalation during the reaction from an anesthetic. This proceeding sometimes seems to prevent vomiting. Some patients awake from anesthesia as from a quiet sleep; others are noisy, turbulent, and violent. The duration of the period of reaction varies with the anesthetic used, the amount given, and the personal tendencies of the patient. The patient must not be allowed to sit up for several hours at least. No food is to be allowed for at least six hours. Unless the operation has been upon the stomach, I do not forbid water, but allow the patient to drink freely of hot water. This dilutes any irritant material in the stomach and dissolves mucus, and if vomiting does occur it serves to wash the stomach out. All fat patients, all patients with respiratory difficulties, or in whom we apprehend respiratory complications should, if there is no contra-indication, be placed in a sitting or, at least, a semi-erect posture as soon as reaction from anesthesia is obtained. If this plan is followed, ether-pneumonia and other respiratory troubles will very seldom develop.

After-effects of Anesthetics.—**Vomiting.**—I am convinced that in many cases postanesthetic vomiting is due or is largely due to irritation of the stomach caused by swallowing considerable quantities of an irritant anesthetic. The liability to it is greatly lessened by washing out the stomach before the patient leaves the operating table, and allowing the patient (in suitable cases) to drink freely of hot water as soon as he returns to consciousness. Most patients vomit more or less, but if the man has been drinking hot water an act of vomiting washes out his stomach and he may not vomit again. Violent vomiting may occur in spite of all our efforts, and may persist for hours, greatly exhausting the patient and doing infinite harm, it may be, especially if the operation has been upon the brain or an intra-abdominal structure. If vomiting continues, forbid food absolutely. Very hot water in doses of a teaspoonful should be given at frequent intervals. Drafts of hot water may relieve the condition by washing out the mucus from the stomach. Other remedies which may succeed are: inhalations of vinegar, hot black coffee by the mouth, a mustard plaster over the stomach, fresh air in the room, small pieces of ice placed in the mouth and sucked, small doses of iced champagne, and drop doses of a 3 per cent. solution of cocain or 3-drop doses of a 5 per cent. solution of eucain. The best remedy for persistent vomiting is lavage of the stomach. Some persons, as Dudley W. Buxton points out, suffer greatly from nausea, although

there is little or no vomiting. In such cases Buxton uses 1 min. of tincture of nux vomica in a teaspoonful of hot water every ten minutes until six doses have been taken. If this plan fails, he gives drop doses of wine of ipecac or minim doses of dilute hydrocyanic acid.[1]

Vomiting from chloroform is usually more difficult to check than vomiting from ether. In any case of persistent vomiting examine for acidosis (see page 1348).

Backache.—This is a very common and often a very distressing consequence of anesthesia. It is complained of soon after consciousness is regained, it may persist for several days, and it is a not uncommon cause of wakefulness. It is usually greatly aggravated by turning and twisting, and by attempting to rise up from the bed. The pain is located in the lumbar and sacral regions and is often accompanied by rigidity of the lumbar muscles. Various explanations have been given of it. One view is that it is due to renal congestion. Another, that it results from congestion of the spinal cord. I believe that the explanation of most cases is that given by John Dunlop ("New York Med. Jour.," July 10, 1909), viz.: "The patient during the operation lay upon a flat table without support to the lumbar curve, consequently the sacro-iliac synchondroses were strained. The backache may be largely prevented by placing a small pillow so that it will support the lumbar curve during anesthesia."

Respiratory disorders are more often noted after ether than after chloroform. Bronchitis may follow or bronchopneumonia (*ether-pneumonia*). Respiratory difficulties may be due to chilling the patient by bringing him from a warm operating room through a cold hall and into a cool bedroom. Bronchopneumonia is especially common in septic patients, and may be due in some cases to septic emboli and in others to aspiration of septic material into the bronchi (cases of cancer of the tongue and pharynx, and cases with stercoraceous vomiting). They are treated by ordinary methods. If chloroform is given when a gas-light is in the room the vapor is decomposed and certain highly irritant products are formed, which, when inhaled, produce laryngeal spasm and possibly bronchitis. The irritant material is probably $COCl_3$. The treatment is to admit fresh air freely into the room, and to have the patient inhale vinegar and, later, oxygen. Ether-pneumonia must not be confounded with postoperative pneumonia, described by Wm. H. Bennett.[2] This latter condition may arise from seven to fourteen days after operation in robust, gouty people, and is usually unilateral. Some cases of respiratory disorder result from chilling while in the operating room, or while coming from it, rather than from the anesthetic. If the patient is placed in a sitting position or, at least, semi-erect in bed, as soon as he reacts from the anesthetic the danger of serious respiratory disorder will be at a minimum.

Renal Complications.—After the administration of an anesthetic, blood, albumin, sugar, acetone, or diacetic acid may appear in the urine, and the secretion may become scanty or even be suppressed. It is usually maintained that chloroform is less apt to irritate the kidney epithelium than ether, but there has been much dispute on this point. If casts and albumin are present before anesthetization, the condition may be rendered worse if ether or chloroform is given. If neither casts nor albumin are present, they will not be so apt to appear after taking chloroform as after taking ether, but if they do appear after chloroform, they remain longer than after ether (Legrain). The truth of the matter probably is, that if the kidneys are healthy a small or moderate amount of either drug is not particularly irritant; but if the kidneys are diseased, a small amount, and even if they are healthy, a large amount, of either drug produces decided renal irritation. Chloroform is less irritant because less chloroform than ether is given to secure and maintain anesthesia. Scantiness or suppression of urine

[1] "Anesthetics," by Dudley W. Buxton.
[2] "Practitioner," December, 1896.

may be due to operative shock rather than to ether or chloroform. If the urine becomes somewhat scanty or if albumin appears in it, give non-irritant diuretics, diaphoretics and cathartics, and employ proctoclysis. The treatment of acidosis is set forth below. If the urine becomes very scanty, use hypodermoclysis. If postoperative suppression arises, it is the usual custom to give intravenous infusion of hot saline fluid, but I am doubtful of its value. Exposure of each kidney in the loin and incision of its capsule to relieve tension is justifiable and may do good.

Acid Intoxication.—This condition has been called *delayed poisoning*, *acetonuria*, and *acidosis*. Acidosis has been discussed on page 192. Diabetic coma is due to acid intoxication. It is known that even in healthy urine there may be a trace, but a bare trace, of acetone. A diabetic individual deprived absolutely of carbohydrates is apt to get acetone and diacetic acid in the urine. In such cases carbohydrates cause the prompt disappearance of the acetone and diacetic acid. Any victim of a wasting disease, of fear, of alcohol, of shock and any person who is underfed may have acetonuria. If we purpose anesthetizing a person with acetonuria adopt Bainbridge's plan. Purge and for several days before operation give by mouth several ounces of milk-sugar a day. Render the urine alkaline by giving bicarbonate of soda by mouth and by rectum. Or for two days before operation give twice daily retention enemata of half an ounce of glucose and half an ounce of bicarbonate of sodium. (Quillian, in "Annals of Surgery," 1916, lxiiii). Even people who do not suffer from acetonuria or diabetes may develop acetonuria after anesthesia. In certain cases in which dangerous symptoms arise after anesthesia the urine shows increased acidity, may contain albumin or casts, and contains acetone bodies (particularly β-oxybutyric acid), diacetic acid, or both of these substances. The blood contains an excess of free fat and shows diminution of alkalinity. Acid intoxication is very much commoner after the administration of chloroform than of ether, but may follow the giving of any general anesthetic. It may occur in individuals whose tissues contain areas of fatty degeneration, but it also occurs in those entirely free from degeneration; in fact, children particularly suffer in this way after the use of chloroform. The actual operation has nothing to do with the trouble, and sepsis is not causative. The drug used as an anesthetic causes acute fatty degeneration of the liver and other organs and quantities of acid bodies are formed and are not eliminated and these acid bodies are directly or indirectly responsible for the symptoms. Diacetic acid and β-oxybutyric acid are by-products of the process and are antecedents or precursors of acetone. The symptoms arise after the patient has emerged from anesthesia and reacted from shock. There is persistent vomiting of thin and foul fluid, the pulse is rapid, there is dyspnea, the patient is extremely restless and much excited, there may be delirium, but dulness and heaviness may take the place of restlessness and excitement and coma may arise. Usually the temperature is subnormal, but sometimes there is elevated temperature. In many cases jaundice arises. There is an odor of acetone on the breath. Latent cases free from symptoms usually get well. Slight cases and even some grave cases recover, but most of the grave cases die in from one to five days. A knowledge of this condition explains some otherwise inexplicable deaths, and also some cases of persistent postoperative vomiting and of retarded convalescence. In acid intoxication there is fatty degeneration of the kidneys, of the liver, of the suprarenal glands, and of the gastric mucosa. The occurrence of such a condition is an impressive admonition that a surgeon should operate quickly, that as little of the anesthetic should be given as possible, that the urine should be carefully examined each day after operation for certainly several days and that chloroform should not be used for prolonged administration. The indication for treatment is to saturate the patient with alkalis. Sodium carbonate is usually selected. It may be given by the rectum, by the

mouth, by hypodermoclysis, or intravenously. Rectal administration produces irritation and diarrhea. In acetonuria without clinical symptoms alkalinize the urine by 4 or 5 dr. of sodium bicarbonate daily, given by the mouth. When the urine becomes alkaline it is to be kept so. When symptoms appear give from 10 to 20 teaspoonfuls a day by the mouth and give glucose and bicarbonate of soda by slow proctoclysis. If symptoms do not soon disappear give the drug intravenously. Severe acid intoxication is treated as follows: Encourage skin activity by wrapping the patient in blankets and surrounding him with hot-water bags. Give carbonate or bicarbonate of sodium intravenously, and a glucose drip into the rectum (5 per cent. solution of anhydrous glucose). A solution of bicarbonate of a strength of from 3 to 5 per cent. is used. Labbé gives from 1 to 2 liters. If the patient improves, the sodium bicarbonate is again given by mouth. Some surgeons give citrate of sodium. Drennan gives a salt of calcium. Bevan and Farill ("Jour. Am. Med. Assoc.," Sept. 20, 1905) reported 1 case and collected 27 from literature. In this series there were 2 recoveries. (On this subject see Lewis Beesly, in "Brit. Med. Jour.," May 19, 1906; J. A. Kelly, in "Annals of Surgery," Feb., 1905; A. D. Bevan and H. B. Farill, in "Jour. Am. Med. Assoc.," Sept. 20, 1905; Geo. E. Brewer, in "Transactions Am. Surg. Assoc.," vol. xx, 1902; Labbé, in "Arch. gen. de med.," Dec., 1911, and in "Presse méd.," Feb. 5, 1910; Braun, in "Brit. Med. Jour.," Feb. 25, 1911; Geo. W. Crile, in "Annals of Surgery," 1915, lxii; A. G. Burnham, in "Am. Med.," 1916, xi; G. W. Quillian, in "Annals of Surgery," 1916, lxiii; J. Harold Austin, in "Penn. Med. Jour.," Feb., 1917.

Postanesthetic Paralysis or Narcosis Palsy.—Paralysis may arise during anesthesia as a result of cerebral hemorrhage or embolism.

It sometimes happens that when a person has come out of the anesthetic sleep a palsy of some part is found to exist, the condition being peripheral and not central in origin. Peripheral narcosis palsies are pressure palsies or traction palsies, although it is held by some that the anesthetic has a toxic influence which distinctly lowers the capacity of the nerves to sustain pressure. Certain it is that palsy sometimes follows what seems a degree of pressure inadequate to cause such a result. Narcosis palsies may be due to pressure of an extremity upon a table edge or to pressure upon nerves by placing the patient in certain positions.[1] Such palsies are most common in the upper extremity but may occur in the face or in the lower extremity. When the Trendelenburg position has been employed, the flexures of the knees are in contact with the edge of the table, and paralysis of one or both external popliteal nerves may be induced. When the patient lies upon the side any nerve of the arm or forearm may suffer, but the circumflex and radial are most liable to be damaged. When the arm is elevated to the side of the head, or when it is drawn out strongly from the body, the brachial plexus may be compressed by the head of the humerus (Braun, in "Deutsche Med. Woch.," 1894). When the arm is in external rotation and is drawn backward and outward the median nerve is stretched, and when the forearm is flexed and supinated the ulnar nerve is stretched (Braun, Ibid.). In most cases the paralysis involves muscles supplied by the brachial plexus and is due to drawing the arm upward and backward over the head, a position which may squeeze the cords of the plexus between the collar-bone and the first rib. Garrigues shows that the plexus is particularly apt to be squeezed when it is stretched by the head being drawn to the opposite side or being allowed to fall back.[2] According to Büdinger the mounting up of the clavicle squeezes the plexus as its cords cross the first rib. This surgeon thinks that extreme abduction of the arm may squeeze the cords. Molinari (Abstract in "Surgery, Gynecology, and Obstetrics," Feb., 1914 from "Zentralb. f. d. ges. Chir., u. i. Grenzgeb.") says: "If an individual is upon his back he can raise his

[1] H. J. Garrigues, in "Am. Jour. Med. Sciences," Jan., 1897.
[2] Ibid.

arm forward higher than the shoulder without dragging on the plexus. When the arm is drawn backward there is tension of the plexus over the head of the humerus and tension becomes extreme when the upper arm is rotated inward and the head is turned toward the opposite side. If the arm is now raised to a vertical position the tension becomes greater and soon the plexus is squeezed between the clavicle and first rib."

The prognosis is good, as a rule. Slight cases are soon recovered from; more serious cases, in which degeneration occurs, may not be recovered from for months. The treatment is that of any pressure palsy.

Primary Anesthesia.—Instruct the patient to count aloud and hold one arm above his head. Give the ether rapidly. In a short time he becomes mixed in his count and his arm sways or drops to the side. There is now a period of insensibility to pain lasting only about half a minute, and during this period a minor operation can be performed. The patient quickly reacts from primary anesthesia without vomiting (Packard).

Mixtures are used by some because of the belief that a mixture might eliminate some unpleasant feature or some danger from a particular anesthetic.

Mixture of Ether and Chloroform.—This may be used in varying proportions. Hewitt at times employs 2 parts of chloroform to 3 parts of ether.

Vienna mixture contains 1 part of chloroform and 3 parts of ether.

Mixture of Alcohol and Chloroform.—All the chloroform mixtures produce the effects of chloroform, but we are giving the drug in an unknown amount. It was believed by Sansom, who devised this mixture, that the alcohol prevents concentration of chloroform vapor by retarding evaporation. When used, 1 part of alcohol is added to 4 parts of chloroform.

Nitrous Oxid and Oxygen.—(See page 1352).

A. C. E. Mixture.—This mixture was originally used by Harley in 1864. It is often valuable in cases in which ether cannot be given. It is composed of 1 part of alcohol, 2 parts of chloroform, and 3 parts of ether. Its action is supposed to be between that of chloroform and ether. The objection to the A. C. E. mixture, as to any mixture, is that the materials do not evaporate in the ratio in which they are mixed, hence an uncertain amount of chloroform vapor is being inhaled (Buxton). This mixture is given by some from a Junker and by others from an open inhaler. Plenty of air should be given with it. The anesthetic acts similarly to chloroform.

Billroth's mixture contains 1 part of alcohol, 3 parts of chloroform, and 1 part of ether.

Schleich's Mixture for General Anesthesia.—Schleich, in 1895, introduced *a new anesthetic agent* which he claims is safer than chloroform. This surgeon maintains that a material is safe as an anesthetic only when almost all of the amount taken in at an inspiration is expelled on expiration. The anesthetic is unsafe in direct proportion to the amount absorbed; and the lower the boiling-point of an anesthetic, the less is absorbed, hence an anesthetic agent, to be safe, should have a low boiling-point. Schleich makes three solutions. The first contains (by volume) 1½ oz. of chloroform, ½ oz. of petroleum ether, and 6 oz. of sulphuric ether. The second contains 1½ oz. of chloroform, ½ oz. of petroleum ether, and 5 oz. of sulphuric ether. The third contains 1 oz. of chloroform, ½ oz. of petroleum ether, and 2⅔ oz. of sulphuric ether. No. 1 is used for light anesthesia, No. 2 for medium anesthesia, and No. 3 for deep anesthesia. The anesthesia can be given from an open inhaler or a towel. The anesthetic state is quiet, reaction is rapid, and vomiting occurs in but half the cases. The superiority of this new anesthetic has not been proved. It sometimes causes dangerous symptoms, and has produced death. Some surgeons, who formerly approved of it, have abandoned it. It will certainly not displace ether or chloroform. Schleich's mixtures are now seldom or never used in the United States. Petroleum ether has no anesthetic power, and Meltzer shows that it is dangerous

and tends to paralyze the respiratory muscles. Willy Meyer ("Med. Record," August 15, 1908) believes in the Schleich principle, but substitutes ethyl chlorid with a boiling-point of 59° F. for the petroleum ether. He uses 17 per cent. volume of ethyl chlorid with 83 per cent. volume of the molecular mixture of ether and chloroform.

Ethyl bromid was first used by Nunneley, of Leeds, in 1849. It was reintroduced in 1882 and again in 1896. It is still sometimes used for short operations. It is given while the patient is recumbent. The unconsciousness is obtained in from one to three minutes and is rapidly recovered from, and there is no after-sickness. The unconsciousness lasts about three minutes. Three drams are given to a child, and 6 dr. to an adult. A towel is put over the face and the entire amount is poured on at once, and as soon as the patient is unconscious the towel is taken away and no more of the drug is given (Cumston). Even if consciousness is regained too quickly to suit the purposes of the surgeon, it is not safe to give more of the drug, a notable objection which chlorid of ethyl does not possess. Cases have been reported in which sudden death has followed the administration of this drug, and it should not be given if there is disease of the heart, lungs, or kidneys.[1] Twenty-four deaths from bromid of ethyl are on record (Guadiana). If it kills, it acts like chloroform. It may be given *before* ether to prevent unpleasant effects, but it is usually not considered proper to give before chloroform. Zematski, however, has used it before chloroform in 2000 cases ("Vratch," August 25, 1901). I know of 2 unpublished deaths from it in Philadelphia. I never use it and regard it as unsafe. The drug rapidly deteriorates, and the deteriorated drug is very dangerous.

Chlorid of ethyl is a rapid anesthetic and statistics imply that it is a safe one. My faith in it has been greatly shaken by knowledge of 3 unpublished deaths in Philadelphia. It was first used by Heyfelder in 1848. A committee of the British Medical Association condemned it in 1880. Carlson and Thiesing reintroduced it in 1895 (McCardie, in "Lancet," April 4, 1903). It may be sprayed upon a mask covered by six to eight layers of gauze, so that the drug will not evaporate too quickly in the air. Many anesthetists give it in a closed apparatus, the patient respiring into and from a rubber bag. I believe it should be mixed with air and that concentrated vapor is a danger to the heart. The odor of the drug is agreeable. From 5 to 10 gm. of ethyl chlorid are given for a short operation if the mask is used. The patient must always be recumbent when taking it. Early in the inspiration the pulse and respiration become rapid. When unconsciousness comes they should be normal. The anesthetic state is induced, when the mask is used, in from two to three minutes, and as soon as it is obtained the patient is allowed to get air. If the closed inhaler is used unconsciousness is obtained more rapidly. Excitement does not precede unconsciousness. The anesthetic condition lasts from one to three minutes, and it is recovered from rapidly, usually without vomiting or unpleasant after-effects. If the patient recovers too rapidly for the surgeon's purpose, more ethyl chlorid can be given. It is to be noted that complete muscular relaxation does not occur, in many cases the conjunctival reflex is not completely abolished, and often the pupils do not dilate. It has no superiority over nitrous oxid, except as to cost and portability, and sometimes it fails to produce complete unconsciousness. A large dose rapidly given is dangerous, as it may cause cessation of respiration and spasm of the diaphragm. A contraindication to its use is any respiratory obstruction. In many cases there is spasm of the masseters. Concentrated vapor administered for a considerable time lowers the blood-pressure, induces cyanosis and asphyxia, and would eventually cause death by respiratory failure (McCardie, Ibid.). Lotheisser, in a study of 2500 cases of anesthesia by this agent, reports 1 death. Ware col-

[1] See Cumston, in "Boston Med. and Surg. Jour.," Dec. 20, 1894.

lected 12,436 cases, with 1 death ("Jour. Am. Med. Assoc.," Nov. 8, 1902). Seitz, of Konstanz, collected 16,000 cases, with 1 death. Miller ("Jour. Am. Med. Assoc.," Nov. 23, 1912) estimates that there is 1 death in 13,365 administrations. It is perhaps safer than chloroform, not nearly so safe as nitrous oxid, and not so safe as ether. The drug is used for a brief operation or examination. It can be given to infants a few days old with reasonable safety, and it has been administered many times to the aged. When it kills, it acts in a similar manner to chloroform. I have often given it *before* ether to prevent unpleasant symptoms and to hasten the advent of anesthesia, but it must *never* be given before chloroform. Recently I have practically ceased to administer ethyl chlorid.

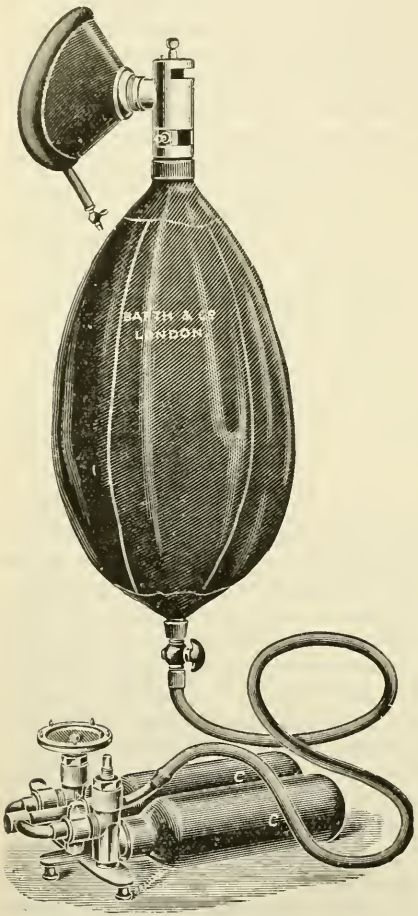

Fig. 877.—Hewitt's nitrous oxid apparatus

Nitrous oxid gas may be used to obtain anesthesia for brief operations. It is contra-indicated when high-blood pressure indicates vascular degeneration, because apoplexy may follow its administration. It should never be given when the air-channel is narrowed, as in Ludwig's angina, abscess in or below the tongue, and thyroid enlargement (F. W. Hewitt, in "Lancet," July 20, 27, and August 10, 1907). This gas is stored in steel cylinders, in which it is liquefied. The gas is passed into a rubber bag (Fig. 877), and is given to the patient by means of a tube and a mouth-mask, a wedge being placed between the patient's molar teeth, and the nostrils being closed by the anesthetist's fingers. The wedge must be held by a string, so that it cannot be swallowed. The patient becomes unconscious in about one minute, and we know the patient is anesthetized by the stertor and cyanosis and the insensitiveness of the conjunctivæ. The pulse should be watched, and if it flags the administration must be suspended at once. The striking phenomena are asphyxial, stertorous respiration, cyanosis, and even convulsions, dilatation of the pupils, rapidity of the heart, and swelling of the tongue.[1] Muscular relaxation is not as complete as in ether-anesthesia. Slowing of the heart is a danger sign. If nitrous oxid causes death, it does so by asphyxia or by asphyxia and cardiac inhibition. A person rouses very rapidly when the administration of nitrous oxid is suspended. It is a useful plan to give nitrous oxid first and follow this with ether (see page 1355). By this method the patient is anesthetized rapidly and pleasantly with the nitrous oxid, and the anesthesia is maintained by the ether.

It was formerly taught that nitrous oxid necessarily produces cyanosis, because the gas can only cause anesthesia by partially asphyxiating the patient. We know this is untrue, because if *nitrous oxid is mixed with oxygen* or atmospheric air anesthesia is obtained without cyanosis. Nitrous oxid is a genuine

[1] See Hewitt, "Brit. Med. Jour.," Feb. 18, 1899.

anesthetic agent. If a prolonged administration of nitrous oxid is desired, pure nitrous oxid can be given, a breath of fresh air being allowed, from time to time. By this method Preston has anesthetized many patients, the duration of the anesthesia being from ten to fifty minutes. A better plan is to give nitrous oxid and oxygen. I do not believe it is wise to give nitrous oxid even with oxygen over thirty minutes because of the destructive effect of the gas on hemoglobin. A trouble frequently encountered is persistent rigidity. This can often be prevented by a preliminary dose of morphin. Postanesthetic vomiting is rare (Teter, on "Thirteen Thousand Administrations of Nitrous Oxid with Oxygen,"

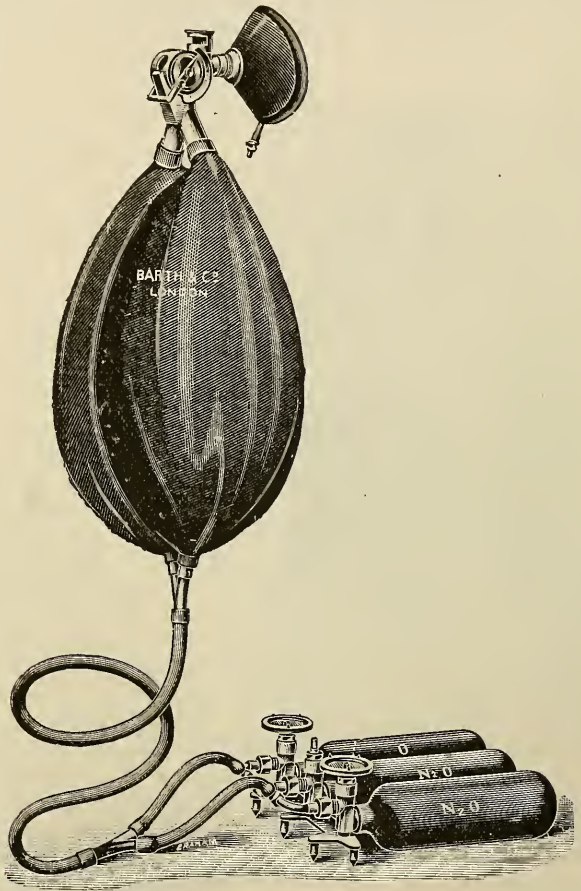

FIG. 878.—Hewitt's nitrous oxid and oxygen apparatus.

"Jour. Am. Med. Assoc.," August 7, 1909). Hewitt[1] formulates the following views as to the use of oxygen and nitrous oxid:

"In order to obtain the best form of anesthesia oxygen should be administered with nitrous oxid by means of a regulating apparatus (Fig. 878), the percentage of the former gas being progressively increased from 2 to 3 per cent. at the commencement of the administration to 7, 8, 9, or 10 per cent., according to the circumstances of the case. The longer the administration lasts, the greater may be the percentage of oxygen admitted.

"The next best results to those obtainable by means of a regulating apparatus for nitrous oxid and oxygen are to be secured by administering certain

[1] "Brit. Med. Jour.," Feb. 18, 1899.

constant mixtures of these two gases. Mixtures containing 5, 6, or 7 per cent. of oxygen are best for adult males, and mixtures containing 7, 8, or 9 per cent. are best for females and children. The next best results to those last mentioned are to be obtained by means of mixtures of nitrous oxid and air, from 14 to 18 per cent. of the latter being advisable in anesthetizing men and from 18 to 22 per cent. in anesthetizing women and children."

Crile uses nitrous oxid and oxygen as the anesthetic of choice for many operations, even major operations. He believes it produces less shock, less nausea, and less lowering of vital resistance to infection than does ether. He insists on the necessity of having a highly trained administrator and of keeping the patient *pink* during the administration. Respiratory failure is met at once by turning off the nitrous oxid and substituting pure oxygen. If relaxation is impossible (and it may be in a very muscular subject), ether is given until relaxation is attained and then a return is made to nitrous oxid ("Transactions of Southern Surg. and Gynec. Assoc.," 1909). Crile gives a small dose of morphia and scopolamin before operation to prevent too early postoperative appreciation of the "operative trauma."

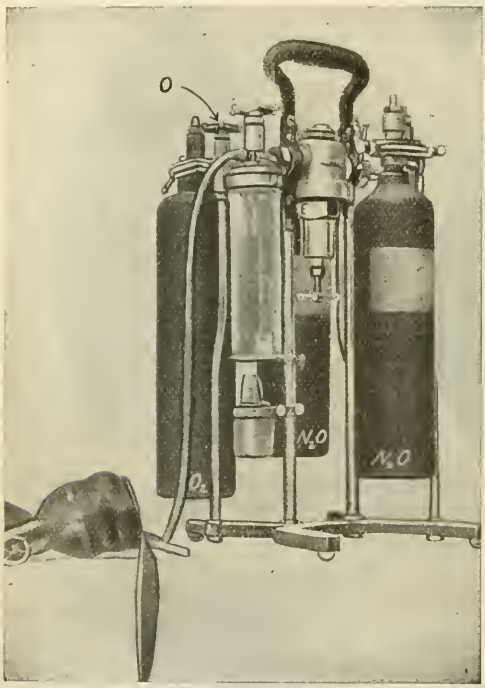

FIG. 879.—Gwathmey-Woolsey nitrous oxid oxygen apparatus with tanks in place: *O*, Regulating valve for oxygen; O_2, oxygen tank; N_2O, nitrous oxid tank.

The Gwathmey-Woolsey apparatus is a very useful one for nitrous oxid and oxygen administration (Fig. 879). When the operation is to be brief, when there is bronchial or pulmonary disorder, or when nephritis exists nitrous oxid with oxygen is the method of choice. I agree with Baldwin that it is not free from danger ("Med. Record," 1916, xc). A number of deaths have been reported (Baldwin refers to over thirty). The method is expensive, requires a specially trained administrator, should not be adopted as a routine, and should not be used in operations requiring more than thirty minutes.

Bichlorid of Methylene.—The composition of the so-called bichlorid of methylene is a matter of dispute. Some high authorities believe it to be a mixture of methyl alcohol and chloroform. It rapidly produces unconsciousness and the patient returns quickly to consciousness when the administration is suspended. Some surgeons have thought highly of it, and claimed that it is pleasant, safe, and is not followed by vomiting as often as chloroform. The weight of opinion is that it is dangerous, death being similar to death from chloroform. It is given by means of a Junker apparatus.

Anesthetic Successions.—Bromid of Ethyl Followed by Chloroform or Ether.—(See page 1351.)

Chlorid of Ethyl Followed by Ether.—(See page 1351.)

Chloroform Followed by Ether.—Chloroform is sometimes given until the sensation becomes more or less obtunded, when ether is substituted. This is

done to save the patient from the unpleasant sensation of etherization. It is a practice not to be commended, because it is precisely in the beginning that chloroformization is most dangerous.

Ether Followed by Chloroform.—When the patient cannot be relaxed or rendered unconscious by ether, or when some other complication develops, it is common practice to suspend ether and substitute chloroform. If the change is made, chloroform should be given cautiously. A large quantity should never be poured upon the inhaler at one time. The change should never be made when the patient is struggling, because the deep respirations which attend or follow struggling may lead to the rapid inhalation of a dangerous dose of chloroform vapor. Further, as Hewitt points out, when the patient is deeply under the influence of ether the change should not be made unless it is imperatively necessary.

Nitrous Oxid Gas Followed by Ether (Gas and Ether).—This very valuable method was suggested by Clover. I have used it repeatedly with great satisfaction. The patient is *made* unconscious by nitrous oxid and is *kept* unconscious by ether. Thus are avoided excitement, struggling, choking, and the very unpleasant sensations induced by ether. It lessens the amount of time requisite to obtain anesthesia and lessens the amount of ether used. More important even than this, the method is safe. It is more satisfactory in women and children than in men. In very muscular men and in very stout elderly men it should not be used. In many cases nitrous oxid causes a flow of mucus from the respiratory tract. Because of the frequency of this happening it is wise to precede gas and ether anesthesia twenty minutes by a hypodermatic injection of morphin and atropin (Van Kaathoven, in "Annals of Surgery," Sept., 1908), or of atropin alone. Many operators first anesthetize with nitrous oxid, using an ordinary dental apparatus, and then give ether on an ordinary inhaler. The anesthetist must bear in mind that ether must be given gradually, not suddenly, poured on in large amount. Others prefer to use a combined gas-and-ether inhaler. I use the Gwathmey-Woolsey apparatus (Fig. 879).

Hewitt ("Anesthetics and Their Administration") thus describes the administration by means of Clover's portable ether-inhaler fitted with a stop-cock and a detachable gas bag:

"If the patient be lying upon his back, his head should be turned to one side. The face-piece with the charged ether chamber is then applied during an expiration. Air will be breathed backward and forward. When the respiration is seen to be proceeding freely, and the face-piece fits well, the charged gas bag is attached to the ether chamber. Air will still be breathed, but not through the valves of the special stop-cock. When the valves are heard to be working properly 'gas' is turned on, and is likewise breathed through the valves. Three or four respirations (or about one-half of the contents of the bag) are allowed to escape. The valve action is now stopped by turning the tap at the upper part of the stop-cock. At the same moment at which the patient begins to breathe 'gas' backward and forward, the rotation of the ether chambers for the addition of ether vapor should be commenced. The administrator will, in fact, find that he can, in a few seconds from the commencement of the administration, rotate the ether chamber as far as '1' or '1½.' Should swallowing or coughing arise, he must rotate more slowly. Respiration soon becomes deep and regular, and more and more ether may be admitted. At about this juncture, if the apparatus has been fitting the face well, signs of nitrous oxid narcosis may appear, especially in those who are quickly affected by this gas. Should jerky breathing or 'jactitation' arise, one full inspiration of air may be admitted at the air-tap. It should be remembered, however, that in giving 'gas and ether' by this method, the object is just to steer clear of the clonus and 'stertor' of nitrous oxid narcosis and gradually but increasingly to mix ether with the gas.

"In muscular and vigorous subjects the quantity of gas above mentioned will be found to be, as a general rule, insufficient to lead to the usual signs of deep nitrous oxid anesthesia. The rotation of the ether chamber should be continued till the indicator points to '2,' '3,' or 'F.'

"The mistake that is most commonly made is that of admitting air too soon. Should air be given during the first half or three-quarters of a minute, the patient will partially come round, hold his breath, set his teeth, and give a good deal of trouble. Duskiness of the features must be expected. Speaking generally, air should not be allowed until the patient is stertorous, when one breath may be given. In this manner the patient will continue breathing a mixture of nitrous oxid, ether, and air till the usual signs of deep ether-anesthesia appear, when the gas bag may be detached, and the little bag ordinarily used with Clover's inhaler substituted."

Hewitt prefers to use a modified Clover inhaler, which permits of the introduction of ether after the inhalation of nitrous oxid has begun.

Hypnotic Anesthesia.—It is well known that Esdaile in India did numbers of operations upon patients in hypnotic anesthesia. Cloquet, as long ago as 1829, amputated a breast of a woman who was held free from pain by hypnosis. In 1851 Guérineau amputated the thigh of a hypnotized person and there was no sign of pain. But all subjects are not susceptible. Even susceptible subjects require to be hypnotized again and again for days before the operation. The method has its own dangers and has been entirely abandoned.

Scopolamin-morphin Anesthesia.—This method has been enthusiastically praised and I have used it with satisfaction in a number of cases, but I have grown afraid of it. In a patient in the Jefferson Hospital dangerous symptoms arose after a dose of $\frac{1}{100}$ gr. of scopolamin. Ely records a death from respiratory failure two hours after the administration of $\frac{1}{8}$ gr. of morphin and $\frac{1}{100}$ gr. of scopolamin ("New York Med. Jour.," Oct. 20, 1906). A number of deaths have been reported following its use and there are, beyond doubt, unreported cases. Four deaths in 2400 cases were certainly directly due to it (H. J. Whitacre, in "New York Med. Jour.," March 31, 1906). It has even been stated that the death-rate is 1 in 100 ("Semaine Medicale," Jan. 11, 1905). Scopolamin is chemically identical with hyoscin and must never be used unless fresh, as it decomposes in air and light. If given without morphin, it is inefficient. Large doses are certainly dangerous, and the combination should never be given in sufficient amount to induce surgical anesthesia unaided. If used at all, it should only be as an aid to local anesthesia or to general anesthesia by ether or chloroform. I have used it as an aid to local anesthesia in 6 goiter operations in 2 cases of removal of the Gasserian ganglion and in several prostatectomies. It should not be used in heart disease (Hayem); in persons under sixteen or over sixty (Korff); in any one with a tendency to pulmonary edema or with any acute condition of the throat which interferes with respiration (A. C. Wood, in "American Medicine," Nov. 11, 1905).

It produces a drowsy, heavy state or actual sleep, and the patient can be kept unconscious with an extremely small quantity of ether or chloroform. For five or six hours after the operation the sleep continues, and in most cases there is no postoperative vomiting.

If it be used, a mixture is freshly made containing $\frac{1}{100}$ gr. of scopolamin and $\frac{1}{6}$ gr. of morphin, and this is given hypodermatically one-half an hour before the operation. During the operation the sleep may be maintained by small amounts of ether or chloroform. If symptoms of poisoning occur, artificial respiration and oxygen inhalations may be required, external heat is needed, and nitroglycerin, strychnin, or caffein should be given.

I agree with Kochmann that we are not as yet justified in recommending this method of anesthesia ("Münchener medizinische Wochenschrift," 1905, No. 17). The Tubingen Clinic abandoned it after thorough trial.

Anesthesia in Obstetrics.—Light ether anesthesia is used by some, light chloroform anesthesia by others. If it is night and there is gas lamp or candle light be sure, if ether is used, that there is sufficient ventilation to prevent an explosion, and, if chloroform is used, to prevent the decomposition of chloroform vapor by naked flame into highly irritant gases. Scopolamin-morphin anesthesia was introduced by Steinbüchel in 1903. In 1906 it came to be called the Freiburg method of Gauss. It has since been widely and most improperly advertised as "twilight sleep." I leave the discussion of its merits or demerits to the obstetricians. In 1880 Klikowisch began to use nitrous oxid and oxygen in obstetrics. Webster took it up in 1905. He gives the gas during the pains and withdraws it between the pains. The administration is begun in the second stage of labor when the pains become severe. It is said to increase rather than to arrest expulsive contraction, the consciousness is retained and the child is not injured.

Fig. 880. — Gebauer's ethyl-chlorid tube.

Local Anesthesia.—In every case requiring operation we should inquire whether local anesthesia should be used instead of general anesthesia. Many really extensive operations can be done under the former, and its field has been greatly broadened by the knowledge that viscera innervated by purely visceral nerves are insensitive and sensation exists only in those which receive branches from the somatic nerves (K. G. Lennander, in "Mittheilungen aus dem Grenzgebeiten der Medicin und Chirurgie," 1902, Bd. x, Heft 1 and 2). Lennander shows that the parietal peritoneum is sensitive to pain, but not to touch —that the intestine, stomach, edge of the liver, mesentery, gall-bladder, urinary bladder, kidney parenchyma, lung, anterior wall of the trachea, testicle, and epididymis are insensitive, though the coverings of the testicle and epididymis are sensitive. My experience is that the viscera may be cut, sutured, and handled without any severe pain if they are not pulled upon. In removing an appendix the only pain felt will be when the meso-appendix is pulled upon or adhesions to the parietal peritoneum are separated. The advantages of operation under local anesthesia are freedom from the danger of anesthetic accidents, blood changes, and postanesthetic discomforts and dangers. The disadvantage is the knowledge of the patient as to what is taking place. He may become alarmed and turbulent, and may thus interfere with a necessary procedure at a vital moment. There are many methods of local anesthesia.

Freezing.—*Ice* and *salt* may be used. Take ¼ pound of ice, wrap it in a towel, and break it into fine bits; add ⅛ pound of salt; then place the mixture in a gauze bag and lay it upon the part. The surface becomes pallid and numb, and, in about fifteen minutes, decidedly analgesic. A *spray of rhigolene* freezes a part in about ten seconds. It is highly inflammable. *Ether-spray* anesthesia was suggested by Benjamin Ward Richardson. *Chlorid of ethyl* comes in glass or metal tubes (Fig. 880). Remove the cap from the tip of the tube and hold the bulb in the palm: the warmth of the hand causes the fluid to spray out. Hold the tube some little distance from the part, and let the fine spray strike the surface. The skin blanches and whitens, and is ready for the operation in about thirty seconds. Freezing is only of value in a trivial operation and when only a single cut or stick is required.

Hypodermatic Injection of Cocain Hydrochlorate.—Cocain was discovered by Gaedeke in 1855. In 1884 Köller, of Vienna, demonstrated the value of cocain as an analgesic in ophthalmic practice. In 1885 J. Leonard Corning, of

New York, showed that cocain when applied to a mixed nerve in man abolished nerve conduction, as it was already known to do in the lower animals. In 1885 Halsted and Raymond induced anesthesia in the nerve distribution by injecting cocain about the inferior dental and lingual nerves (perineural injection). This was done before pulling a tooth. Schleich introduced infiltration anesthesia. Braun, Van Hook, and Matas did much to develop local anesthesia. A tremendous impetus was given to infiltration anesthesia by Harvey Cushing's report on herniotomy under local anesthesia ("Annals of Surgery," 1900, vol. xxxi). He used a very weak solution of cocain (1 : 1000). Cocain hydrochlorate is soluble in water, but should not be boiled. To boil it impairs its anesthetic power. A tablet of the drug should be sterilized by dry heat and dissolved in sterile water. Always bear in mind that cocain is sometimes a decidedly dangerous agent. There are a number of deaths from cocain on record. The urethra is a particularly dangerous region, and so is the face. It is undesirable to use more than $\frac{2}{3}$ gr. upon a mucous surface, and to inject hypodermatically more than $\frac{1}{3}$ gr. The drug must not be injected into a vein. Moderately severe cases of cocain-poisoning are characterized by great tremor, restlessness, pallor, dry mouth, talkativeness, and weak pulse. In dangerous cases there is syncope or delirium. Death may arise from paralysis or from fixation of the respiratory muscles. Cases with a tendency to respiratory failure require the hypodermatic injection of strychnin. In cases with tetanic rigidity of muscles hypodermatic injections of nitroglycerin or inhalations of the nitrite of amyl should be given. In cases marked by delirium, if the circulation is good, hyoscin is given. In any case stimulants are given, a catheter is used, and diuresis encouraged. Cocain-poisoning is always followed by a wakeful night. Cocain should not be used in any considerable amount if the kidneys are inefficient. In using cocain try to prevent poisoning. Because of the dangers inherent in cocain, have the patient recumbent. One minute before giving the cocain administer hypodermatically 1 drop of a 1 per cent. solution of nitroglycerin and repeat the dose once during the operation. In operating on a finger, after making the part anemic, tie a tube around the root of the digit before injecting cocain, and after the operation gradually loosen the tube. A hot solution of cocain is more efficient than a cold solution, hence hot solutions can be used in much less strength and are safer. The method of injection is as follows: A sharp needle is held at an angle of 45 degrees to the surface and is pushed into the Malpighian layer. One or 2 min. of a 2 per cent. solution are forced into the Malpighian layer, and a whitened elevation forms. The needle is withdrawn, at the margin of the wheal is reinserted, and more fluid is introduced, and so on until the region to be operated upon has been injected. After waiting five minutes the operation is begun. If, after cutting the skin, it is necessary to cut the subcutaneous tissue, inject a few drops of a 1 per cent. solution into the tissue. After the completion of the operation, if a rubber band has been used, it is loosened for a few seconds, tightened for a few minutes, again loosened and readjusted, and so on several times (Wyeth). In this way only a small quantity of cocain is admitted into the circulation at one time and toxic symptoms are prevented. For operations upon the eye a 1 to 4 per cent. solution is employed; 1 drop of fluid is instilled every ten minutes until 3 drops have been given. Rarely use over a 10 per cent. solution on mucous membrane, although in laryngeal operations a 20 per cent. solution may be required. For the nasal mucous membrane a bit of wool soaked in a 5 per cent. solution is inserted or a spray of 4 per cent. solution is thrown from an atomizer into the nostrils. In the rectum, vulva, vagina, and uterus use a 5 per cent. solution; in the urethra, a 4 per cent. solution, and in the bladder, a 2 per cent. solution.

Cocainization of a Nerve-trunk.—Krogius, Halsted, and Raymond pointed out that if cocain be injected into the tissue about a nerve-trunk (perineural injection), anesthesia will follow in the area supplied by the nerve. The anes-

thesia will be produced in five minutes, and will last fifteen minutes. If cocain be injected about the root of the finger, all of the tissues of the digit will become insensitive. Injection over both supra-orbital notches renders the middle of the forehead insensitive. Injection over the ulnar nerve causes complete anesthesia in its trajectory. This plan is extensively used in Helsingfors.

It has been demonstrated by Crile ("Jour. Am. Med. Assoc.," Feb. 22, 1902) that the injection of cocain into a nerve-trunk (endoneural injection) interposes an absolute block to the transmission of afferent and efferent impulses and greatly lessens operative shock. In 3 cases I employed this method to secure anesthesia for amputation of the leg. None of the patients felt pain and shock was trivial.

In two amputations of the entire upper extremity, although the patient was under ether, the brachial plexus was cocainized to minimize shock and shock was very slight. The cocain was injected directly into the trunks (endoneural injection). The combination of local anesthesia and general anesthesia is part of Crile's **anoci-association operation,** a plan to rule out all noxious or noci influences ("Jour. Am. Med. Assoc.," July 13, 1912). He points out that though a person under ether is without feeling, the greater part of the brain is still awake, nerve impulses still reach the brain and cause functional depression and morphological alterations in the brain cells (Crile's "Ether Day Address," 1910). He would prepare a patient by filling him with calm confidence, giving him morphin and scopolamin previous to operation, administering nitrous oxid, and isolating the brain from the field of operation by infiltrating the region with 1:400 solution of novocain. At the conclusion of the operation the region may be injected with the hydrochlorid of quinin and urea.

Eucain hydrochlorate (β-eucain) is not entirely nontoxic but is far safer than cocain used in full doses, and in many cases is to be preferred to it. It is injected in the strength of from 2 to 5 per cent. It is soluble in water and can be boiled without destroying its properties, and hence can be readily rendered sterile. It occasionally, though rarely, happens that the injection of eucain causes sloughing, especially at the extremities, in fatty tissue, in tendon-sheaths, and in bursæ. It can be used on mucous membranes.

Stovain.—This agent is a local anesthetic introduced by Fourneau. It is as powerfully analgesic as cocain, is only one-third as toxic, and is slightly germicidal. It is dissolved in cold water or salt solution, and is used in a solution of the strength of 0.5 per cent. Adrenalin can be given with it. (See Sonnenburg, in "Deutsche medicinische Wochenschrift," March, 1905.)

Quinin-urea hydrochlorid in from ¼ to 1 per cent. solution causes prolonged local anesthesia. A solution of 1 per cent. is too strong—it causes the wound to heal slowly and produces induration. The drug has no toxic effect and can be used in considerable quantity; it lessens bleeding, and, by producing an effect for many hours, lessens postoperative pain. Quinin-urea hydrochlorid is used by infiltration (see below). It is dissolved in water or normal salt solution.

Novocain of a strength in solution of from 1:200 to 1:400 is preferred by some surgeons. It may be given alone or mixed with stovain. It is given by infiltration. The drug is soluble in water and the solution can be boiled without being impaired in anesthetic power. It is one-sixth as toxic as cocain.

Infiltration anesthesia is in most instances the preferred method of local anesthesia. It is a term used to indicate a form of local anesthesia in which the tissues are not only injected, but are distended decidedly with a fluid anesthetic indifferent in nature. It is called *terminal anesthesia* because the anesthetic acts upon the terminal branches of sensory nerves. It is called *regional anesthesia* because the fluid injected affects a particular part of a sensory nerve in its course. Infiltration anesthesia was devised by Schleich, of Leipsic, who

was dissatisfied with cocain, because it is not safe and sometimes fails to produce complete local anesthesia, owing to want of thorough diffusion. He found that salt solution (0.2 per cent.), if injected into uninflamed parts, produced anesthesia. To obtain this anesthesia the part must be distended by wide infiltration. If minute quantities of cocain, morphin, and carbolic acid are added to the solution, the anesthesia becomes more thorough and more prolonged, and can be obtained even in inflamed areas. Schleich uses three solutions:

No. 1, a strong solution, which is used in inflamed areas: cocain hydrochlorate, 3 gr.; morphin hydrochlorate, $\frac{2}{5}$ gr.; sodium chlorid, 3 gr.; distilled sterile water, $3\frac{2}{5}$ oz.; phenol (5 per cent.), 2 drops.

No 2, medium solution, which is employed in most cases: cocain hydrochlorate, $1\frac{1}{2}$ gr.; morphin hydrochlorate, $\frac{2}{5}$ gr.; sodium chlorid, 3 gr.; distilled sterile water, $3\frac{2}{5}$ oz.; phenol (5 per cent.), 2 drops.

No. 3 is the weak solution used to infiltrate extensive areas: cocain hydrochlorate, $\frac{1}{6}$ gr.; morphin hydrochlorate, $\frac{2}{5}$ gr.; sodium chlorid, 3 gr.; distilled sterile water, $3\frac{2}{5}$ oz.; phenol (5 per cent.), 2 drops.

The addition of adrenalin chlorid to the cocain solution is an advantage, as it retards the circulation and hence favors analgesia and lessens bleeding during the operation. A satisfactory fluid for infiltration is 1 part of a 1:1000 solution of adrenalin chlorid and 9 parts of a 0.5 per cent. solution of cocain

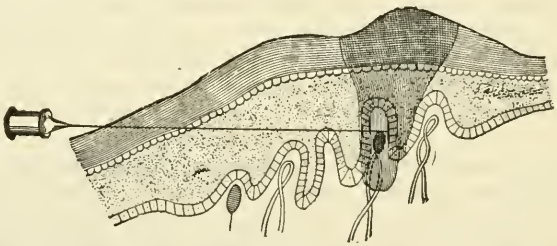

Fig. 881.—The syringe-point stops at the papillary layer, and the fluid lodges in the skin itself (Van Hook).

(Gangitans, in "Riforma Medica," Sept. 9, 1903). Eucain and adrenalin are preferred by some. Barker uses distilled water, 100 gm.; pure sodium chlorid, 0.8 gm.; β-eucain, 0.2 gm.; chlorid of adrenalin, 0.001 gm. After injecting Barker's fluid the surgeon waits for twenty minutes before operating.

The injections are begun *in* the skin, not *under* it (Fig. 881), and are made one after another until the area to be operated upon is surrounded above, below, and on all sides with Schleich's solution. At each infiltrated area a wheal forms in the skin. This infiltration can be made painlessly by touchng with pure carbolic acid the point where the needle is to be inserted, or by freezing this spot with ethyl chlorid. After infiltration of the skin with the cocain solution the surgeon waits for a minute or two and then operates; incision is made, and when deeper tissues are reached they are infiltrated before incising them. If a nerve comes in sight, touch it with a drop of pure carbolic acid. Van Hook says that the anesthesia obtained by this method is due to artificial ischemia, pressure upon the tissues, the direct action of the drugs, and the lowered temperature.[1] The method is very efficient, and can be used for operations of considerable magnitude. Matas uses a special apparatus to infiltrate the tissues. The fluid is driven by compressed air, and widespread or *massive infiltration* is produced.

An ideal fluid to be injected should be isotonic with the blood, and should contain the smallest percentage of chemical agent necessary to render the part anesthetic. The solution recommended by Dr. James Mitchell, of Washington, D. C., seems to meet these requirements as closely as practically possible.

[1] "Med. News," Nov. 16, 1895.

Mitchell uses a tablet containing ¾ gr. of cocain and 1/400 gr. of adrenalin. The tablets are dry sterilized, and just before operation are dropped into cups containing normal salt solution. Two strengths of solution are prepared: one tablet is dissolved in a cup containing 50 c.c. of the saline solution, one in a cup containing 100 c.c. The stronger solution is used for infiltrating the skin, blocking nerves, or for any particularly sensitive area; the weaker solution is employed for general infiltration of tissue. As Karl G. Lennander ("Local and Subarachnoid (Spinal) Anesthesia," in "Keen's Surgery," vol. v, page 1054) has pointed out, "Cocain has a greater affinity for the sensory than for the motor nerves. The effect of cocain in a certain proper concentration upon peripheral mixed nerves is to abolish, first, the sense of tickling, then the sense of temperature, thereafter the sense of pain, and, lastly, the sense of touch (pressure), and only thereafter the motor faculty, which may remain unaffected. although all the modalities of sensation have been paralyzed. During the retrogression of poisoning the faculty of motion is the first to return, then the sense of pressure, next the sense of pain, and lastly the sense of temperature." The addition of the adrenalin to the cocain solution is an advantage, in that it retards the circulation by contracting non-striped muscle-fibers in arteries and capillaries. The cocain is thus localized, its anesthetic action prolonged, and bleeding diminished during the operation. I do not believe that adrenalin in any way modifies the toxic action of cocain; indeed, Berry ("Am. Jour. Med. Sciences," Nov., 1905) seems to prove that it actually increases it. With the extremely weak solution recommended by Mitchell I have never seen the slightest physiological action of cocain. The total dosage of cocain given by infiltration should not exceed 1½ gr. In 1 case I observed superficial sloughing of the skin when, by an operating-room error, three tablets had been dissolved in 50 c.c. of saline. I believe the slough was due to the high percentage of adrenalin.

The field of operative achievement under infiltration anesthesia has broadened to such an extent that it is difficult definitely to limit its possibilities when it is in the hands of one skilled in its use. It is necessary for the surgeon operating by this method to use an essentially different technic from that commonly employed in operations under a general anesthetic. He should be calm, equable, content to wait, and patient in spite of delay. He must be skilled in clean operative dissections, and accustomed to refrain from handling tissues unnecessarily. Failure is certain if the operator is not constantly engaged in this kind of work, for he must have learned, above all things, gentleness and willingness to spend plenty of time, and must have acquainted himself accurately with the sensibilities of the various tissues encountered in different operative fields. For the occasional operator to attempt major operations under infiltration anesthesia is to court failure. The patient should be informed that operation is to be a matter of intelligent co-operation, and in major operations it is wise to give a hypodermatic injection of morphin (¼ gr.) a half-hour before beginning. This is usually sufficient to allay the apprehension natural in one about to undergo an operation. A tactful assistant should be detailed to sit by the patient's head and engage him in conversation, sponge his face, administer small sips of water, and, in other words, be what may be called the "psychic" anesthetist. The patient should not see any of the preoperative preparations; instruments should be carefully excluded from the range of his vision. Needless conversation between assistants, nurses and spectators and other noise should be avoided.

The special instruments required are: two Record syringes of 2 c.c. capacity and one of 5 c.c.; two fairly fine needles 1½ inches in length and two coarser needles 2 inches in length; a pair of Mayo's 5½-inch straight dissecting scissors with keen edges; dissecting forceps with teeth, and fine-pointed artery clamps. For example, let us take an appendectomy in a patient with a frank tuberculosis

of the lung; a case in which general narcosis would cause damage and might prove fatal. The patient, having been prepared for operation (care having been taken to administer morphin a half-hour previously), is placed upon the operating table and made as comfortable as possible. The head is arranged upon a pillow, the arms are disposed comfortably at the sides, and a folded blanket is placed under the lumbar spine. The patient's wishes may be consulted as to whether he desires a piece of gauze placed over his eyes or not. Usually the patient, unless addressed, keeps his eyes closed. The "psychic" anesthetist engages the patient in conversation, the surgeon must show full confidence, be cheerful, and endeavor to communicate this frame of mind to his subject.

The easiest method of approach to the appendix under infiltration anesthesia is McBurney's muscle-splitting incision. Begin infiltration by taking the 2 c.c. syringe filled with the stronger cocain and adrenalin solution. Use a fine needle. Pinch up a small piece of skin, informing the patient that you are going to stick him slightly with a fine needle. Holding the needle almost parallel with the skin, barely insert the point under the epidermis and, at the same time, press on the piston of the syringe so as to obtain an infiltrated spot simultaneously with the introduction of the needle. The pain caused by the first introduction of the needle is trivial and even that degree is absent during subsequent insertions. A small wheal is produced, the integument assuming a blanched, pig-skin appearance. From the center of this infiltrated circle the needle may now be inserted painlessly to its full length *in* the skin (not *under* the skin), parallel with the surface. Do not insert the needle too deeply at this time. As the point of the needle travels the solution should be fed from the syringe. Ordinarily 2 c.c. of solution will infiltrate 1½ to 2 inches of skin. After the superficial infiltration a coarser and longer needle should be used to infiltrate subcutaneous tissues. The incision may now be carried down to the aponeurosis of the external oblique. Infiltrate the muscular and aponeurotic portion of the external oblique. Make a split in the aponeurosis by a knife and continue by Mayo's scissors. Gentle clips with the scissors cause less pain than knife dissection. Retract carefully the aponeurotic layer. Infiltrate the internal oblique and split it. The transversalis and peritoneum are infiltrated with the stronger solution, which we employ at this point for the first time since the infiltration of the skin. These layers are then incised. Incisions in all layers of the abdominal wall must be of ample size to avoid unduly strong retraction. Up to this stage the patient should experience no pain unless one has thoughtlessly clamped a vein without previous infiltration about it with the stronger solution. The visceral peritoneum may be cut, clamped, burned, and stitched with impunity, but undue traction upon the mesentery immediately causes general cramp-like abdominal pain with consequent rigidity of the abdominal wall. The appendix, therefore, is sought for by gently following the anterior longitudinal band intra-abdominally rather than by attempting to pull the cecum out of the abdominal incision. Once the base of the appendix is found, the rest is easy. Traction on the meso-appendix must be gentle, and, before tying it, infiltrate it with the stronger solution. The crushing, ligation and inversion of the base of the appendix are accompanied by pain. Occasionally the necessary traction on the mesocolon will cause the patient to have nausea, which is relieved as soon as the traction ceases. Suture of the abdominal wall now follows without special incident, except that very small rubber tissue drains should be inserted just under the skin at one or both ends of the incision when infiltration anesthesia has been used. These drains take care of any possible oozing that may occur after the effect of the adrenalin has worn off.

By the use of infiltration anesthesia I have operated with satisfaction in the following cases: Tracheotomy, tuberculous glands of the neck, rib resection, goiter, drainage of a cerebral cyst, ligation of the thyroid arteries, gastrostomy,

inguinal colostomy, typhoid perforation, abscess of the lung, chronic and acute appendicitis, gangrenous appendicitis, appendicitis in the interval, appendiceal abscess, jejunostomy, radical cure of inguinal, femoral, and umbilical hernia, strangulated hernia, incisional hernia, resection of the bowel, suprapubic cystostomy, extirpation of the external carotid artery (Dawbarn's operation), ligation of the femoral artery, cholecystostomy, suture of fractured patella, amputation through the arm, amputation through the thigh, amputation of the leg, removal of stone from the pelvis of the kidney, gastroenterostomy, kidney abscess, psoas abscess, varicocele, hydrocele, circumcision and large numbers of minor conditions.

Patients after abdominal section under infiltration anesthesia very rarely vomit at all, never have as much postoperative pain as those who have been under a general anesthetic, and seldom have backache. Distention of the bowel is uncommon. The catheter is rarely required, and, of course, the blood changes, renal difficulties, and postoperative pneumonias are much less frequent than after general narcosis. Infiltration anesthesia cannot be ignored in such cases as diabetes, Addison's disease, sepsis, advanced Basedow's disease, diseases of the cardiac muscle, liver, both kidneys, etc. In children and high-strung individuals infiltration is usually impossible; in operations for extensive malignant growths, or during which complete muscular relaxation must be obtained, this form of anesthesia is absolutely contra-indicated.

To those interested in infiltration anesthesia I would suggest a careful study of Spalteholz's admirable illustrations of nerves (especially those of the extremities),[1] together with the perusal of the following writings:

H. Braun: "Die Lokalanästhesie, ihre wissenschaftlichen Grundlagen und praktische Anwendung," Leipzig, 1907. (A very full bibliography accompanies this excellent work.) Translated by Percy Shields. Lea and Febiger, 1914.

George Hirschell: "Text-book of Local Anesthesia." Translated by R. E. S. Krohn. Wm. Wood and Co.

Bier's Intravenous Method of Local Anesthesia.—This plan was described by Bier at the German Surgical Congress of 1908.[2] It permits of serious operations upon the limbs, operations for which ordinary methods of local anesthesia would prove quite inefficient. Suppose the surgeon intends to resect an elbow-joint: Mark the position of the veins on the asepticized extremity. Apply an Esmarch bandage from the tips of the fingers to well above the elbow-joint. This is the expulsion bandage. A thin soft-rubber band is applied around the arm above the Esmarch bandage, the bandage is removed, and a like band is applied below the elbow. The anesthetic is injected into a superficial vein of this bloodless area (the basilic or cephalic). The tissues above and about the vein are infiltrated. The vein is exposed, the syringe of the cannula is introduced, and ligatures are used as though we were going to give an ordinary intravenous injection of salt solution, except that the cannula is pointed to

[1] "Hand Atlas of Human Anatomy," by Werner Spalteholz. Edited and translated by Lewellys F. Barker.

[2] Bier: "Ueber einen neuen Weg Lokalanästhesia au den Gliedmaassen zu erzeugen," "Arch. f. klin. Chir.," 1908, lxxxvi, No. 4.

the periphery. The fluid used is a 0.25 or 0.5 per cent. solution of novocain. The syringe, containing 50 c.c of fluid, forces the solution downward into the veins and the limb swells.

If the stronger solution is used, 50 c.c. are enough; if the weaker solution is used, 100 c.c. will be required. If resecting the knee, the injection should be made into the internal saphenous vein using twice the amount advised for the elbow.

After injecting the strong solution operation may be begun at once. After injecting the weak solution we should wait ten minutes. The bloodless area between the bands becomes anesthetic very promptly after the injection—the bones as well as the soft parts. The peripheral portion of the limb beyond the area between the bands becomes anesthetic after a short time and motor paralysis may follow. Such paralysis is eventually recovered from. If anesthesia between the bands is not attained within five minutes there has been some failure in technic (Bier, "Edinburgh Med. Jour.," 1910, v, No. 2). The analgesia is entirely satisfactory and passes away as soon as the band is removed. When the operation has been completed, wash out the vein with salt solution in order to prevent toxic effects.

By this method the anesthetic passes through the vein walls and becomes fixed in the tissues, and when the bands are removed it returns very gradually to the circulation, hence we may give greatly larger doses than admissible by any other method. Adrenalin should not be given with the novocain. Toxic symptoms are rare. The method is contra-indicated in arteriosclerosis. (See Carroll Smith, in "Jour. Am. Med. Assoc.," March 23, 1912; Page and McDonad, in "Lancet," Oct. 16, 1909; Hitzrot, in "Annals of Surgery," 1909, vol. i.)

Anesthesia by Infiltration with Sterile Water.—When the tissues are well infiltrated with warm or cold sterile water, anesthesia ensues promptly. I have not found it as complete as when cocain or eucain is employed, even when a considerable amount of fluid is introduced. Gant uses it in rectal operations and commends it strongly ("New York and Phila. Med. Jour.," Jan. 28, 1904).

Spinal Analgesia.—J. Leonard Corning in 1885 discovered that cocain injected between the spines of the eleventh and twelfth dorsal vertebræ produced analgesia of the lower limbs ("New York Med. Jour.," Oct. 31, 1885). From this observation spinal anesthesia springs. Bier produced complete anesthesia of the entire body except the head by the injection of a small amount of cocain into the subarachnoid space of the spinal cord. A solution of cocain of a strength of from 0.5 per cent. to 1 per cent. is used by some, but cocain cannot be boiled without impairment of its anesthetic power, and carbolic acid must be added to it in small amount. Hence cocain so prepared is not certainly sterile, and the carbolic acid added may induce harmful symptoms. (See Neugebauer, in "Wien. klin. Woch.," 1901, Nos. 50, 51, 52.) Some surgeons use a solution of eucain which can be boiled, but it is not so rapid and certain as cocain. Some use tropacocain (Illwicz). A solution of this drug can be boiled, is less poisonous than cocain, and somewhat slower in action. Experimenters tell us that ½ to 1½ gr. of cocain may be given, but it is not wise to give over 0.5 gr. I have used stovain in a number of cases. Some combine it with adrenalin, but the combination is not desirable in the subarachnoid space. The dose is 1 c.c. of a 5 per cent. solution. The analgesia lasts from one-half an hour to an hour or more, and was followed in my cases by retention of urine. Some have used novocain alone or combined with adrenalin.

A. W. Morton ("Jour. Am. Med. Assoc.," Nov. 8, 1902) takes chemically pure crystalline hydrochlorate of cocain, places it for fifteen minutes in a dry temperature of 300° F., and puts it in sterile tubes until wanted. The dose depends upon the locality in which he wishes to induce analgesia, and varies between 0.3 and 0.5 gr. The required dose is placed in the barrel of the

sterile syringe and is dissolved in cerebrospinal fluid drawn into the syringe for that purpose. I now follow the plan of Mr. Arthur E. Barker. He believes that the specific gravity of the fluid containing the drug plays an important part in its localization within the canal ("Brit. Med. Jour.," March 16, 1912). He uses a fluid as nearly as possible isotonic with the blood. It consists by weight of 5 parts of stovain, 5 parts of glucose, and 90 parts of distilled water. Adrenalin is never added. It may do harm, it can do no good. This fluid seeks the lowest level it can find and mixes but little with the cerebrospinal fluid. The average dose is 1 c.c. of the 5 per cent. solution.

The syringe used is of glass and of a capacity of 2 c.c. The needle is the hollow one of Bier. The needle must be sharp, else it will not go through the dura. Barker's fine blunt cannula goes through the lumen of the needle.

The fluid to be injected is kept in sealed Jena glass ampoules, and should not be more than a week or two old. The fluid is drawn into the syringe from the ampoule. The patient lies upon his side with the head and shoulders well raised and with the back curved. The back has been previously sterilized. The dressings are removed and the region to be punctured is resterilized. The spines of the third and fourth lumbar vertebræ are located, and the needle is entered in the midline beneath the spine of the third or fourth lumbar vertebra and is pointed upward and forward. The surgeon determines that he has punctured the subarachnoid space by lessened resistance and the appearance of fluid at the needle-opening. The injection is made slowly, the needle is withdrawn, and the puncture sealed by collodion. In performing the operation care must be taken to prevent the escape of the cerebrospinal fluid.

If the patient remains upon the side the nerve-roots of the dependent side are rendered analgesic some time before those of the uppermost side. If he be turned for a time upon the other side the nerve-roots of that side will quickly become anesthetized. To turn him upon the back will do the same thing, but less rapidly. If he is placed in a sitting position the rectum and anus are quickly rendered anesthetic.

The usual position for operation is that with the patient on his back, but he may perhaps be upon his side. When the patient is placed upon his back promptly after injection the anal region becomes anesthetic in from one to two minutes, the lower extremities in from three to six minutes, and the upper extremities in from fifteen to thirty minutes. The anesthetic condition lasts from one to three hours or even longer, and is due to the contact of cocain with the nerve-roots (A. W. Morton, "Jour. Am. Assoc.," Nov. 8, 1902).

After cocainization of the spinal cord surgical operations can be performed on many regions without causing pain. Among the operations which have been performed are resection of the knee, resection of the ankle, osteotomy, amputation of the leg, amputation of the thigh, hysterectomy, perforation of gastric ulcer, intestinal obstruction, strangulated hernia, excision of bowel, acute appendicitis, gastro-enterostomy, oöphorectomy, removal of ovarian cysts, and removal of the rectum.

Spinal analgesia is not growing in popularity. It is regarded by most surgeons as a method to be used in exceptional cases. It should never be used as a routine procedure, and it will not displace ether or chloroform. I see no occasion in the eighth edition of this book to alter the view which I put forth in the seventh edition. By it analgesia can usually be secured. A. W. Morton (Ibid.) used it 673 times without a failure, and 60 of these operations were above the diaphragm. If we desire to obtain analgesia of the upper portion of the body the patient must be placed in the Trendelenburg position after the fluid has been injected. Most operators have had failures, especially above the diaphragm. In Sonnenburg's 1117 cases there were 78 utter failures ("Jour. de Chir.," Oct., 1908). Bier says that failures occur in 4 per cent. of cases; Moynihan says in 14 per cent.; Legueu says in one-seventh of the cases. In

Barkers' last 100 cases there were 3 failures. No one should attempt it who is not well trained in aseptic methods, because infection of the cord or its membranes will prove fatal. Untoward effects are common, and they may arise during or after the operation.

Sonnenburg had them in 193 out of 1117 cases. Among the untoward effects reported are grave collapse, temporary paralysis of the abducens nerve, of the facial nerve, of the hypoglossal nerve, meningitis, retention of urine, chills, elevation of temperature, incontinence of urine, persistent paraplegia, pain in the back and legs, perhaps lasting for weeks or even for months, nausea and vomiting during and after the operation, sweating, overaction of the heart, dimness of vision, cramps in the limbs, dyspnea, violent headache, involuntary evacuation of feces, and cardiac overaction. Many of the immediate symptoms are probably due to the absorption of the drug injected. The headache is due to tension and is relieved when some cerebrospinal fluid is withdrawn by lumbar puncture. In 20 per cent. of Barker's cases ("Brit. Med. Jour.," March 16, 1912) there was more or less transient headache. In 16.3 per cent. there were nausea and vomiting.

Headache, vertigo, weakness, paresthesia, neuralgia may, in a few cases, persist for months or even years (Hohmeier and König, in "Archiv für klin. Chir.," Oct. 8, 1910).

Whether or not permanent harm ever comes to the cord is not certain. Bristow ("Brooklyn Med. Jour.," 1902, xvi, page 410) reported the case of a man, fifty-five years of age, on whom he operated for hemorrhoids after spinal cocainization. An examination one month later indicated degeneration of the posterior and lateral columns of the cord (spastic lower extremities, ataxic gait, increased knee-jerk, ankle-clonus, and inability to retain urine). Marx ("New York Med. Record," Dec. 22, 1900) states that 1 case in his experience, after cocainization of the spinal cord, developed typical locomotor ataxia. Dandois ("Jour. de Chir. Brux.," April–May, 1901) reports a case upon which he had operated for traumatic rupture of the urethra. Spinal cocainization was employed. Paraplegia developed and lasted two months. Several cases of hemorrhage into the subarachnoid space are on record. Legueu states that persistent paraplegia and persistent incontinence of urine may arise ("Rev. de Chir.," Oct., 1908).

Is there any danger of death from spinal analgesia? If the operation be not performed with scrupulous aseptic care it is very dangerous. Even when performed by the best surgeons death may occur. Tuffier places the mortality at 3 in 2000, but excludes from consideration 3 deaths ("La Presse Médicale," vol. lv, 1901, page 190). Reclus finds 6 deaths in less than 2000 cases (Address before the Paris Academie de Médicine, March 19, 1901). Hahn, in 1708 cases collected from literature, found 8 deaths ("Mitt. a. d. Grenzgeb. d. Med. u. Chir.," 1900, iii, 337). The mortality is usually supposed to be about 3 in every 1000 cases. Wm. N. Perkins ("New Orleans Med. Jour.," Jan.–Sept., 1902) collected 2345 cases with 16 deaths or 1 death in 146 administrations. Strauss's table shows 46 deaths in 22,717 cases (quoted by Hardonin in "Archiv Générale de Chir.," August, 1908). In Barker's 2354 cases there were only 3 deaths "which could be in any way put down to the spinal method of anesthesia" ("Brit. Med. Jour.," March 16, 1912). Hohmeier and König ("Archiv für klin. Chir.," Oct. 8, 1910) collected 2400 cases of spinal anesthesia: 12 deaths were due to it directly; 4 of them died of paralysis of re piration; 7 of the fatal cases were over seventy years of age. One victim was only thirty-two.

Cocain seems to act like a toxin on the pia and arachnoid. Examination of fluid withdrawn after cocainization shows that it contains polymorphic leukocytes (Ravant and Aubourg, in "Gaz. Hebd. de Méd. et de Chir.," June 27, 1901).

My belief is strong that the method should only be used for operations below

the diaphragm, and I hold this belief in spite of the claim of Jonnesco that he operates with the aid of spinal anesthesia on any part of the body. It is most successful in operations below the umbilicus. I very seldom use it for operations above that level.

In a case in which, because of heart disease, pulmonary disease, kidney disease, or some other condition in which a general anesthetic is inadmissible, spinal cocainization is justifiable. It should be reserved exclusively for cases in which other forms of anesthesia are positively contra-indicated. The method should not be employed on those under fifteen years of age or on the subjects of central nervous disease. Barker disapproves of spinal anesthesia in "cases of extreme asthenia due to carcinoma, and of advanced toxemia depending upon septic peritonitis or obstruction, especially in later life" ("Brit. Med. Jour.," March 16, 1912), although some surgeons regard such conditions as particularly demanding spinal in preference to general anesthesia.

A solution of Epsom salts has been used by Blake, Haubold, and Willy Meyer. It was discovered (Meltzer and Auer, "Am. Med.," Nov. 25, 1905) that subcutaneous injections of salts of magnesiüm produce local anesthesia. The same investigators later pointed out ("Med. Record," Dec. 16, 1905) that subarachnoid spinal injections of Epsom salts produce widespread and complete anesthesia. A 25 per cent. solution is used and 1 c.c. of this is given for every 25 pounds of body weight. After three or four hours the drug causes paralysis and analgesia of the legs and pelvic region. Sensation and motion do not return for from eight to fourteen hours. Retention of urine may last two days. The pulse and blood-pressure are unaffected, but the respiration is slowed. Large doses would endanger life by respiratory arrest. In view of the fact that in some cases the effect of the drug is inordinately prolonged, it is wise, when the operation is completed, to puncture the theca of the cord again and wash it out with salt solution. Guthrie and Ryan ("Amer. Jour. of Phys.," August 1, 1910) deny that magnesium salts have specific anesthetic properties and claim that anesthesia folllwing their injection is due chiefly to asphyxia.

Paravertebral and parasacral anesthesia was devised by Sellheim of Freiburg in 1905. He injected with cocain the intercostal nerves just after their emergence from the vertebral column, and the ilio-inguinal and iliohypogastric nerves on a level with the anterior superior spine of the ilium.

Braun injected the sacral nerves just as they emerged from the sacral foramina.

Novocain is much safer than cocain. Paravertebral anesthesia is said to be successful in laparotomies and parasacral anesthesia on vaginal and perineal operations. In certain pelvic operations both are used. I have no experience in the method. (It is fully described by Kroenig and Siegel, in "Surgery, Gynecology, and Obstetrics," May, 1916.)

XXXI. DISEASES OF THE SKIN AND NAILS

Dermatitis venenata is a dermatitis resulting from irritants. It may be caused by wearing garments containing arsenic. A common cause is rhus-poisoning. Rhus-poisoning arises from the poison-oak (White, Editorial in "Jour. Am. Med. Assoc.," Aug. 5, 1906), the poison-ash, the poison-ivy, and some other species of sumach. Actual touching of the plants is usually, but not always, necessary. Some suffer if they simply come near them as the irritant can be carried by the wind. The irritant may be conveyed by tools, materials or insects. The smoke of burning poison plants conveys the irritant. Some people are immune to rhus-poisoning, some are slightly susceptible, some are more strongly predisposed. It is believed by some that toxicodendric acid

is the irritant agent. The poison is not bacterial, is not gaseous, is not volatile and is contained in the resinous sap which exudes from an injured plant (McNair quoted in editorial of "Jour. Am. Med. Assoc.," Oct. 4, 1916). The condition is most apt to arise when the skin is moist from perspiration.

The **symptoms** are burning, itching, redness, and edema of the affected parts. Vesicles or even blebs may form. The hands and forearms are most apt to suffer, but any part may be attacked. The palms seldom suffer. If the penis and scrotum suffer from rhus-poisoning there is great swelling from edema. The fluid of a vesicle cannot inaugurate inflammation on sound skin. Usually a vesicular eruption begins between the fingers. The eruption becomes violently inflammatory, and in the form of fierce red edematous inflammation spreads widely over the body. There may be fever. The condition usually begins to abate in from three to six days and desquamation follows.

When one, knowing from experience that he is predisposed, feels the inaugural itching, he should at once apply to the parts a 1 per cent. solution of lactic acid in 95 per cent. alcohol (R. F. Ward, in "New York Med. Jour.," Dec. 26, 1908).

The **treatment**, when a moderate area is involved, comprises the application of cloths wet with a wash of lead-water and laudanum, or a saturated solution of acetate of aluminum (R. F. Ward, Ibid.). If an extensive area be involved, apply grindelia robusta (4 dr. to 1 pint of water) or moisten the surface frequently with sweet spirits of niter. Oxid of zinc ointment, containing 10 gr. of carbolic acid to 1 oz., gives great relief.

Furuncle (Boil).—(See page 148.)

Aleppo Boil (*Endemic Boil of the Tropics, Delhi Boil, Oriental Sore*, etc.).—Papules appear upon the exposed parts of the body. These papules, which ulcerate, do not cicatrize for at least a year, and leave ineradicable scars. The condition is due to a protozoan. Man is infected by means of flies, lice, or other insects. The Aleppo boil was once apparently confined to India, Arabia, Persia, Egypt, Algeria, etc. Of late it is said to have appeared in Panama, the Philippine Islands, and Hawaii.

Erysipelas.—(See page 219.)

Erysipeloid.—(See page 219.)

Clavus, or Corn.—A corn is a tender painful, and circumscribed thickening of the epidermis, and is commonest over one of the joints of the toes. *Hard* corns are situated on exposed parts of the digits; *soft* corns appear between the digits, where the parts are kept constantly moist. Corns are caused by pressure.

Treatment.—The wearing of well-fitting boots will usually cause a corn upon the toe to disappear. Soak the feet often in water containing bicarbonate of sodium, dry them, and apply a circular corn-plaster to the corn to take off the pressure of the boot. Another method is to touch the corn with iodin every night and pare away the hard tissue every morning. An old and valuable plan is to paint the corn every night and morning with a mixture composed of salicylic acid, 40 gr.; extract of cannabis indica, 10 gr.; and collodion and flexible collodion, of each 2 dr. After several days of the treatment soak the parts in hot water and scrape away the mass. *Soft* corns are treated by washing the feet often with ethereal soap, drying, gently removing the sodden epithelium, dusting the toes and between them with borated talc, and placing absorbent cotton between the digits. Incurable soft corns require the removal of the skin from the adjacent sides of the two toes and suturing the toes together (thus converting two toes into one). For inflamed corns employ rest and lead-water and laudanum, and let out pus when it forms. Remember that in old persons the cutting of a corn may cause senile gangrene. In the inflamed and painful feet of a person who has corns nothing gives so much relief as washing the feet with ethereal soap, soaking in hot water, and wrapping the feet for half

an hour in cloths wet with a mixture composed of linseed oil and lime-water, each, 2 oz., and spirits of camphor, 1 dr.

Warts.—(See page 432.)

Onychia is inflammation of the matrix of the nail. Syphilis often causes severe onychia which requires specific treatment (see page 375). A *runaround*, or paronychia, is suppuration of the matrix at the root of the nail, and of the skin about it, of traumatic origin. It requires incision, trimming away of the buried edge of the nail, and packing with iodoform gauze (see page 814).

Malignant onychia, which is inflammation and ulceration of the entire matrix, occurs only in a person of dilapidated constitution. This condition requires removal of the entire nail, cauterization of the matrix, dressing with iodoform gauze, and the internal use of stimulants, tonics, and nourishing diet.

Ingrowing toe=nail (see page 169) is sometimes due to lateral hypertrophy of the edge of the nail, but usually to forcing of the soft tissues over the margin of the nail. An irritable ulcer arises. The condition is treated by splitting the nail, removing the ingrown piece, the soft tissue at the margin and the adjacent matrix, and dressing antiseptically.

XXXII. DISEASES AND INJURIES OF THE THYROID GLAND[1]

The thyroid gland is an essential organ. It possesses functions of the first importance. It has a great influence upon nutrition. It acts by means of its secretion, which is an iodothyroglobulin.

An excess of this secretion if unneutralized in the body causes hyperthyroidism (see page 1378). A diminution of this secretion causes hypothyroidism (see below). If there be a very small thyroid or a functionally inactive thyroid from birth, the child is a cretin (see below). A great deal of the gland can be removed without harm. Charles H. Mayo estimates that one-sixth of the gland can furnish enough secretion for the body needs ("Illinois Med Jour.," Feb., 1913). The older a person is, the less thyroid is apparently needed or, perhaps, the less thyroid, the older a person actually is. "According to Lorand, the deferring of old age requires the continued presence of some of the thyroid throughout life" (Charles H. Mayo, Ibid.). The thyroid of a woman is apt to enlarge at puberty and to become swollen from congestion before a period of menstruation. During pregnancy or at the menopause the thyroid may enlarge and at these periods women are apt to exhibit symptoms of hypo- or hyperthyroidism. Ovid speaks of enlargement of the neck during the early months of pregnancy. Charles H Mayo (Ibid.) points out that increased secretion does not, of necessity, cause symptoms. A considerable excess may be neutralized in the body. In such a condition a shock may at once induce symptoms. Entire loss of the thyroid in an adult causes myxedema. Kocher pointed out that its complete removal in a young or middle-aged person usually causes *operative myxedema* (*cachexia strumipriva*) and perhaps *tetany*. Removal of the gland in an elderly person does not cause these curious conditions. Later knowledge indicates that removal of the thyroid with the parathyroids certainly produces myxedema or tetany, unless aberrant thyroids exist and compensate. Removal of the thyroid without the parathyroids does not induce tetany, even when there are no aberrant thyroids. The thyroid probably furnishes an internal secretion which destroys certain toxic products of metabolism. It is thought that the parathyroids furnish an antitoxin to poisons formed during digestion.

Wounds cause violent hemorrhage which is difficult to arrest. Ligatures may cut out and forceps will not hold. The hemorrhage is arrested by suture-

[1] A valuable recent work is that of André Crotti, on "Thyroid and Thymus."

ligatures, purse-string sutures, the actual cautery, or removal of the bulk of the gland.

The thyroid gland may be absent at birth. **Congenital atrophy** or **congenital hypertrophy** may exist.

Acquired atrophy leads to *hypothyroidism* and *myxedema*. Hypothyroidism may arise during any process destructive of the cellular activity of the thyroid gland. It is seen not unusually in women of from twenty-five to forty who have borne children. It sometimes occurs in men. The patient usually grows fat, is sterile, and neurasthenic. The temperature is subnormal. Complaint is made of headache, backache, shortness of breath and indigestion. In women amenorrhea is the rule. In severe cases there is myxedema. (See Robert L. Pitfield, in "New York Med. Jour.," August 27, 1910.) *Myxedema* is a condition characterized by the presence of a firm subcutaneous swelling in the face, neck, and limbs; slow speech; mental dulness, and subnormal temperature. The condition is identical with that produced by removal of the entire gland.

Cretinism was described by Paracelsus early in the seventeenth century. It is a result of hypothyroidism. It is a form of infantilism and idiocy due to absence of the gland or atrophy of glandular elements in the thyroid. When atrophy of the parenchyma alone exists the size of the gland may be actually increased. The body is dwarfed; bone development is very defective, the face, neck, and extremities resemble those parts in myxedema, and a low grade of idiocy exists. Myxedema and cretinism are treated by the internal administration of thyroid extract.

Thyroid Feeding and Grafting.—Hypothyroidism, with or without myxedema, is greatly benefited by thyroid feeding or the administration of thyroid extract. Some experimenters have transplanted thyroids into thyroidectomized animals. The results show striking but temporary improvement. Such transplanted material eventually disappears. Experiments have been made and are being made on thyroid grafting in the treatment of cretinism and myxedema. Grafts have been placed under the skin, in bone at the junction of the epiphysis with the diaphysis, in the spleen, and in other regions. Encouraging cases have been reported, but the results are temporary.

Congestion of the thyroid may be caused by violent exertion, prolonged effort, febrile maladies, and venous obstruction. It is treated by removing the cause and applying heat locally. Tracheotomy may be required.

Inflammation of the thyroid (*acute* or *inflammatory goiter*) may be induced by a septic or febrile malady, rheumatism, tonsillitis, muscular strain causing vascular rupture, a wound, or contusion of the thyroid. Cases due to typhoid bacilli have been reported. Usually but one lobe is affected. The ordinary symptoms of inflammation are present In addition there are dysphagia, dyspnea, venous congestion of the face, epistaxis, nausea and vomiting and possibly delirium. It may terminate in resolution, suppuration, or fibrous induration.

Tuberculosis of the thyroid is usually a part of general miliary tuberculosis. It is very seldom that a local caseating focus occurs, but such cases have been reported.

Syphilis of the Thyroid.—Early in the secondary stage there is apt to be slight and painless thyroid enlargement. In the tertiary stage gummata may form.

Tumors of the thyroid are of various sorts. Among them are adenomata, cystic adenomata, sarcomata, and carcinomata. Eight cases of teratoma are on record (Isabella C. Herb, "Am. Jour. Med. Sciences," June, 1906). Malignant disease is unusual. I have operated on but 2 cases: 1 of cystic carcinoma in which operation was rapidly fatal, and 1 of round-celled sarcoma. The latter patient was living and apparently well four years after lobectomy. Malignant disease may arise in the normal, but is more apt to arise in a goitrous

thyroid. In over 50 per cent. of the reported cases there is a history of antecedent goiter. Malignant disease is more common in women than in men and is very seldom met with before the age of thirty. It is most common between forty and sixty. One should always suspect malignant disease of the thyroid gland when the growth appears rather suddenly in a patient over forty years of age. If the growth is irregular in outline and is accompanied by pain and difficulty in swallowing, the diagnosis becomes reasonably certain. Later in the case there are symptoms due to pressure upon and infiltration of the nerves; the growth becomes firmly anchored and the lymph-glands adjacent to the thyroid become involved; there may be tracheal bleeding, and perhaps fever, and eventually cachexia develops. Sarcoma or carcinoma may occur and it is seldom possible to determine clinically with which we are dealing. The cancer may be a scirrhus or an epithelioma, but is usually an adenocarcinoma. A sarcoma may be either of the round cell or spindle cell type. In malignant disease of the thyroid, metastasis occurs early in a great majority of cases, the lungs being first involved, and then the bones and other structures; though it has been stated that in adenocarcinoma the lungs are likely to escape and that solitary bone-metastasis is not infrequently noted. Sarcoma (Fig. 882) may involve one lobe, but carcinoma (Fig. 883), even at an early stage, is apt to involve both lobes (Berry, "Diseases of the Thyroid Gland"). These growths soon penetrate the gland capsule, become anchored to surrounding parts, and involve the vocal cords, trachea, and even the great vessels of the neck. Malignant growths if not cystic are apt to be hard and nodular and they grow rapidly. At first the gland moves with deglutition, but later becomes anchored to surrounding parts. In malignant disease of the thyroid it is usual to find difficulty of swallowing and paralysis of the vocal cord on the side of the growth. Malignant disease is rapidly fatal. Many die within six months and few survive over eighteen months. Radical operation is proper only before the growth breaks through the capsule, although at any stage it may be necessary to operate in order to prevent suffocation.

Fig. 882.—Sarcoma of thyroid gland.

A **goiter**[1] is an enlargement of the thyroid gland not due to a malignant tumor or to inflammation. Hippocrates makes no mention of goiter. Juvenal and Pliny refer to it. Juvenal speaks of its being common among Alpine mountaineers and Pliny states that certain wells seem to disseminate the disease. The enlargement may affect a small portion of the gland, one lobe, both lobes, or both lobes and the isthmus, and it may occur either sporadically or endemically. It is far more common in women than in men. It is very common in adolescent girls. It may exist in children. Adenomata may even be congenital.

[1] For a study of the "Pathological Anatomy of Goiter" see W. C. MacCarty, in "New York State Jour. of Med.," Oct., 1912. This study is founded on 2500 cases from the Mayo Clinic.

There are a number of forms of ordinary goiter. The most common is what is called *simple* or *parenchymatous* goiter (Fig. 884). In this condition all portions of the gland enlarge, and the goiter is consequently bilateral. It does not appear first in one lobe and at a considerably later period in the other, but each lobe is enlarged equally or nearly equally. Parenchymatous goiter is often spoken of as simple goiter, and is sometimes, though not with entire accuracy, designated hypertrophy of the thyroid gland.

The common goiter of adolescence is "an edematous condition of the gland due to watery colloid" (C. H. Mayo, "Illinois Med. Jour.," Feb. 1913).

Adenomatous goiter (Fig. 885) is a condition due to the growth of encapsuled adenomata in the thyroid gland. There may be a single adenoma, but frequently there are multiple growths. One or both lobes may be involved. The goiter, however, usually seems to begin in one lobe; and if both lobes enlarge, one generally does so at a period distinctly subsequent to the enlargement of the other. In some cases growth seems to originate simultaneously in both lobes, but even then the growths seldom increase equally. Adenoma may develop in a healthy thyroid gland, but adenomatous growth is usually associated with some parenchymatous growth.

Fig. 883.—Cystic carcinoma of thyroid gland.

Cystic goiter, or *bronchocele*, is a condition in which the chief mass of the enlargement is composed of a cyst or of multiple cysts. When cysts form, the thyroid gland is usually hypertrophied or adenomatous; occasionally, however, cysts form in a non-hypertrophied thyroid. The great majority of cysts are due to cystic degeneration of adenomata; some are formed by the coalescence of overdistended thyroid vesicles, and some few follow blood-extravasation into the thyroid tissue. The liquefaction is due to mucoid or colloid degeneration, and the fluid of the cyst is sometimes clear and thin, sometimes viscid, and often coffee-ground in appearance.

A *fibrous goiter* is a fibrous induration. It is likely to arise in old bronchoceles, which may actually pass into a calcareous condition. By the term *malignant goiter* is meant malignant disease of the thyroid gland, either carcinoma or sarcoma. As stated above, such cases are not really goiters. When hemorrhage takes place into a goiter the condition is often spoken of as a *hemorrhagic goiter*. A *colloid goiter* is a form of parenchymatous goiter in which there is an extremely large amount of colloid material. *Exophthalmic goiter* is discussed on page 1377. A simple, or an adenomatous goiter, because of degenerative changes or overstimulation, may form toxic material or an excess of secretion and may cause symptoms of toxemia (*simple toxic goiter*). "These cases may have all the nervous symptoms and heart complications of a bad case of Basedow's disease without the protruding eyes" (C. H. Mayo, "Illinois Med. Jour.," Feb., 1913). This evolution gives rise to what we name a *toxic goiter* and the French call a *Basedowified goiter* (Morestin, in "Rev. de Chir.," Nov. 10, 1899). A goiter that develops with great rapidity is sometimes called an

acute goiter, and one that induces marked dyspnea is designated a *suffocating goiter*. Syphilitic, tuberculous, and amyloid enlargements are extremely rare, but occasionally occur. Further, a goiter may be back of the sternum, that is, *substernal* or *retrosternal*. A very movable goiter, which is now above and now below the sternal notch, is called a *wandering* or *diver goiter*. A goiter within the thorax is called *intrathoracic;* and such a goiter may be *retrosternal*, *retrotracheal*, or *retro-esophageal*. When a number of persons in the same region are attacked with goiter the condition is frequently referred to as *epidemic goiter*. When the condition is common in a certain district it is called *endemic goiter*. When a person living in a district in which the disease is rare develops goiter, we speak of the condition as *sporadic goiter*. It has long been known that *accessory* or *aberrant thyroids* exist. The term "aberrant" is better than "accessory" because in some reported cases the thyroid proper has been absent (V.L. Schrager, in "Surg., Gynec., and Obstet.," Oct., 1906). Aberrant thyroids are masses of tissue composed of structure identical with the thyroid gland,

Fig. 884.—Parenchymatous goiter.

Fig. 885.—Adenomatous goiter.

and distinct and separate from the thyroid gland proper. Median aberrant thyroids are found about the hyoid bone and are formed from remnants of the thyroglossal duct. Lateral aberrant thyroids are found and develop from the remains of the lateral anlages of the thyroid (Ibid.). Aberrant thyroids vary in number: there may be none, one, several, or chains of them. An aberrant thyroid may enlarge with the thyroid, may not enlarge even though the thyroid does, or may enlarge when the thyroid proper remains normal. I recently saw a median tumor of the base of a man's tongue which on removal, proved to be composed of thyroid tissue (lingual goiter). Nearly 100 cases are on record, 90 per cent. of them in women. In a number of cases myxedema has followed removal. When cachexia strumipriva does not develop after complete thyroidectomy, the patient has been saved by enlargement and functionation of accessory thyroids.

Causes of Goiter.—It is known that goiter is extremely common in the valleys at the foot of certain mountain ranges in Switzerland, southeastern France, northern Italy, the Austrian Tyrol, and in the Himalayas and the Andes. In a portion of England it is so common that it is referred to as the Derbyshire neck. There are goiter regions in Pennsylvania and in other parts of the United States. Endemic goiter has been known since the fourteenth century. It seems evident that the disease is due to the introduction of some poisonous element into the system; but what this element is, is not known.

Some writers maintain that individual liability is developed by habits of life; others think that susceptibility depends upon hygienic surroundings; and some attach great importance to hereditary influence. The probability is, however, that the disease is due to the existence of some poisonous substance in the drinking-water. Some observers have blamed snow-water; many have laid the cause of the trouble at the door of water impregnated with salts of lime; but the real cause has not been demonstrated.

Some observers believe that simple goiter is due to bacteria in the intestinal canal, an important function of the gland being to save the body from poisons which reach the blood from the intestines, an excess of poison or certain powerful toxins causing the gland to enlarge.

The ordinary parenchymatous goiter of adolescence seems to be a work hypertrophy. A number of years ago I suggested the view that the gland has undergone such an enlargement and has become distended with colloid material because the human body has demanded more of the secretion of the gland than the normal gland has been able to supply; as a consequence, the normal gland has enlarged its capacity and increased its output.

Signs and Symptoms of Goiter.—One may determine that a growth is in the thyroid gland or is connected with it by studying a number of facts. A goiter, as a rule, follows the movements of the larynx and the trachea during deglutition, and this sign may be obtained in the great majority of instances. There are, however, rare conditions, such as hyoid cyst, in which a movement of the mass takes place during the act of swallowing, although the thyroid gland is not involved. Then, again, a malignant or an inflammatory growth of the thyroid usually becomes anchored to the surrounding tissues and does not show this mobility. Certainly, however, in the great number of cases an enlarged thyroid moves with the larynx and the trachea during swallowing.

Goiters vary greatly in size. Cases in which the goiter was as large as an adult's head, and some cases in which the goiter hung in front of the breastbone, and reached to below the level of the ensiform cartilage, have been described. A very large goiter may have a stalk.

When the entire gland, as well as the isthmus, is enlarged, or when the isthmus alone is involved, the swelling may appear to be in the median line of the neck. If the condition begins in one lobe, the growth will, for a time at least, be distinctly one sided; though when such a growth has attained a large size, it may displace the windpipe and come itself to the middle line of the neck.

A goiter of any considerable size pushes the sternocleidomastoid muscle externally and anteriorly, and the muscles that run from the sternum to the hyoid bone and to the thyroid cartilage overlie the front of the growth. The carotid artery is displaced externally and posteriorly. The relation of the jugular vein to the carotid artery is usually profoundly altered. The artery, as already stated, goes externally and posteriorly, while the vein is actually pulled anteriorly and is flattened out upon the side or the anterior surface of the goiter; hence the vein may lie to the inner side of the artery. This curious alteration in relationship is due to the fact that the common carotid artery has no branches, and therefore is pushed externally with ease; but the internal jugular vein receives branches that lie in the tumor, pull upon the vein, and prevent its displacement with the artery (Lücke).

Berry alludes to the fact that the tumor, unless it be very small, usually reaches the upper level of the sternum, and frequently passes below this level; and that only extremely large goiters hang in front of the sternum, but that it is not at all unusual for prolongations from a goiter to extend for quite a distance into the mediastinum. A substernal goiter is productive of very dangerous symptoms and offers many difficulties in diagnosis. A goiter will occasionally wander, now appearing in the neck and again disappearing behind the sternum.

Some goiters are said to pulsate. This takes place in exophthalmic goiter, the vessels of the goiter pulsating as do the other vessels of the body; but in the ordinary simple goiter what is called pulsation of the goiter is usually the transmitted pulsation from the carotid artery.

Some of the most important symptoms of goiter are due to pressure and to the displacement of anatomical structures. Pressure upon the veins at the root of the neck causes great enlargement of the veins above the goiter and in it. Pressure upon the recurrent laryngeal nerve may induce characteristic symptoms (spasm of the glottis or paralysis of a vocal cord), but the dyspnea of goiter is due to pressure upon the trachea and not to interference with the recurrent laryngeal. Paralysis of a vocal cord is most common in malignant, goiter, but the records of the Mayo Clinic show that in almost one-fifth of all cases of goiter there is paresis on even paralysis of one or both vocal cords. Pressure upon the cervical sympathetic may cause contraction of the pupil and narrowing of the palpebral fissure (Berry). Pressure upon the cervical plexus or the brachial plexus causes paresthesia, anesthesia, or paralysis in the parts supplied by nerves from the compressed plexus. Pressure upon the larynx and the trachea may cause very great displacement, and any such displacement is productive of marked dyspnea. This displacement is usually to the side; and it may cause such a flattening out of the tracheal rings that when the tumor is removed the trachea collapses and the patient perishes of suffocation.

A parenchymatous goiter usually begins insidiously and grows slowly. It occasionally ceases to grow for a considerable period of time, and may even shrink. It frequently enlarges temporarily during menstruation or pregnancy, and occasionally attains an enormous size by changing into the cystic form. Alterations in its consistency and outline may be due to the development of adenomatous masses. A goiter may at any time give rise to toxic symptoms which may be temporary or may persist (rapid pulse, palpitation, tremor and other symptoms of Graves's disease, except exophthalmus).

In making a diagnosis between the different forms of goiter, one should remember that a fairly symmetrical, bilateral growth is probably parenchymatous; if it has been symmetrical from the start the probability of its being parenchymatous is enhanced; that sudden enlargements are produced by hemorrhage; that cyst formation may lead to very great enlargement, and possibly to fluctuation; that if a non-malignant goiter induces dyspnea, it almost invariably does so by pressing upon the larynx and the trachea, whereas a malignant goiter may do so by interfering with the nerves of the part or by infiltration of the trachea; that a non-malignant goiter very rarely produces difficulty in swallowing, but that a malignant goiter frequently does so; and that cough often exists if there be pressure upon the larynx or the trachea, such a cough being metallic in nature and unassociated with impairment of the voice.

In any goiter there may be cerebral symptoms, such as anemia, syncope, or even convulsions. Rapidly growing goiters are often fatal, and slowly growing goiters are very rarely so. A malignant goiter grows with great rapidity, becomes adherent, infiltrates, and quickly produces metastases, and both sarcoma and carcinoma produce metastases by way of the venous system. A goiter may grow slowly or rapidly during pregnancy. At the end of pregnancy it may disappear.

Metastasis of Non-malignant Goiter.—An ordinary goiter which presents no sign of being malignant may suddenly be disseminated. The deposits are apt to take place in the bones and in the lungs. Tumors have been removed without any thought of thyroid trouble being responsible, and examination has shown thyroid structure. Patel collected 18 cases of thyroid metastasis ("Tumeurs bénignes du corps thyroide donnant des métastases," "Rev. de Chir." No. 29, 1904). The bones most apt to receive metastases are the

bones of the cranium, the lower jaw, the vertebræ, the pelvis, and the long bones. In 4 of these 18 cases the spine was affected. Dercum has reported a case of thyroid metastasis to the spine ("Jour. of Nervous and Mental Dis.," Mar., 1906). Colloid goiters are particularly prone to metastasis. Some surgeons maintain that if a metastatic deposit grows and destroys bone, the primary tumor should be regarded as malignant, no matter what histological studies indicate.

Treatment of Goiter.—The goiters of adolescents, certain nontoxic colloidal goiters and parenchymatous goiters are the only forms amenable to medical treatment. Iodid of potassium and arsenic internally have been advised. An ointment of red iodid of mercury[1] locally is advocated by some writers. It should be rubbed in while the goiter is exposed to the direct rays of the sun. The administration of thyroid extract may do much good in a case of parenchymatous goiter, but it is useless in other forms of the disease. It should be associated with the local use of tincture of iodin or ointment of red iodid of mercury. Iodin and thyroid extract are most serviceable in the goiters of adolescent girls. Large doses of iodin are unsafe. Kocher pointed out years ago that too much of the drug might cause a goiter to become Basedowefied. McCarrison ("Proceedings of the Royal Society of Medicine," Feb., 1912) grew cultures from the feces of individuals with goiter. He prepared a mixed vaccine. He also isolated certain bacteria and prepared vaccines from them. Cases of goiter were treated with the vaccines. It is claimed that the vaccines, especially the mixed vaccine, will cure recent parenchymatous goiter. The vaccine is said to act more promptly than thyroid extract. In times past it was customary to treat cystic goiters by aspiration and injection with a solution of iodin. Electrolysis has been used for softer goiter, the negative pole being pushed into the growth, the positive pole being applied to its surface. In many cases the *x*-rays prove of benefit. In considering the propriety of operation remember that a goiter which begins at puberty may pass away. We should operate on every non-malignant goiter which is increasing in size steadily or rapidly, which is making injurious pressure, which is causing pain, which is interfering with important nerves or which is actively toxic. Operation is justifiable even if there is not pressure because the mortality is very small, and it saves the patient from the possibility of malignant change, of hemorrhage, and of inflammation. Pregnancy increases greatly the risk of operation. Abortion is apt to follow. I used to operate under local anesthesia. There is less bleeding under local anesthesia than under ether. It is a great advantage to have the patient conscious, because by asking him to speak during the operation the surgeon can tell if the recurrent laryngeal nerve is being approached or touched. Two cases of violent hemorrhage in conscious patients taught me a lesson. Each patient was conscious that something was wrong, became terrified and uncontrollable, and greatly increased the danger and difficulty. I now give ether (by intratracheal insufflation) unless there be very high blood-pressure, serious tracheal obstruction, or disease of the heart, lungs, or kidneys (C. H. Mayo, "Illinois Med. Jour.," Feb., 1913). When ether is to be given I precede its administration twenty or thirty minutes by $\frac{1}{6}$ gr. of morphin and $\frac{1}{120}$ gr. of atropin, given hypodermatically. In some cases I follow Charles H. Mayo's plan and combine local anesthesia with light general anesthesia. In some cases intraglandular *enucleation* is performed, in other cases *extirpation*. Occasionally these two methods are combined (Bergeat). Some surgeons advise simple division of the isthmus. Ligation of the thyroid arteries has been recommended. *Exothyropexy* is the operation of exposing the thyroid gland, dislocating it through the wound, and leaving it in this situation. Exothyropexy is now almost never performed, on account of the safety of the operation of thyroidectomy. Atrophy of the gland follows exothyropexy. Enucleation, if possible,

[1] This ointment consists of 1 part of red iodid of mercury to 28 parts of vehicle (white wax and almond oil).

is the desirable operation. It may easily be employed for the removal of a single adenomatous, colloidal, or cystic area. *Thyroidectomy* (extirpation) is employed when enucleation is impossible. The entire thyroid is not removed for an innocent growth: at least a portion of a lobe is left behind, otherwise operative myxedema will probably arise. Unilateral extirpation (*lobectomy*) is the method usually chosen. In cancer and in some cases of sarcoma complete extirpation may be attempted if the growth be movable. If it be immovable operation is useless. The operation in malignant disease will occasionally prolong life, but it will rarely effect a cure. In malignant disease tracheotomy may be rendered necessary by urgent dyspnea. The operation is often very difficult because the growth may cover the trachea, the trachea may be deviated a considerable distance from its proper position, and the veins may be very large. After the performance of the operation it is usually impossible to use an ordinary tracheotomy tube, and in such a case König's long, flexible tube (Fig. 886) is employed.

Intrathoracic Goiter.—Goiter in this situation causes great pressure on the veins and on the trachea and distention of the veins of the neck, dyspnea and cyanosis. It is reached by dividing the manubrium longitudinally or dividing the entire sternum. Endotracheal anesthesia is used.

Endotracheal Goiter.—Such a goiter may be due to misplaced thyroid tissue, or may be a prolongation from the thyroid gland. Occasionally the growth is situated in front; but, as a rule, it is attached to the posterior surface of the larynx or trachea. The first symptom is dyspnea, which increases and becomes very severe. An examination with a laryngoscope makes the condition evident. Endotracheal goiter is much more common in the female than in the male. It is believed to begin usually at about the age of puberty, though it may exist for a long time unnoticed. In some reported cases the patients were forty years of age before having been seen. The proper treatment for an endotracheal goiter is the performance of a preliminary tracheotomy and then extirpation.

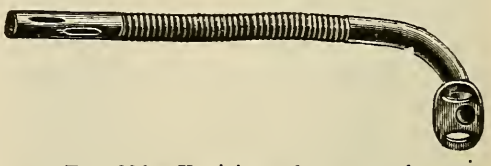

Fig. 886.—König's tracheotomy tube.

Exophthalmic Goiter (*Graves's Disease; Basedow's Disease; Pulsating Goiter*).—This condition was first described by Graves, of Dublin, in 1835. It is a condition of chronic overactivity of the gland (hyperthyroidism) in which the secreting structure of the gland is increased in amount by hyperplasia. The increase of parenchyma may perhaps be general, may perhaps be in separated areas (C. H. Mayo, "Illinois Med. Jour.," Feb., 1913). The symptoms are very variable, depending upon the amount and nature of the thyroid secretion and also upon the nervous tendencies of the victim. It is ten times more common in women than in men, and is most common between the ages of twenty and forty. It may arise at puberty but is very rare in children under ten years of age. The Mayos operated on only 5 such cases in 8 years ("St. Paul Med. Jour.," 1914, xvi). It has been stated that child-bearing has little influence in its causation, but I have seen the development of it in a woman three times in three different pregnancies. There is no proof of heredity, but it is not unusual to find more than one member of a family with it. It is not particularly prone to appear in ordinary goitrous families, although a person with an ordinary goiter sometimes develops all the nervous symptoms and heart symptoms of Graves's disease (see page 1372, Basedowified Goiter). It may arise after emotional excitement or depression, fright, shock, hemorrhage, or an acute illness. It may develop during the existence of locomotor ataxia, paresis, epilepsy, neurasthenia, hysteria and other nervous troubles, and abdominal and pelvic diseases. A

shock or fright does not cause hypersecretion. That existed before, but there were no symptoms because the body had been neutralizing the poison. Shock develops symptoms by abolishing neutralization (C. H. Mayo, "Illinois Med. Jour.," Feb., 1913). Crile ("Am. Jour. Med. Sci.," Jan., 1913) believes that "Graves's disease is not a disease of a single organ or the result of some fleeting cause," that it originates in fear, and is exicted by "some stimulating emotion intensely or repeatedly given, or some lowering of the threshold of the nerve receptors, thus establishing a pathological interaction between the brain and thyroid." Digestive toxemia is thought by many to be the underlying cause. It is frequently associated with marked anemia the result of excessive vomiting. The disease is a toxemia and the real cause of the symptoms is hypertrophy of the thyroid and excessive secretion of the gland (*hyperthyroidism*). This view is rendered more probable when we recall that a condition known as myxedema possesses many symptoms directly opposite to those of Graves's disease and that myxedema is due to deterioration, great diminution or absence of thyroid secretion, and the unopposed action of adrenal secretion. The administration of thyroid extract to an individual may produce some symptoms observed in exophthalmic goiter and partial thyroidectomy may improve or cure Graves's disease. Iodothyroglobulin is, perhaps, the poisonous element.

Fig. 887.—Exophthalmic goiter and total blindness from protrusion of eyes (Hansell).

An apparent objection to this view is that Graves's disease may exist without detectable thyroid enlargement, but this objection loses force when we recall that the thyroid may be somewhat enlarged, though we cannot detect the increase, and that a gland may be diseased even when not enlarged. It is probable in exophthalmic goiter that whether or not there be an excess of thyroid products passing into the circulation, toxic materials of some sort are formed in the gland and are taken into the lymph and blood. The real cause of exophthalmic goiter is not positively proved, but it seems probable that the disease is due to the action on the sympathetic system of large amounts of thyroid material, of some poisonous product of thyroid activity, or of some toxin the thyroid fails to destroy.

In exophthalmic goiter the vessels of the gland are not dilated—in fact, they are "usually smaller and less numerous than in a parenchymatous goiter of the corresponding size" (Berry, on "Diseases of the Thyroid Gland") but the vessels of the capsule are dilated. The surface of the gland is smooth. On section, the cut surfaces seem solid and very little colloid is visible. The enlargement is due to growth of the glandular epithelium, either general or in localized areas, and this epithelial proliferation may be induced by different exciting causes.

In many cases of Graves's disease the thymus is enlarged by hyperplasia. This is most apt to be the case in young subjects. Status lymphaticus may exist and if it does the danger of operation is much enhanced.

In exophthalmic goiter the lymphatics within the lobules are usually obliterated, but the lymphatics around the lobules are present in increased number and are of exaggerated size. Sometimes the thyroid becomes fibrous, and in such cases myxedema is apt to arise. In a typical case there are rapid pulse or *tachycardia* and protrusion of the eyeballs or *exophthalmus*. Some suppose that the exophthalmus is due to a collection of fat back of each eye, but the variability in the degree of protrusion seems to contradict this view. It is almost certainly due to involvement of the sympathetic system, and enlargement of the thyroid gland or *goiter*. Either thyroid enlargement or exophthalmus may be absent—in fact, in some rare cases both are absent. The pulse-rate in most cases is from 90 to 140. Exophthalmus is present in at least 80 per cent. of cases. The enlargement of the thyroid is bilateral. Unilateral enlargements are instances of Basedowified goiter—that is, are cases in which toxemia arises in the course of an ordinary goiter (see page 1372). A systolic bruit is usually audible over the thyroid region, and the large vessels at the root of the neck pulsate strongly because of arterial dilatation. The cardiac symptoms are of great importance. Acute cardiac dilatation occurs during tachycardia, and for a time, at least, disappears as tachycardia abates. Even trivial fatigue brings on temporary dilatation. Dilatation may become permanent (and does after one year), valvular insufficiency may arise, or cardiac hypertrophy may occur (Grocco, in "R. Crit. di Clin. Med.," Jan. 2, 1904). *Von Graefe's sign* may be present; this is inability of the lids to follow the eyes in looking down. *Stellwag's sign* is retraction of the upper lids. The lids in some cases cannot be completely closed, and when the eyeball is suddenly turned up, the lid and brow may fail to act together. *Moebius's sign* is inability to maintain the eyes in convergence. In some cases ocular palsies exist, in others there is photophobia or nystagmus. Patients may suffer from neuralgia, colic, choreic movements, tremor, flushes of heat, and gastric crises. Tremor is practically always present when the arms and forearms are extended, the palms of the hands are turned down, and the fingers are spread apart. Widespread tremor is apt to arise from any excitement, shock, or surprise. Dyspnea often exists and albuminuria and polyuria are not uncommon. Hemoptysis, hematemesis, or mental disturbance is sometimes noted. The patient is usually greatly depressed mentally, sometimes is excited, and may have outbreaks of violent hysterical excitement or even of mania. The usual expression is one of fright. There may be insomnia, elevated temperature, excessive sweating, or sudden attacks of diarrhea. All symptoms are increased by fear or fright. Sugar may be found in the urine. Exophthalmic goiter is sometimes associated with osteomalacia. This fact is important in connection with MacCallum's observations on the action of the parathyroids in controlling calcium metabolism. Kocher emphasizes the importance of the blood-picture. In nearly all cases there is lymphocytosis. Halsted ("Annals of Surgery," August, 1913) says of his cases: "Almost invariably the proportion of lymphocytes was increased, once being as high as 65 per cent. But in 1 case, the most serious of all, the total percentage of lymphocytes was only 9." Halsted regards enlargement of the thymus as probably responsible for the lymphocytosis, and the thymus is enlarged in at least 75 per cent. of marked cases. After operation lymphocytosis gradually diminishes (Halsted, Ibid.). The duration of a case is entirely uncertain. It is usually very chronic, with remissions or actual intermissions. Sometimes the patient gets entirely well, but this result is rare. There is often a partial cure, which may at any time be followed by a renewed outbreak. Sometimes the condition passes away rapidly, but abatement is usually gradual. Some cases get progressively worse and die. Certain cases are acute and these are apt to result fatally. A man in the Jefferson Hospital died in five weeks after the first symptoms were noted. He was delirious for several weeks. Another case died in four weeks in spite of ligation of the two superior thyroids. Very grave

cases of exophthalmic goiter are probably often associated with disease of the thymus (Rehn). C. H. Mayo ("Illinois Med. Jour.," Feb., 1913) says: "While the large majority of cases can be easily diagnosed from the nervous symptoms, tachycardia, goiter, and eye symptoms, there are a few cases in which it is difficult to diagnose true hyperthyroidism from pure neurasthenia, myocarditis, or Bright's disease, as well as a few cases in which there may be a complication by affection of the hypophysis, thymus, or adrenals." Children seem to suffer less when hypothyroidism exists than do adults.

Treatment.—Thyroid extract does harm. Medical treatment in a severe case should comprise rest in bed, the use of an ice-bag over the heart, and the administration of adrenalin. When the patient gets about again, he must avoid alcohol and all forms of excitement. Gentle exercise is desirable, but never violent exercise. Diet is to be nutritious, but non-stimulating. Electricity is said to be of benefit. Experiments in organotherapy are being tried in this disease. Thymus extract has been used. Ballet and Enriquez assumed that the thyroid gland furnished an antitoxin to certain body poisons, that an excess of thyroid secretion over the amount required to neutralize toxin caused the condition known as Graves's disease, and that the symptoms of Graves's disease would disappear if sufficient toxin were administered to antidote the excess of thyroid secretion (Hubert Richardson, in "Am. Medicine," August, 1906). The two observers mentioned above obtained blood-serum from thyroidectomized dogs and injected it into individuals suffering from Graves's disease and claim that they noted improvement. In 2 of their patients, however, tetany developed. Lanz has used the milk of thyroidectomized goats instead of the serum of thyroidectomized dogs. The serum of thyroidectomized sheep, powder made from the dried goiter of a cretin, and the powdered flesh of the thyroidectomized sheep have been used (Hubert Richardson, Ibid.). What is known as *thyroidectin* is the dried serum of an animal from which the thyroid gland has been removed. John W. Rogers and S. P. Beebe have made some extremely interesting studies on the production and application of a serum. Rogers makes two sera, using one or the other, according to the needs of the case. One serum, called the normal serum, is obtained from sheep or rabbits after injecting them with the combined nucleoproteins and thyroglobulin of healthy thyroids; the other, called the pathological serum, is obtained from the animals after having injected them with combined nucleoproteins and thyroglobulin obtained from the thyroids of Graves's disease. In 1 severe case I have seen rapid improvement and apparent cure follow the use of Rogers's serum. The value of serum treatment is as yet undetermined. It is certainly not free from danger and some deaths have followed its use. One cause of diverse results after the use of goat serum may be found in the fact that some of the animals were probably incompletely thyroidectomized. The goat possesses aberrant thyroids and these must be removed as well as the gland proper. Beebe and Beveridge ("N. Y. Med. Jour.," Dec. 25, 1915) state that 50 per cent. of more than 3000 treated were cured "in the sense that they are strong and able to meet all the demands made upon them."

There are upon the market three preparations to combat hyperthyroidism:

1. Thyroidectin (or thyreoidectin) is a powder made from the dried blood serum of thyroidectomized animals. It is given in 5-gr. capsules. The dose is 1 or 2 capsules three times a day.

2. Beebe's serum is the serum of thyroidectomized animals.

3. The antithyroidin of Moebius is the serum of sheep's blood, the animal having had its thyroid gland removed at least six weeks before the serum was obtained.

Jaboulay of Lyons suggested cutting the cervical sympathetic nerve on each side. Jonnesco of Bucharest suggested bilateral extirpation of the cervical ganglia. Bilateral extirpation of the cervical ganglia of the sympathetic and

division of each nerve below the ganglion have been employed, it is alleged, with benefit. I have not employed the operation for this disease. It benefits exophthalmus, perhaps, more than does thyroidectomy. Ligation of the thyroid arteries may do good. Its chief use is preliminary to thyroidectomy but it will cure exophthalmic goiter in a child. Partial thyroidectomy is the operation commonly employed in severe cases; it cures within six months from 50 to 75 per cent. of the cases operated upon. One lobe, the isthmus, and a portion of the other lobe are removed. Some cases do not improve; others improve slowly and relief is only partial. It is the operation which I prefer. The Mayos have obtained a splendid series of results from this operation. It is their custom to apply the *x*-rays daily for several weeks and then to operate. The rays produce decided but temporary improvement. The operation is intracapsular extirpation of one lobe. Ether is given to most cases (by intratracheal insufflation). In some cases thyroid intoxication follows operation. In other cases very rapid growth follows incomplete removal, and the operation seems actually to have done harm. Sudden death occasionally follows the operation. The removal of an exophthalmic goiter is difficult; the capsule and blood-vessels rupture from slight force. Not all cases should be operated upon. (See Operation for Exophthalmic Goiter on page 1385.) The *x*-rays frequently have a very beneficial effect upon the symptoms of exophthalmic goiter. They probably destroy some of the secreting glandular epithelium, and thus diminish the amount of the thyroid secretion and alter its character. They also induce fibroid changes, and 80 per cent. of cases are relieved. Frequently they cause great improvement and occasionally they will produce a cure. In one case the *x*-rays caused such atrophy that myxedema arose and it became necessary to administer thyroid extract. Makenzie reported a similar case ("Lancet," 1916, cxci). It is my custom to use the rays preliminary to operation in order to decrease the vascularity of the capsule, to lessen the amount and diminish the toxic quality of the thyroid secretion, and to modify the various symptoms. If status lymphaticus exists operation is decidedly dangerous. Enlargement of the thymus without status lymphaticus does not seem to increase the danger of operation to any decided degree, but if the enlargement be great it is wise to precede operation by the administration of thymus tablets and exposures to the *x*-rays.

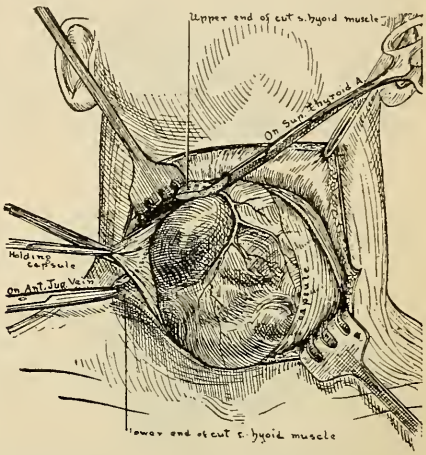

FIG. 888.—Enucleation of cystic goiter; capsule opened (C. H. Mayo).

Operations on the Thyroid Gland.—The removal of a goiter is a major operation and one beset with difficulties and dangers. Nevertheless it is a very successful operation. I lost a case of supposed adenomatous goiter which turned out to be a metastatic hypernephroma. The patient died from secondary hemorrhage. I lost a case of carcinoma of the thyroid and a case of simple adenoma. My mortality in ordinary goiter has been under 2 per cent. In 1200 cases of ordinary goiter the Mayos had a mortality of 1 per cent. following extirpation. In the Mayo Clinic from Jan. 1, 1907 to Jan. 1, 1918 there were 6668 thyroidectomies for simple goiter with a mortality of 7 per cent. Kocher's mortality is 0.4 per cent. Certain anatomical points are to be borne in mind. The internal jugular vein is frequently found to the inner side of the

carotid artery and lying on the goiter (because the vein has branches which run from the goiter and hold the vessel against the thyroid). The recurrent laryngeal nerve ascends along the side of the trachea back of the gland, and is in contact with the esophagus before it passes through the cricothyroid membrane. On the right side the nerve is very close to the inferior thyroid artery, sometimes passing over it, sometimes under it. On the left side it is deeper and not so near the artery. The parathyroids are behind the thyroid and usually behind the capsule.

In view of the fact that one or both recurrent laryngeal nerves may be paretic from pressure, all cases should be examined with the laryngeal mirror before the operation to determine this point. If the paresis is on one side only, the sound vocal cord may possibly compensate by advancing across the midline. In such conditions the paresis may be first observed following operation, leading the operator to think that he has injured a nerve (C. H. Mayo, in "Surg., Gyn., and Obst.," July, 1907).

Intraglandular Enucleation (Socin's Operation).—By this operation an adenoma, a colloidal area or a cyst of the thyroid gland can be removed, the encompassing glandular tissue being left in place. The capsule of such a

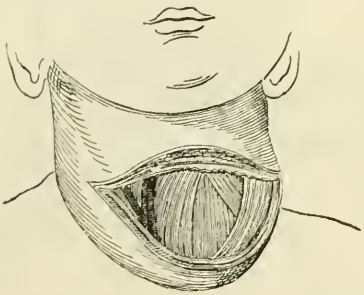

FIG. 889.—Kocher's transverse incision exposing the muscles and median veins of the neck (Kocher).

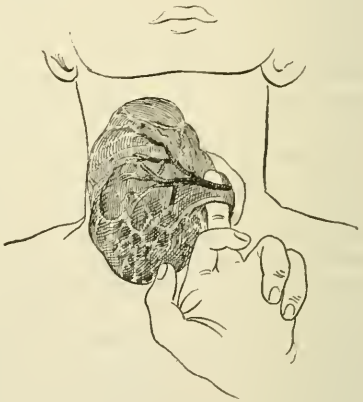

FIG. 890.—Isolating the accessory veins (Kocher).

growth is glandular tissue. The operation of enucleation is not suited to the removal of multiple tumors and it cannot be performed for parenchymatous goiter or exophthalmic goiter. Intraglandular enucleation is performed as follows: The thyroid is exposed by an oblique or by a transverse incision. An incision is made through the capsule of the thyroid gland and through the glandular tissue until the cyst or solid tumor is reached. As a rule, the tumor can be recognized by the fact that its color differs from the color of the thyroid tissue. The tumor is turned out by the fingers, a special scoop, the knife handle, or a dry dissector. In some cases a cyst can be most easily removed if, after exposure, it be incised and emptied and its wall then grasped by strong forceps. A solid tumor should, if possible, be removed intact. The wound is packed temporarily with gauze, the edges of the cavity are grasped by forceps, the gauze is removed, and every bleeding point is carefully ligated. The wound is closed by three layers of sutures—"one in the gland, one in the muscles, and a third in the skin" (James Berry, on "Diseases of the Thyroid Gland"). If the tumor is large, drain for twenty-four hours; otherwise, do not drain.

Enucleation is a very successful operation if performed upon properly selected cases, and can be performed rapidly, but the arrest of bleeding is often tedious and troublesome.

Extracapsular Extirpation.—This term means removal of the entire gland (*complete thyroidectomy*) or a portion of the gland (*partial thyroidectomy*) with the glandular capsule, the operation being an extracapsular procedure. Usually but one lobe is extirpated (*lobectomy*), or one lobe, the isthmus, and a portion of the other lobe. This method enables the operator to tie the chief vessels before he cuts them; as his vision is not abscured by bleeding, he can avoid cutting the glandular capsule (which would provoke copious bleeding), and he keeps a safe distance away from the recurrent laryngeal nerve.

If the patient suffers from grave respiratory trouble with myocardial disease,

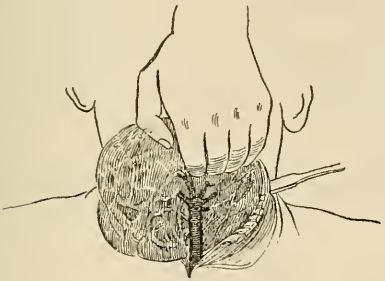

FIG. 891.—Exposure of veins of lower end before ligation (Kocher).

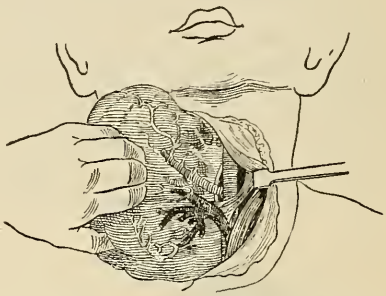

FIG. 892.—Dislocation of the goiter toward the right (Kocher).

a general anesthetic is contra-indicated. If ether is used, after unconsciousness is obtained the ether is continued by intratracheal insufflation. The patient is placed recumbent, with the shoulders a little raised and the neck laid upon a sand-pillow so as to throw the head back as far as is consistent with comfortable respiration.

An oblique incision, a horseshoe-shaped incision, or a transverse collar incision (Fig. 889) may be made. I usually employ an incision shaped like an incomplete horseshoe, the convexity being downward. Layer by layer the

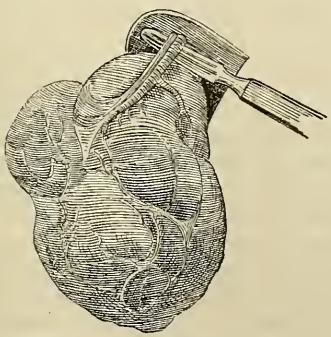

FIG. 893.—Isolation of the superior thyroid artery and vein (Kocher).

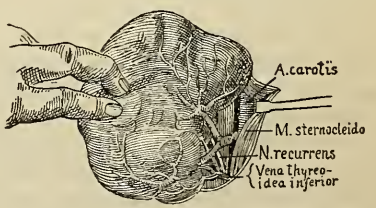

FIG. 894.—Ligation of the inferior thyroid artery (Kocher).

tissues are divided. Vessels are carefully tied as divided or before division. The muscles which run from the sternum to the hyoid bone may in some cases be separated, but the extirpation of a large goiter requires transverse division of the muscles high up. The capsule of the lobe is exposed, and is separated from external parts (Figs. 890, 891, and 892). The upper portion of the gland is cleared. The superior thyroid vessels are found, tied with two ligatures each, and divided between the ligatures (Fig. 893). The clearing of the gland is carried on toward the median line and some rather large veins are encountered

and tied (Fig. 895). The lower portion of the lobe is cleared and the inferior thyroid vessels are found. Near this point the recurrent laryngeal nerve lies and may be located. If the operation is being done under a local anesthetic adjacency to the nerve is readily determined, because if the nerve is pulled upon, or if it is pressed upon or touched by a blunt instrument, the patient's voice becomes metallic. A deliberate attempt is made to locate the nerve, and the patient is engaged in a conversation requiring answers while the surgeon is investigating. The lobe is lifted from its bed and dislocated from the wound and the inferior thyroid vessels are tied close to the border of the gland in order to avoid the recurrent laryngeal nerve (Fig. 894). The vessels are tied and cut across as were the superior thyroid vessels. The isthmus is next exposed, clamped, ligated, and cut across, every care being taken to prevent colloid from being squeezed into the wound (Fig. 896). After dividing the isthmus, any bleeding point is ligated and the stump is cauterized. The divided muscles are sutured with catgut, a drainage-tube is inserted, and the superficial wound is closed with sutures of silkworm-gut or silk.

Intracapsular Extirpation.—This operation is warmly advocated by the Mayos. The preservation of the posterior portion of the capsule protects the

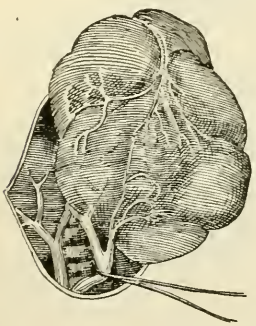

Fig. 895.—Isolation of the venæ thyreoideæ imæ (Kocher).

Fig. 896.—Isolation and clamping of the isthmus (Kocher).

recurrent laryngeal nerve and greatly lessens the risk of injuring the parathyroids. Ether is given unless there is grave respiratory difficulty with myocardial degeneration, and half an hour before administering the ether the patient is given a hypodermatic injection of $\frac{1}{4}$ gr. of morphin and $\frac{1}{100}$ gr. of atropin. The ether is continued by intratracheal insufflation. When anesthetized, the patient is placed in the reversed Trendelenburg position and the shoulders are elevated (C. H. Mayo, in "Surg. Gyn., and Obst.," June, 1907). Kocher's transverse collar incision is made. Muscles are separated or divided as in ordinary extraglandular extirpation. If the ribbon muscles are divided the cut is made near their upper insertion to save their nerve supply and prevent the muscle scar from being in line with the skin scar. The gland is elevated. The vessels entering and leaving the raised lobe are double clamped and tied. The capsule is incised along the outer side of the gland, is pushed back with gauze, and the lobe is drawn toward the midline, and vessels are caught by forceps, the tissues being grasped in line with the midline of the body (C. H. Mayo, Ibid.).

Every structure bearing any resemblance to a parathyroid is allowed to remain. The isthmus is clamped, divided, and closed by suture. The muscles and skin are sutured. Drainage is required after removal of large growths, a separate incision being made to permit of it.

Dangers in Goiter Operations.—During any operation for goiter sudden death may occur. In some cases a general anesthetic is responsible. In

others suffocation arises from pressure upon or bending of the trachea or collapse of the trachea as the goiter is lifted from its bed. In rare cases dangerous dyspnea arises from irritation of the laryngeal nerves, and cardiac inhibition may be induced in the same manner. The parathyroids may be injured or removed and tetany may result. Rough handling and flooding the wound with colloid may be followed by great and even fatal hyperthyroidism. The trachea or esophagus may be opened. The recurrent laryngeal nerve may be injured. Air embolism seldom occurs. Reactionary or secondary hemorrhage is usually due to slipping of the ligature on the superior thyroid artery "caused by including a piece of muscle" (C. H. Mayo, in "Surg., Gyn., and Obstet.," June, 1907).

Acute Thyroidism (Hyperthyroidism).—When colloid from the thyroid is squeezed into the wound during the operation or leaks into it later, it is absorbed and may produce serious symptoms or even death. This is most apt to happen in exophthalmic goiter. The symptoms always appear within forty-eight hours and usually within twenty-four. Sometimes they arise quickly after operation. In some cases in which this happens the patient never reacts from the operative shock, but develops a very rapid pulse and intense dyspnea, and dies in a few hours. In less severe cases there is a period of circulatory excitement, dyspnea, and elevated temperature (*thyroid fever*). The surgeon seeks to prevent acute thyroidism by limiting leaking of colloid, by cauterizing the stump, by washing the wound with adrenalin solution, by suturing the capsule over the raw stump of the gland, and by inserting drainage.

The Operation for Exophthalmic Goiter.—The operation of thyroidectomy is not to be performed during an acute exacerbation. (See Judd and Pemberton in Surgery, Gynecology, and Obstetrics, March, 1916.) To do it then will very probably cause death. Delirium is a contra-indication. So are gastric crises. The operation is very dangerous when there is great cardiac dilatation. After the disease has existed one year it is highly probable that marked dilatation exists.[1] Hence, early operations are much safer than late ones. If a case is seen early, and if the *x*-rays (and perhaps serums) fail to cure, operation should be recommended. In any case with serious symptoms the surgeon seeks to modify those symptoms before thyroidectomy by means of rest, the ice-bag over the heart, drugs, the *x*-rays, and perhaps serums. If under this treatment the dangerous symptoms disappear or greatly abate, thyroidectomy may be performed.

If the dangerous symptoms are little modified or not modified at all by medical treatment, preliminary ligation of one of the thyroid arteries is indicated. Ligation of an artery will not cure a case, but will probably greatly improve it. The operation is strictly palliative and preliminary. Tie the right superior thyroid. Wait one week. If the symptoms are not greatly improved, tie the left superior thyroid and wait a while. In severe cases tie both superior thyroids at one operation. The operation is done under infiltration anesthesia. It is not entirely free from danger and may cause death. Halsted ("Annals of Surgery," August, 1913) ties one inferior thyroid or both inferior thyroids. He says that by the inferior operation we obtain a better cosmetic effect, leave a scar largely beyond the incision which will subsequently be used for lobectomy, and tie vessels which are larger than the superior arteries. In 1 of his cases four arteries were tied in 4 operations before lobectomy. C. H. Mayo[2] points out that the ligature of the superior thyroid should be applied very close to the pole or should actually include some of the thyroid tissue, "so that a reversed circulation in anastomotic branches with the inferior thyroid artery may not occur."

[1] C. H. Mayo in "Collected Papers by the Staff of St. Mary's Hospital," Mayo Clinic, 1912; Halsted, "Annals of Surgery," August, 1913.

[2] "Collected Papers by the Staff of St. Mary's Hospital," Mayo Clinic, August, 1912.

When it is esteemed safe the surgeon prepares to perform partial thyroidectomy. In most cases ether is given, preceded by a hypodermatic injection of morphin and atropin. After the patient is anesthetized by ether the tracheal tube should be introduced and the unconsciousness maintained by insufflation anesthesia. If there is grave cardiac dilatation and we determine to operate, infiltration anesthesia is relied upon.

At the operation an entire lobe (except a thin slice), the isthmus, and a portion of the other lobe should be removed. The more of the gland removed, the better the prospect of cure Halsted, "Annals of Surgery," August, 1913). At least one-half of one lobe must be left in order to prevent myxedema. The parathyroids are protected by leaving a small slice of the posterior portion of each lobe (Halsted, "Annals of Surg.," Aug., 1913). After the removal of one lobe the other usually undergoes considerable atrophy. After thyroidectomy, lymphocytosis gradually decreases, and an enlarged thymus generally disappears (Ibid.). Thyroidectomy may cure the case; it may greatly improve it; may fail or nearly fail, or may cause death. Cure is gradual and may be attained after several months only. From 50 to 75 per cent. of patients are cured by the operation. Many others are vastly and permanently improved. Some are improved, but are subject to temporary relapses. In Halsted's 39 cases there was not a death from operation.

In the first 16 cases operated upon by the Mayos the mortality was 25 per cent. At present the factors which forbid operation are recognized. In 3709 operations for exophthalmic goiter their mortality was only 3 per cent. (Personal communication to the author). They have had 278 consecutive cases without a death, a truly wonderful record.[1]

The elder Kocher ("Jour. Am. Med. Assoc.," April, 1910) reports upon 535 partial thyroidectomies for exophthalmic goiter. The mortality was 3.1 per cent.: 3 died from the anesthetic, and now his clinic uses local anesthesia preceded by Crile's plan of psychic narcosis; 3 others died from kidney disease which existed at the time of operation. Now no operation is recommended in his clinic if kidney disease exists. There were 3 thymus deaths; 4 with status lymphaticus died suddenly while being prepared for operation. Such patients should not be operated upon before they have been greatly improved by medical treatment. Kocher, like Halsted, says that the degree of improvement depends upon the amount of gland removed. In such cases use medical treatment and the *x*-rays first. If this plan fails, tie one or more of the thyroid arteries before doing thyroidectomy.

My personal experience in exophthalmic goiter is small; in fact, I know of no one in Philadelphia who has performed any great number of operations for it. I have performed thyroidectomy for exophthalmic goiter 14 times, with 2 deaths.

The Parathyroid Glands and Tetany.—(See collective review in "Internat. Abstract of Surgery," May, 1915, by Eugene H. Pool). These glands were discovered by Sandström in 1880, and their vital functions were pointed out by Gley. He showed that removal of the parathyroids causes tetany.

The parathyroids are brownish red and are larger in adults than in infants. They are constant in man, never being congenitally absent.

They are usually four in number and are ordinarily placed external to the thyroid capsule. In some cases, however, one or more of them may be found embedded in the thyroid gland, but even when they appear to lie within the thyroid they are always separated from it by a capsule of connective tissue.

While there are usually four parathyroids, there may be only three, or there may be five, six, seven, or eight. Accessory parathyroids may be found over wide areas. One was discovered by Rogers and Ferguson in the middle of the

[1] C. H. Mayo, in "Collected Papers by the Staff of St. Mary's Hospital," Mayo Clinic, 1912.

posterior portion of the pharynx; and there was found in the thorax by Ogle a gland that was partly parathyroid.

From their situation the parathyroids are divided into superior, or external, and inferior, or internal. Walsh describes these glands in adults as being each from 6 to 7 mm. in length, 3 to 4 mm. in breadth, and 1½ to 1 mm. in thickness. Each of these glands is supplied by a terminal artery, and the supply is very largely obtained from the inferior thyroid artery or from the branch of anastomosis between the superior and inferior thyroid vessels.

If the parathyroid glands be extirpated from an animal, tetany usually develops (*experimental tetany*). This is positively the case in dogs. These glands certainly have most important functions in the metabolism of the body. They are essential for normal metabolism (Mayo and McGrath, in "Annals of Surgery," Feb., 1912). MacCallum and Voegtlin ("Johns Hopkins Hosp. Bull.," March, 1908) believe that damage to or removal of them causes great changes in calcium metabolism.

Very little is known of diseases of the parathyroid glands. A few cases of tumor have been reported, each being an example of either work-hypertrophy or adenoma. One of these cases was reported by the author in "Surg., Gyn., and Obst.," Jan., 1909. In this case the tumor was removed under the impression that it was an adenoma of the right lobe of the thyroid gland. The pathological report, however, showed it to be a parathyroid. No trouble of any kind followed the operation, though at a later period enlargement of the opposite side of the neck occurred. This has been let alone through fear that it may be a left parathyroid. In spontaneous tetany histological changes have been found in the parathyroids and there is some evidence that traumatism may produce functional insufficiency.

Some persons have maintained that deficiency of parathyroid secretion is the cause of paralysis agitans, but this idea has been warmly combated and lacks evidence. Some observers believe that there is a deficiency of parathyroid secretion in exophthalmic goiter.

In view of the well-known fact that removal of or damage to the parathyroids may result in tetany (*hypoparathyroidism*), provided that several of these glands or all of them are damaged or removed, it becomes the duty of the surgeon, when operating for goiter, to exercise the utmost care that he does not remove any of these bodies. The safest way to avoid them is to retain the posterior portion of the capsule of the thyroid gland. If, during operation, any small body that resembles a parathyroid be detected, it should be let alone; or if such a body has been accidentally removed, it should immediately be implanted into the capsule of the lobe of the thyroid gland that has been left undisturbed. It is highly improbable that the removal of even both parathyroids on one side will cause tetany if there are two normal parathyroids on the opposite side.

On account of the possibility of the development of tetany the question of the transplantation of parathyroids from animals becomes extremely important. Halsted has made some very valuable experiments upon the auto- and isotransplantation of the parathyroid glands in dogs ("Annals of Surgery," Oct., 1907; "Jour. of Experimental Med.," vol. xi, No. 1, 1909). He has shown that if the parathyroid be transplanted into an animal with normal parathyroids failure will follow, and the transplanted glandule will disappear. If, however, there be parathyroid deficiency in the animal into which the transplantation is made, the glandule will attach itself and grow. He obtained the best results by placing the parathyroid beneath the posterior sheath of the rectus muscle of the abdomen. Some observers have placed it in the spleen; others, within the peritoneum and in various other regions.

One of the dogs experimented upon by Halsted and reported upon in "Jour. of Exper. Med.," vol. xi, No. 1, 1909, lived in perfect health "for fifteen months

and was in good health until the performance of the final operation, at which a parathyroid autograft" was removed. The dog died in three months from hypoparathyroidism (Ibid., No. 3, 1912).

If tetany follows thyroidectomy, it may be treated by the intravenous, rectal, or stomach administration of a 5 per cent. solution of lactate of calcium (MacCallum and Voegtlin, Loc. cit.). Von Iselsberg gives parathyroid tablets and, if these fail, practices parathyroid transplantation. Beebe and Berkeley have prepared a parathyroid serum which they claim to be efficient. Charles H. Mayo maintains that in tetany either the serum or the calcium lactate should be used, in the hope of tiding the patient over until parathyroid glands can be secured and implanted ("Annals of Surgery," July, 1909). Human parathyroids are preferable. They should be obtained from infants which died during delivery or from adults killed by accident. The calcium salt may be given intravenously, subcutaneously, by the stomach, or by the rectum. Joseph H. Branham ("Annals of Surg.," August, 1908) has reported tetany following thyroidectomy cured by the subcutaneous injection of parathyroid emulsion. The emulsion was made by grinding up fresh glands of beeves in a mortar, and then pouring 400 c.c. of sterile salt solution into the mortar. The preparation was filtered through sterile gauze and was administered beneath the patient's breast.

J. Clarke in 1815 and S. L. Steinheim in 1830 described tetany. The name was coined by Corvisart. The condition has been described in association with many very different conditions (pregnancy, gastric dilatation, childhood). It is assumed that in all forms of tetany there is impaired secretion of the parathyroids because of damage by toxins or traumatism. The form we are considering here is due to removal of or injury to the parathyroids (Erdheims designates it *tetany parathyreopriva*). Cases of tetany in the newborn have been reported.

When tetany begins to develop in a patient there are usually headache, dizziness, and pain in the extremities. The muscles in one or both forearms and hands are liable to be affected. The hand flexes at the wrist, while the fingers are extended, and in some cases the forearm flexes at the elbow. Now and then the fingers will flex at the metacarpophalangeal joints, but the distal phalanges will remain extended. These spasms are painful. Similar spasms may occur in the feet and toes. In most severe cases the trunk muscles and those of the chest, throat, and eye may be involved.

Trousseau, years ago, showed that a spasm may be brought on in the affected limb by pressing upon the nerve-trunks and blood-vessels; this is called the *Trousseau sign*. Pressure upon the facial nerve may induce the spasms, and it is called *Chvostek's sign*. *Erb's sign* is a great increase in the galvanic irritability of the motor nerves. *Hoffmann's sign* is excessive sensitiveness of the sensory nerves. *Schultze's tongue sign* ("Münch. Med. Woch.," Oct. 31, 1911) is said to be invariably present in adults with tetany. If the side of the tongue be tapped the organ responds by grooving itself on that side. If the tongue be lifted by a spatula and the dorsum be tapped a constriction like a waist forms.

Tetany due to absence of the parathyroids will inevitably prove fatal if not treated actively.

Before we understood the necessity of guarding the parathyroids tetany after goiter operations was not uncommon. The preservation of the posterior portion of the capsule has almost abolished this peril. In 3203 operations on the thyroid performed at the Mayo Clinic in St. Mary's Hospital, Rochester (up to Dec. 1, 1911) there was but 1 case of tetany and the symptoms in that were slight and transitory.

XXXIII. THE CAROTID GLAND; THE THYMUS GLAND

The Carotid Body or Gland.—This structure was discovered by Haller in 1743. It has no known function. It is about the size of a grain of rice and lies in or very near the carotid bifurcation, being adherent usually to the common carotid, occasionally to the external or internal carotid by the ligament of Mayer. Tumors may form in this little body. The type found is the perithelioma. They are most common in those between twenty and thirty years of age. Such a tumor grows slowly, is hard, is movable from side to side, but not up and down, and is lifted with each beat of the carotid artery. In the long run it tends to become malignant. As the tumor grows it eventually surrounds the common carotid artery. Dr. Wagner of Wilkesbarre, Pa., referred to me a patient with rapidly growing bilateral tumors of the carotid bodies. No operation was performed. The tumors were removed postmortem and proved to be sarcomatous.

Treatment.—Callison and MacKenty ("Annals of Surgery," 1913, lviii) collected 54 operations. Of these 32 recovered and 22 died. Of the cases which survived 3 had hemiplegia with aphasia, 4 dysphagia, 1 constant cough, 5 deviation of the tongue, 4 eye symptoms and 4 facial palsy. Winslow has collected 10 more cases ("Annals of Surgery," 1916, lxiv). Operation on an advanced case is very difficult, will probably require ligation of the common carotid, and will cause grave injury to important nerves. In one of the author's patients the common carotid was tied and the patient developed laryngeal palsy and hemiplegia. Early operation may permit of removal of the tumor without tying the common carotid artery. In a second case the author was able to accomplish this. My first case led me to agree with Reclus that these tumors should be let alone unless they are productive of dangerous symptoms. I have come to the conclusion that the time to operate is early, long before there are dangerous symptoms. To wait for obvious malignancy is to court failure or disaster (see the author in "N. Y. Med. Jour.," Feb. 7, 1914, also Callison and MacKenty, in "Annals of Surgery," Dec., 1913).

The Thymus Gland.—This bilobed ductless gland becomes fully developed toward the end of the second year of life. From that period it remains stationary for a time and then undergoes retrogression. At puberty retrogression becomes rapid. Finally, the gland almost entirely disappears, although a small vestige of it usually remains through life. Studied in the very young child, it is found to consist of a thoracic portion and a cervical portion. The chief part of the gland lies directly back of the sternum and upper four costal cartilages of each side in the superior and anterior mediastinal spaces. On each side are the pleura and lung. Posteriorly it lies upon the pericardium, superior vena cava, innominate vein, and pulmonary artery. The two lobes from the gland rise into the neck in front of the trachea. The left lobe overlaps the common carotid; the right lobe, the innominate artery. A strand of fibrous tissue usually passes from the lobe which ascends highest to the corresponding lobe of the thyroid gland. The lobes of the thymus receive numerous veins from the thyroids. The inferior thyroid artery is the chief source of arterial blood. The thymus is composed of may lobules separated by septa. The undegenerated thymus contains both lymphoid and epithelial structures.

The cells of the reticulum are epithelial. In the medulla of the lobules are the concentric corpuscles of Hassall which are derived from the epithelium of the reticulum. The small thymic cells are probably lymphocytes. In Hammar's words: "The thymus is an epithelial organ which is permeated with lymphocytes" (quoted by Charles H. Mayo and Bernard F. McGrath in their thorough and impressive study of "The Surgical Importance of the Thymus." See "Collected Papers by the Staff of St. Mary's Hospital," Mayo Clinic, 1912).

The function of the thymus is as yet undetermined. Some believe it is merely a lymphatic structure and furnishes no internal secretion. Others believe that it furnishes an internal secretion of great, perhaps of essential, importance in development. Some observers believe that the thymus destroys toxins, and that deficiency of thymus permits the accumulation of toxic matter in the system. These studies of hypothymization were made on thymectomized animals.

Experiments to determine the result of excessive thymus function (hyperthymization) are peculiarly contradictory, unsatisfactory, and inconclusive. In these experiments thymus glands have been implanted, thymus juice has been injected, and thymus feeding has been practised.

Mayo and McGrath (Ibid.) conclude "that the thymic function is concerned in the general process of nutrition, particularly with the ossification of bone;" further, it is probable "that the thymus and the chromaffin portion of the adrenals act antagonistically on the sympathetic."

Although the thymus should have practically disappeared between the twelfth and twentieth year, there are cases in which it fails to disappear at all. There may never have been any symptoms to suggest persistence and the gland may be discovered at a necropsy. It is known that the thymus persists in castrated animals (Renton, in "Glasgow Med. Jour.," 1916, lxxxvi).

The thymus gland may enlarge. The enlargement is most usual in childhood, but if the thymus be persistent, may occur much later in life. The condition is hypertrophy or hyperplasia. Enlargement of the gland may be met with in exophthalmic goiter, leukemia, Hodgkin's disease, and status lymphaticus. It may produce no symptoms whatever. It may be responsible for asthma and for sudden death (*thymic asthma* and *thymic death*). Enlargement may sometimes be recognized by the *x*-rays—by no means always.

Infectious and wasting diseases in children may cause atrophy of the thymus. The gland may be the seat of hemorrhages, inflammation, tuberculosis, calculi formation, and necrosis (in diphtheria). In congenital syphilis the thymus may be the seat of gummatous change or fibrosis.

Dubois's abscesses occur in syphilis of the thymus. Many spaces form and the spaces are full of a fluid resembling or actually pus.

Enlargement by cysts or tumors may occur. Innocent tumors (fibroma, myxoma, and adenoma) are rare. Malignant tumors (carcinoma and sarcoma) are more common. The most common tumor is lymphosarcoma (*thymoma*). Spindle-cell sarcoma and endothelioma may arise (see James Ewing on "The Thymus and its Tumors" in "Surgery, Gynecology, and Obstetrics," April, 1916).

Tumors of the thymus cause the symptoms of mediastinal tumor (cyanosis, dyspnea, exophthalmus, cough, alterations in voice, circulatory disturbance). Metastases are often early. Such a tumor may be rapidly fatal by asphyxia. With not a few cases of thymus tumor myasthenia gravis has been associated. No symptoms are reported to suggest sympathetic disturbance of the chromaffine system (Ewing, Ibid.).

Status Lymphaticus (*Status Thymicus; Lymphatism*).—This condition is associated with enlargement of the thymus. (See page 249.)

Operations for Thymus Enlargement or Tumor.—(See Oliver, in "Archiv. gén. d. Chir.," vi, 138, 1912.) Operators have removed the thymus in goiter operations and also when the thymus alone has been enlarged.

To perform *exothymopexy* expose the thymus by an incision above the sternum, catch the gland and capsule with forceps, draw them up as far as possible, and suture to the fascia. This operation is without much value. A decompression operation can be done by resecting the manubrium. It does not cure, but may give relief.

Thymectomy has been performed a number of times. It may be extracapsular or intracapsular, partial or complete. In 42 reported cases there were 15 deaths.

XXXIV. DISEASES AND INJURIES OF THE LYMPHATICS

Wounds, Ruptures, and Occlusions of the Left Thoracic Duct.—It was long believed that wounds of any part of the thoracic duct were almost certainly fatal. It is now known that wounds of the duct at the root of the neck are rarely very dangerous unless the duct be divided close to the vein. A wound of the duct, as the result of an accident, is rarely seen because the adjacent vital structures are apt to be injured at the same time and death rapidly ensues. Wounds of the duct or of its large branches, occasionally but very rarely, are inflicted during surgical operations. Benetau speaks of 12 cases thus inflicted; in 8 cases the operation was for tuberculous glands, in 3 for malignant glands, and in 1 for ligation of the subclavian artery. One alleged danger of wound of the duct is entrance of air into the adjacent vein. This is said to have happened in 1 case. As a rule, the short end of the cut duct does not bleed, the duct valves preventing hemorrhage. In Fullerton's case, when a grooved director was passed along the stump of the duct by way of a terminal into the vein, blood at once appeared. In most cases the injury is not recognized at the time, but later, when white fluid escapes from the wound. The discharge may continue or may cease spontaneously. If it continues, there is rapid loss of flesh and strength. I assisted Dr. Keen in the case in which he did recognize the wound at the time it was inflicted. A thin fluid was observed flowing rhythmically from a tear in the duct. It is to be remembered that the course of the cervical part of the duct is very variable and sometimes the duct lies very high above the clavicle. There was 1 death in 17 recorded cases (Dudley P. Allen and C. E. Briggs, in "Amer. Med.," Sept. 21, 1901).

The discharge from a cut duct may continue to leak—perhaps a pint or more flowing out during twenty-four hours. If leakage continues, constitutional effects will sooner or later become evident. In Schoff's case ("Wien. klin. Woch.," Nov. 28, 1901) it was not known that the duct had been injured until the stitches were removed from the wound in the neck. The wound was found distended with chyle and Schoff packed it with iodoform gauze. Fifteen days later the patient died from chylothorax and pulmonary compression.

Rupture of the thoracic duct or of the receptaculum chyli may occur from traumatism or be a secondary consequence of tuberculosis or carcinoma. Rupture leads to death by starvation, or to fatal compression by the exuded fluid (Harvey W. Cushing, in "Annals of Surgery," June, 1898). Occlusion of the main duct may be followed by rupture of the receptaculum chyli. Gradual occlusion by a tuberculous or inflammatory growth may not produce any serious symptoms. Cushing assumes that in such a case the lymph-current is reversed and is taken up by the right thoracic duct. In gradual obstruction masses of dilated lymph-vessels may be found, particularly in the thorax and abdomen. If lymph-vessels rupture, chyle flows out and, according to the situation, there arises "chylous ascites, chylothorax, chyluria, or chylous diarrhea" (Ibid.).

Treatment of Wounds.—If the wound in the neck does not completely divide the duct, and if the duct wound is discovered at the time of operation, suture the duct. Allen sutured the duct and had no further leakage. Keen sutured the duct and recovery followed. If the duct be completely divided, follow Cushing's advice: "It would seem advisable to place a provisional ligature about the duct on the proximal side of the wound, and to control the leakage, if possible, by a gauze tampon. This would act as a safety-valve, and allow chyle to escape, if the pressure in the duct became too great and there was difficulty in establishing a collateral lymphatic circulation. The patient meanwhile should be given a meager diet. If the leakage should become uncontrollable and threaten starvation, the provisional ligature should be tied,

with the hope of a final readjustment of collateral circulation or trusting in the presence of some anomalous anastomotic branch which might suffice to carry the lymph into the venous circulation" (Ibid.). Fullerton tied both ends of a divided duct and the patient recovered ("Brit. Med. Jour.," June 16, 1906). Deanesley ("Lancet," Dec. 26, 1903) inserted the divided duct into the internal jugular vein and sutured it in place. There was some leakage, but recovery ensued. After ligation, the duct on the proximal side of the ligature may distend greatly and may actually rupture. When a wounded duct is leaking the patient should be fed exclusively on proteins. The diet should be scanty and the patient must be kept absolutely quiet in order to keep pressure in the duct at as low a level as possible during the establishment of a collateral lymphatic circulation (Fullerton, Loc. cit.). Nasaroff (Abstract, in "Surgery, Gynecology, and Obstetrics," Jan., 1914) reported a case of injury to the duct during a surgical operation, and collected 62 others from literature. Most cases heal after prolonged chylorrhea. Tamponade and ligation must be considered in the treatment.

Lymphangitis is inflammation of lymphatic vessels. *Reticular* or *capillary* lymphangitis (erysipeloid), which is inflammation of lymphatic radicles, is seen in some circumscribed inflammations of the skin. It is apt to attack the hands, causing redness and swelling, fading at the point of initial trouble while it spreads at the periphery; it is caused by micro-organisms derived from decomposing animal matter (see page 219). Erysipelas also causes it (see page 219). *Tubular* lymphangitis, which is due to the entry into the lymphatic ducts of virulent micro-organisms or toxic materials, is seen after the infliction of dissecting wounds, septic wounds, snake-bites, etc. It is announced by edema and by minute, hard, red streaks running from the wound up the extremity. Suppuration may occur.

Septic or **infective lymphadenitis,** or inflammation of the glands, may follow lymphangitis or may be due to the deposition of infective material, the lymph-vessels not being inflamed. In this form of lymphadenitis there are pain, tenderness, and swelling; in severe cases there are a chill and a septic fever. Suppuration may arise.

The **treatment** is to drain and asepticize the wound, to apply iodin, blue ointment, or ichthyol over the glands and vessels, and to employ rest, heat and compression. Internally, milk-punch, quinin, and nourishing diet are required. If the glands do not rapidly diminish in size after disinfection of a wound, and if they are in an accessible region, extirpate them. If suppuration of the glands occurs, incise and drain.

Acute lymphadenitis, or acute inflammation of the lymphatic glands, may be due to tubercle, syphilis, glanders, cold, or traumatism. Suppuration may or may not occur. In inflammatory lymphadenitis there are pain, heat, and nodular swelling. In severe cases there is fever.

The *treatment* is to asepticize any area of infection, place the glands at rest, apply heat and ichthyol ointment, or inject into the gland every day 5 minims of a 3 per cent. solution of carbolic acid to prevent suppuration. If the glands do not rapidly shrink, extirpate them. If pus forms, evacuate it, drain, and asepticize.

Chronic lymphadenitis is almost invariably syphilitic or tuberculous. It requires constitutional treatment and the local use of ichthyol, iodin, or blue ointment. If these remedies are not rapidly successful, tuberculous glands should be removed, but syphilitic glands rarely require such radical treatment.

Lymphangiectasis (*varicose lymphatics*), or dilatation of the lymphatic vessels, is due to obstruction. It may be congenital (macroglossia; lymphatic nevus, see page 420). It may be acquired. Many external causes may produce obstruction; for instance, the removal or suppurative annihilation of a considerable group of lymphatics; pressure of a scar or of a new growth upon

lymph-vessels; tuberculosis or neoplasm of a group of glands. In many cases of external pressure upon lymphatics there is no lymphangiectasis because the lymph finds other channels. In fact, it has been proved that ligation of a large lymphatic trunk is not of necessity followed by lymphangiectasis. Even when the condition arises from external pressure, it is usually temporary, although, particularly if glandular tumors exist, it may be permanent.

The persistent cases are usually due to obstruction within the ducts, for instance, endothelial proliferation as a result of chronic lymphangitis, or recurrent attacks of acute capillary lymphangitis (erysipelas) or ordinary acute lymphangitis; or tuberculosis and other chronic infections. There may be such a condition as primary intralymphatic endothelial proliferation ("Med. Record," Sept. 6, 1902). Blocking with *filarial worms* may occur, and if it does, the lymphangiectasis is usually situated in the pubic, the inguinal, or the scrotal region, or on the inner side of the thigh. There are two forms of lymphangietasis: the *varicose*, in which the vessels have a tortuous outline, like varicose veins, but are covered only with surface epithelium; and *lymphatic warts* (*lymphangioma circumscriptum*), in which wart-like masses spring up, these masses being covered with epithelium and filled with lymph. In most cases of lymphangiectasis there is considerable hard edema (*lymphedema*). Lymphangiectasis sometimes develops in an upper extremity after removing the axillary glands, and in the lower extremity after removing the inguinal glands. Periodic attacks of pain and redness occur in the area of lymphangiectasis, and usually at such times fever develops. Rupture of the dilated vessels causes a flow of lymph (*lymphorrhea*). Infection and erysipelas are apt to occur; perhaps again and again. It is uncertain whether these repeated attacks of erysipelas cause and maintain or are predisposed to by lymphangiectasis.

Treatment.—If the entire area can be removed, it should be extirpated. Maitland ("Brit. Med. Jour.," Jan. 25, 1902) shows that many varices are local and can be removed. If the varices are only partially removed, lymphorrhea will probably develop.

Lymphangioma is an advanced stage of lymphangiectasis (see page 420).

The **treatment** in mild cases is to pierce each vesicle with the negative pole of a galvanic battery and to pass a current. In severe cases destroy the mass with the Paquelin cautery or excise it with a knife or with scissors.

Elephantiasis.—*True* elephantiasis (elephantiasis Arabum) is chronic hypertrophy of the skin and subcutaneous tissues following a lymphangiectasis produced by a nematode worm (the Filaria sanguinis hominis). The disease is encountered in the tropics only. Elephantiasis of the scrotum is called *lymph-scrotum*. Elephantiasis of the leg is called *Barbadoes leg*.

Spurious or *pseudo*-elephantiasis (Fig. 897) is hypertrophy of the skin and subcutaneous tissue due to chronic inflammation (for instance, in a leg which possesses an ancient ulcer, or in the scrotum of a man with urinary fistula).

The **treatment** of true elephantiasis is massage and bandaging, sometimes excision of the deep fascia (Konboléon), ligation of the artery of supply, extirpation, or amputation.

Tuberculous Glands.—(See page 276.)

Lymphadenoma (*Malignant Lymphoma; Hodgkin's Disease; Pseudoleukemia*).—Malpighi in 1665 gave an outline of the condition which Thomas Hodgkin described in 1832. In 1865 Sir Samuel Wilks gave it the name of Hodgkin's disease. The term "lymphoma" is used loosely to designate any persistent swelling of a lymphatic gland or glands. Lymphadenoma means a swelling of lymph-glands or lymphadenoid tissue due to endothelial proliferation, is progressive in character, involves group after group of glands, is associated with anemia, and often accompanied by secondary growths in the abdominal viscera.

This disease can attack persons of any age but is most common in those

under forty, and affects males far more frequently than females. Hereditary influence is not apparent. It may start in a seemingly robust person. In many cases the disease arises slowly in apparently healthy glands, and exists for some time before it takes on signs of malignancy and invades distant glands. In some cases the disease comes on acutely and has a tendency to generalization from the start; in others it appears to remain localized for many months. Some regard the condition as neoplastic, others as inflammatory. A gland enlarged from irritation or from tuberculous disease may become lymphadenomatous, and tubercle bacilli can sometimes be found in lymphadenomatous glands. Lazarus asserts that the disease is lymphosarcoma and the tuberculosis accidental. Musser, Sternberg, and others believe that tuberculosis is the disease. Some few believe that lymphadenoma is really tuberculosis, but this view seems to have been definitely disproved. Late in a case miliary tuberculosis is apt to arise. A diphtheroidal bacillus is regarded by some as causal (Yates and Bunting, "Jour. Am. Med. Assoc.," June 12, 1915, also Cunningham, in "Am. Jour. Med. Sciences," March, 1917). Those who believe that the condition is a granuloma due to infection believe the point of entry of the bacilli may be the tonsil, the sinuses, the teeth, the middle ear, the intestine or the skin.

Fig. 897.—Spurious elephantiasis. No filariæ found. Born and lived in Philadelphia.

That the disease is at least similar to sarcoma is held by many. That it is a variety of sarcoma is asserted by some. In Hodgkin's disease Coley's fluid (the mixed toxins of erysipelas and Bacillus prodigiosus) causes reaction as in sarcoma. There is a form of tuberculosis strongly resembling Hodgkin's disease, but I do not believe that the two processes are identical. The glandular and splenic enlargements are neoplastic and not hyperplastic. The new tissue formed is called lymphadenoid tissue and, according to Banti, it is often atypical, tends to invade glandular trabeculæ and capsules, sometimes adjacent tissue, and gives origin to metastases.

Leukemia and pseudoleukemia are closely related, and both, according to Banti, are sarcoma. In leukemia the influence that stimulates proliferation acts chiefly upon the bone-marrow; in Hodgkin's disease, upon the lymph-nodes (Neumann, quoted by Coley, in a forceful article maintaining that Hodgkin's disease is a type of sarcoma, "Trans. Am. Surg. Assoc.," 1908).

Symptoms.—The glands in the neck are usually involved first, especially the glands of the posterior triangle, but the disease may begin in the axillary glands, the thoracic glands, or the intra-abdominal glands.

Two or more regions are sometimes involved simultaneously or almost simultaneously.

When the disease begins in the neck it affects at first one side, and after many weeks or months the other side becomes involved. The glands are at first hard, separated from each other, movable, the skin moves freely over

them and they may remain in this condition. Later the large glands may weld together and form great masses upon both sides of the neck and in the axillæ, obstructing respiration. In contradiction of the general view it is certain that, in acute cases or during acute exacerbations, periglandular structures are invaded. Great subcutaneous induration may occur.

After a time a very large mass may break through its capsule and infiltrate adjacent structures, and in very rare cases the skin becomes adherent and finally breaks. Intrathoracic symptoms point to involvement of the thoracic glands. It may be possible to palpate enlarged abdominal glands.

It is usually held that there is no distinctive blood picture. Yates and Bunting (Ibid.) insist that there is and set it forth as follows:

"There are two distinct types, an early and a late, showing a constant characteristic increase in the number of platelets (unless exhaustion of the bone marrow occurs) with abnormally large forms and either a relative or absolute increase in the so-called transitional cells. In the early type the leukocytes are usually less than ten thousand. Very early there is a moderate increase in the basophils, and when the disease is well established the eosinophils are slightly increased. The polymorphonuclear neutrophils remain within the usual limits, the lymphocytes at or slightly above the normal. The late type shows a leukocytosis which may reach one hundred thousand, the neutrophils are relatively increased to a percentage of from 75 to 92 and the lymphocytes are reduced to 5 per cent., frequently even less. The transitionals, the only other cells found in any numbers, are usually above 8 per cent. unless the leukocytosis is very high, when they may be relatively fewer, but still exceed the lymphocytes in number. This late picture is a result of the intensity of the disease rather than the extent of involvement and is usually largely dependent on duration for its development."

The spleen is enlarged; the thyroid may be enlarged. When anemia becomes marked there are the ordinary symptoms which go with it, viz., palpitation, breathlessness, indigestion, vertigo, headache, pallor, and sometimes epistaxis. Without obvious reason, the glands may suddenly increase in size or rapidly undergo a notable but temporary diminution. In fact, a characteristic feature of the disease is fluctuation in the size, consistency and movability of the glands (Yates and Bunting, in "Jour. Am. Med. Assoc.," June 12, 1915). I have never seen secondary pyogenic infection.

Distinct attacks of fever arise at times in many cases, and ague-like paroxysms may occur. During the existence of fever the glands usually increase rapidly in size.

Diagnosis.—In a widespread case the diagnosis is easy; in a localized case it is difficult. True tuberculous glands are most apt to appear first in the submaxillary triangle; lymphadenomatous glands, in the root of the neck or in the occipital triangle. Tuberculous adenitis is most common in children. As a rule, tuberculous glands caseate, but they may remain localized for years if caseation does not occur. The tuberculous glands usually soon become adherent and immovable. Lymphadenoma is most common after twenty, rarely remains localized for more than a few months, rarely softens unless very large, and the glands are separated and movable until a huge mass forms. The fluctuations in the size, consistency and movability of the glands and the blood picture are important diagnostically. Early softening, prolonged limitation to one region, and absence of pronounced anemia in a person under twenty point to tubercle. In doubtful cases a gland should be removed for microscopical and bacteriological study.

In widespread tuberculous lymphatic involvement, simulating Hodgkin's disease, fever is far more likely to be present than in Hodgkin's disease. LaRoy ("Archives Internat. de Chir.," 1907, vol. iii) says that tuberculous glands are but little improved by the *x*-rays (a statement I do not altogether endorse),

whereas, enlargements in Hodgkin's disease may be greatly benefitted, and that in tuberculous conditions there is no particular tendency to hemorrhage and there often is in Hodgkin's disease. Coley ("Trans. Am. Surg. Assoc.," 1908) shows that the patients with Hodgkin's disease react strongly to the toxins of erysipelas.

Prognosis.—The disease is almost always, if not invariably, fatal. Most cases die within three years, some die within two months, some few live four or five years or more. Acute cases die as a rule in from two to four months. In 1901 Fischer could not find a single authenticated cure on record. Yates and Bunting ("Jour. Am. Med. Assoc.," June 12, 1915) have seen two recoveries, regarding as a cure five years freedom from evidence of the disease.

Treatment.—If the glands are localized to one side of the neck, or even to both sides of the neck, remove the tonsils, put the teeth in order, and treat any disease of the nasopharynx. In any other region seek for any possible portal of bacillary entry and apply suitable treatment. Glandular enlargements localized to certain regions should be extirpated (see Yates and Bunting, in "Jour. Am. Med. Assoc.," March, 10, 1917). Early removal before dissemination has occurred may possibly save the patient. If early or radical removal is not possible, do not operate, but treat the patient with nutritious food, tonics, course of arsenic, the mixed toxins of erysipelas and the Bacillus prodigiosus, and applications of the *x*-rays. The *x*-rays are thought to kill causal bacteria and do cause fibrous changes. Coley treated 2 cases by the mixed toxins. In both cases the lymphatic, hepatic, and splenic enlargements entirely disappeared ("Surg., Gynec., and Obst.," August, 1911). Efforts are now being made to obtain a curative serum. Beck makes nucleoprotein serum from the glands of cases of Hodgkin's disease. Yates and Bunting employ a vaccine (Ibid.). My experience leads me to agree with Holding and Brown ("Jour. Am. Med. Assoc.," March 3, 1917) who say that the only results to be expected from treatment are "temporary ameliorations," that the *x*-rays and radium should be used after operation and that "a Röntgen examination of the chest is indicated in all cases before an extensive surgical removal is considered. This will save many patients from a needless operation."

XXXV. BANDAGES

A bandage is a fibrous material which is rolled up and is then employed to retain dressings, applications, or appliances in contact with a part, to make pressure, or to correct deformity. It may be composed of flannel, of calico, of unbleached muslin, of plain gauze, of gauze infiltrated with plaster of Paris or soaked in silicate of sodium, or of gauze wet with corrosive sublimate solution. Unbleached muslin, which is the best material for general use, is washed to remove the sizing, is torn into strips, and the edges are stripped of selvage. One end is folded to the extent of 6 inches, this is folded upon itself again and again until a firm center is formed, and over this center the bandage is rolled. In a well-rolled bandage the center cannot be pushed out of the roll. A roller bandage is divided into the initial end, which is within the roll, the body or rolled part, and the terminal end, which is free. In applying a bandage the outer surface of the terminal end is first laid upon the part.

A *cylindrical* part of the body may be covered by a *circular* bandage, each turn exactly covering the previous turns. A *conical* part may be covered by a *spiral* bandage, each turn ascending a little higher than the previous turn. As each turn of a spiral bandage is tight at its upper and loose at its lower edge, the *reverse* was devised to correct this inequality; hence a conical part should be covered by a *spiral reversed* bandage. To make a reverse, hold the roller

in the right hand, start the bandage obliquely upward (do not have more than 6 inches of slack), place the thumb across the fresh turn, fold the bandage down without traction, and do not make traction until the turn has been carried well around the limb. A projecting point is covered with *figure-of-*8 turns. The groin, shoulder, breast, or axilla can be covered by figure-of-8 turns, each succeeding turn ascending and covering two-thirds of the previous turn and forming a figure like "the leaves of an ear of corn." Such a figure is called a "spica." In bandaging an extremity the peripheral turns should be tighter than the turns nearer the body. Never apply a tight bandage to the leg or the arm without including the foot or the hand respectively. In firm dressings of the forearm and arm it is well to leave the ends of the fingers exposed, and use them as an index of the condition of the circulation in the part. In firm dressings of the leg and thigh leave the toes exposed.

Spiral Reversed Bandage of the Upper Extremity.—To apply this form of bandage use a roller 2½ inches wide and 8 yards long. Take a circular turn about the wrist, and a second turn to hold the first; pass obliquely across the back of the hand to the extremities of the fingers; ascend the hand to the root of the thumb by several spiral turns; cover the wrist by ascending figure-of-8 turns; ascend the forearm by spiral reversed turns; cover the elbow by a figure-of-8, and the arm by spiral reversed turns; end the bandage by two circular turns, and pin them together (Fig. 898).

Fig. 898.—Spiral reversed bandage of the upper extremity.

Spiral Bandage of All the Fingers (*Gauntlet*).—The gauntlet bandage requires a roller 1 inch wide and 3 yards long. Take two circular turns around the wrist, pass obliquely across the wrist to the root of the thumb, and descend to its tip by spiral turns; cover in the thumb by ascending spiral turns, and return to the wrist. Cover successively each finger in the same manner, and terminate by two circular turns around the wrist (Fig. 899).

Fig. 899.—Gauntlet bandage.

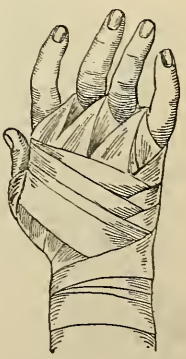

Fig. 900.—Demigauntlet bandage.

Spiral Bandage of the Palm or Dorsum of the Hand (*Demigauntlet*).—The demigauntlet requires a roller 1 inch wide and 3 yards long. This bandage has only a limited value; it must not be applied tightly, as it makes much pressure at the finger-roots, but leaves the fingers free. If it is desired to cover the palm, supinate the hand; if to cover the dorsum, pronate the hand. Take two circular turns around the wrist, sweep around the root of the thumb, and return to the point of origin. Treat each finger in the same way. End by circular turns around the wrist (Fig. 900).

Spica of the Thumb.—For this bandage use a roller 1 inch wide and 3 yards long. Start at the wrist, and reach the tip of the thumb as in applying a spiral bandage of a finger. Make a series of ascending figure-of-8 turns between thumb and wrist, each ascending turn overlying two-thirds of the previous turn; terminate with a circular of the wrist (Fig. 901).

Selva's Thumb Bandage (Fig. 902).—Lay the terminal end of the bandage on the outer side of the second phalanx of the thumb, near the base of the phalanx. Carry it over the palmar side of the pulp of the last phalanx to the inner side of the second phalanx. The surgeon holds this turn in place with his left

Fig. 901.—Spica of the thumb.

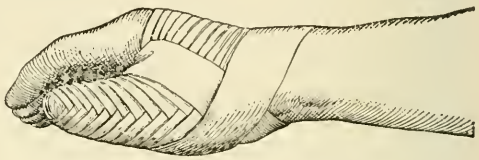

Fig. 902.—Selva's thumb bandage applied.

thumb and index-finger. The roller is returned in a recurrent manner to its place of origin, overlaps the preceding turn, and is placed as much as possible on the dorsum. The roller is carried over the dorsum of the terminal phalanx and is turned around the tip, the loop crossing over the center of the nail. Figure-of-8 turns are now made over the dorsum of the hand, over the palm, and returning to the terminal phalanx, and an ascending spica is made.[1]

Spiral Reversed Bandage of the Lower Extremity.—Take a roller 2½ inches wide and 7 yards long, and make two circular turns just above the malleoli, and an oblique turn across the dorsum of the foot to the metatarso-phalangeal articulation; make a circular turn, and cover the foot with ascending spiral reversed turns; return to the ankle by a figure-of-8; ascend the leg by spiral reverses; cover the knee by a figure-of-8, and the thigh by spiral reverses; terminate by two circular turns (Fig. 903).

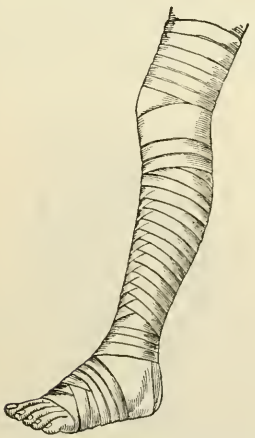

Fig. 903.—Spiral reversed bandage of the lower extremity.

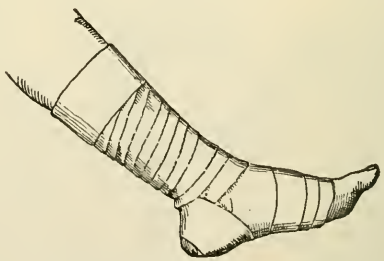

Fig. 904.—Method of covering the heel.

Bandage of the Foot Covering the Heel (*American Bandage of the Foot*).—Take a roller 2½ inches wide and 7 yards long. The bandage is begun as a spiral reversed bandage of the lower extremity. After the foot is well covered by ascending spiral reversed turns, carry the bandage directly around the point of the heel and return to the instep; from this point carry it around the back of the ankle, down the side of the heel, under the heel, up to the instep, around the ankle in the opposite direction, down the opposite side of the heel, and under the

[1] "Medical News," Sept. 28, 1895.

heel and up to the instep; take the roller to above the malleoli, and end by a circular turn (Fig. 904).

Bandage of the Foot Not Covering the Heel (*French Method*).—Take a roller 2½ inches wide and 6 yards long. Make a spiral reversed bandage of the foot and a figure-of-8 of the ankle-joint (Fig. 905).

Spiral Bandage of the Foot Covering the Heel (*Ribbail's Bandage; Spica of the Instep*).—Take a roller 2½ inches wide and 6 yards long. Apply as a spiral reversed bandage of the lower extremity until the metatarsus is well

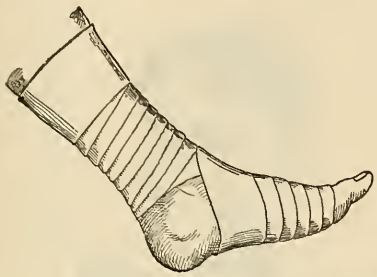

FIG. 905.—Figure-of-8 bandage of the ankle.

FIG. 906.—Spica of the instep.

covered. Carry the bandage, parallel with the margin of the foot (the inner or outer margin, according as to whether it is the left foot or the right), around the posterior aspect of the heel, along the opposite margin of the foot to cross the original turn at the median line of the dorsum. Make a number of these ascending turns, each turn covering in three-fourths of the previous turn; terminate by circular turns above the ankle (Fig. 906).

Crossed Bandage of Both Eyes (*Figure-of-8 of Both Eyes*).—Take a roller 2 inches wide and 6 yards long. Make a circular turn around the forehead from right to left, a second turn to hold the first, a turn downward over

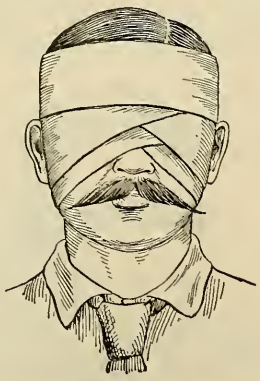

FIG. 907.—Crossed figure-of-8 bandage of both eyes.

FIG. 908.—Barton's bandage or figure-of-8 of the jaw.

the left eye, under the left ear, round the back of the neck, and upward under the right ear and over the right eye; repeat these turns, and terminate by a circular turn of the forehead (Fig. 907).

Borsch's eye-bandage is convenient and useful (Fig. 909). A narrow bandage is laid upon the head, in its anteroposterior diameter, in such a manner that its anterior end will hang over the face and in front of the sound eye. A circular bandage is applied around both eyes, and over the narrow bandage (A). The end of the narrow strip is lifted and pinned, and the sound eye is thus uncovered. Of course, the posterior end of A should first be pinned to the circular turn.

Barton's Bandage (*Figure-of-8 of the Jaw and Occiput*).—Take a roller 2 inches wide and 5 yards long. Place the initial extremity of the bandage behind the inion; pass over the right parietal bone, across the vertex, down the left side in front of the ear, under the chin, up the right side in front of the ear, across the vertex, and across the left parietal bone to the point of origin. A turn is now taken forward along the right side of the jaw to the chin, and backward along the left side of the jaw from the chin to the nape of the neck; repeat these turns, and pin the points of junction (Fig. 908). In Barton's bandage the

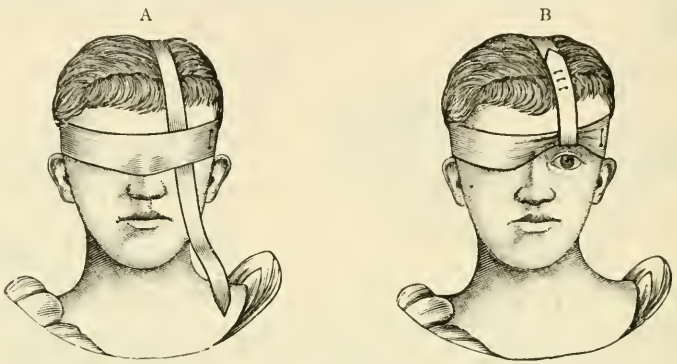

Fig. 909.—Borsch's eye-bandage: A, First step; B, second step.

ear lies in an uncovered triangle. The bandage may be finished by circular turns around the forehead. Barton's bandage is used for fracture of the lower jaw.

Gibson's Bandage.—Take a roller 2 inches wide and 6 yards long. Make three vertical turns around the head and the jaw in front of the ear; reverse the bandage above the level of the ear, and carry it horizontally around the forehead and head three times; drop the bandage to the nape of the neck, and take three turns around the neck and jaw; terminate by taking from the

Fig. 910.—Gibson's bandage.

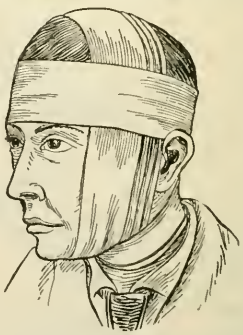

Fig. 911.—Oblique or crossed bandage of the angle of the jaw.

nape of the neck a half-turn upward, carrying the bandage forward to the forehead, and pinning it over the neck and over the forehead. Pin each point of junction (Fig. 910). Gibson's bandage is used for fracture of the lower jaw.

Crossed Bandage of the Angle of the Jaw (*Oblique Bandage of the Jaw*).—Take a roller 2 inches wide and 6 yards long. Make a circular turn around the forehead toward the affected side; and a second turn to hold the first; take the turn to the back of the neck; carry it forward on the sound side, under the ear and chin; now make a series of turns around the head and jaw,

in front of the ear on the injured side, but back of the ear on the sound side: these turns successively *advance* on the injured side only; terminate by going backward under the ear of the sound side to the nape of the neck, and then by taking two circular turns around the forehead (Fig. 911). This bandage is used for fractures of the ramus of the jaw and for holding dressings upon the face and the cranium.

Spica of the Groin (*Figure-of-8 of the Thigh and Pelvis*).—For one groin the roller is 3 inches wide and 7 yards long; for both groins, 3 inches wide and 10 yards long. Take two circular turns, from right to left, around the

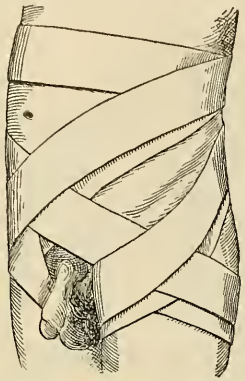

Fig. 912.—Spica of the groin.

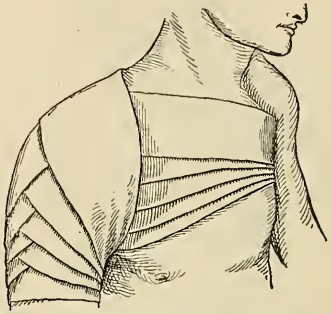

Fig. 913.—Spica of the shoulder.

waist, then down over the front of the right groin, around the back of the thigh, up over the front of the right groin, around the waist, down over the front of the left groin, round the back of the thigh, up over the left groin, and around the waist. The map being thus laid out, the turns are continued upward, each turn overlying one-third of the previous turn, and the bandage is completed by a circular turn around the waist (Fig. 912). Pin the crossed pieces.

Spica of the Shoulder.—Take a roller 2½ inches wide and 7 yards long. Make a circular turn and several spiral reversed turns around the upper arm; then, coming from behind forward, carry the bandage over the shoulder, across the front of the

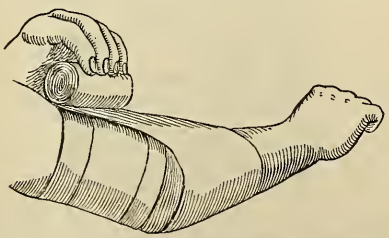

Fig. 914.—Figure-of-8 bandage of the elbow.

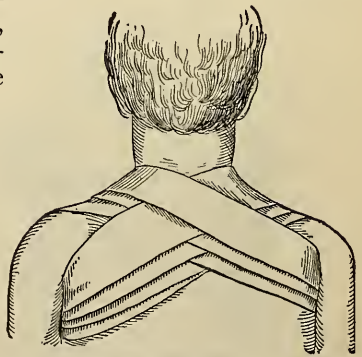

Fig. 915.—Posterior figure-of-8 of both shoulders.

chest, through the opposite arm-pit, and return across the back to the shoulder. Make successive and advancing turns (Fig. 913).

Figure-of-8 bandages of the elbow, both shoulders (posterior figure-of-8), the neck and axilla are shown in Figs. 914, 915, and 916.

A figure-of-8 bandage of the breast is shown in Fig. 921.

Velpeau's Bandage.—Take a roller 2½ inches wide and 10 yards long. Place the palm of the hand of the injured side upon the shoulder of the sound side, interposing cotton between the arm and the side. Start the bandage at

the axilla of the sound side posteriorly, carry it across the back to the shoulder of the injured side, down the front of the arm and under the arm just above the elbow, returning to the point of origin; repeat this turn, but, on reaching the axilla the second time, cross the back and pass around the chest, including the arm; keep on with these turns, each alternate turn going over the injured clavicle, each alternate turn encircling the arm and the body, the first turns advancing and the second turns ascending (Fig. 917). Pin the crossed pieces. This bandage is used for fracture of the clavicle.

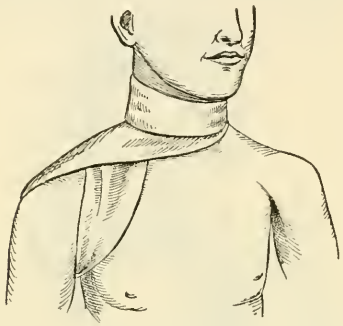

Fig. 916.—Figure-of-8 of neck and axilla.

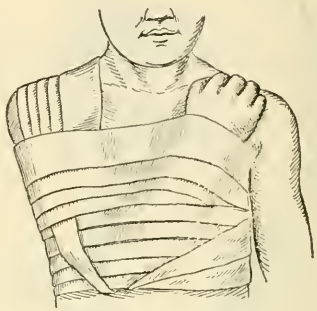

Fig. 917.—Velpeau's bandage.

Desault's Apparatus.—This apparatus consists of three rollers, a pad, and a sling. Each roller is 2½ inches wide and 7 yards long. The pad, which is wedge shaped, is inserted into the axilla with the base up. The *first roller* is used to hold the pad (Fig. 918). The *second roller* binds the arm to the side over the pad. This pad is a fulcrum, the shoulder is the weight, the arm is the lever, and the second roller of Desault corrects the inward deformity of a fractured clavicle (Fig. 919). The *third roller* corrects the downward and forward displacement. It starts in the axilla of the sound side anteriorly, crosses

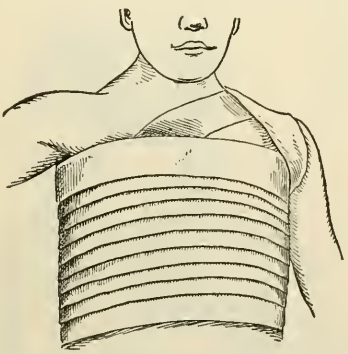

Fig. 918.—Desault's bandage, first roller.

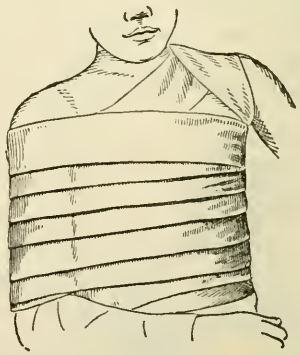

Fig. 919.—Desault's bandage, second roller.

the chest to the shoulder of the injured side, runs down the back of the arm, around the elbow, and crosses the chest to the point of origin, forming the anterior triangle; it is now carried through the axilla of the sound side to the back, crosses the back to the shoulder of the injured side, runs down the front of the arm, around the elbow, and across the back to the axilla of the sound side, forming the posterior triangle (Fig. 920). The formula for the Desault bandage is: start in the axilla of the sound side anteriorly, run from the axilla to the shoulder, from the shoulder to the elbow, from the elbow to the axilla, and pass to the back; from the axilla to the shoulder, from the shoulder to the

elbow, from the elbow to the axilla, and pass to the front. Pin the crossed pieces and hang the hand in a sling (Fig. 920).

Recurrent Bandage of the Head.—Take a roller 2 inches wide and 6 yards long. Make two circular turns horizontally around the forehead and head; when the middle of the forehead is reached, catch the bandage, take a half-turn, carry the bandage to the occiput, let an assistant catch it, take a half-turn, bring the roller forward to the forehead, covering a portion of the preceding turn; continue this process until the scalp is well covered; terminate with two

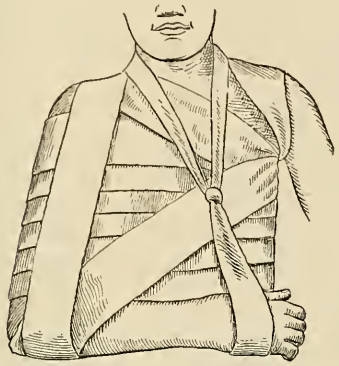

FIG. 920.—Desault's bandage, third roller.

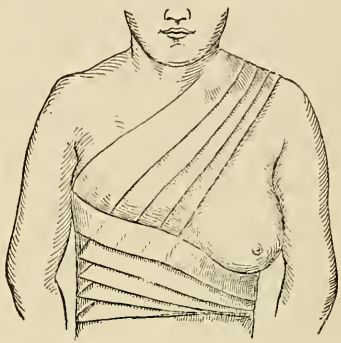

FIG. 921.—Figure-of-8 bandage of the breast.

circular turns around the forehead and head (Fig. 922). It is often advisable to take a turn around the head and chin. Pin the crossed pieces.

Recurrent Bandage of a Stump.—Take a roller 2 inches wide and 6 yards long. Make two light circular turns around the root of the stump; make recurrent turns covering the stump as is done in covering the head; take a circular turn around the root of the stump, oblique turns to the top of the

FIG. 922.—Recurrent bandage of the head.

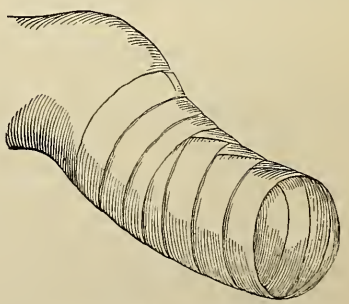

FIG. 923.—Recurrent bandage of a stump.

stump, circular turns around the top, and apply an ascending spiral reversed bandage (Fig. 923).

T-Bandage of the Perineum.—Pass the transverse part around the body above the iliac crests, and pin it in front; bring one of the tails over the dressing and up between the genitals and the thigh of one side, and the other tail over the dressing and up between the genitals and the thigh of the opposite side; secure these tails to the horizontal band.

Handkerchief Bandages.—Take unbleached muslin 1 yard square. The muslin folded once makes an *oblong* bandage; bringing its diagonal angles

together makes a *triangle* bandage; a *cravat* is formed by folding a triangle bandage from summit to base; a *cord* is a twisted cravat. The triangle makes an admirable sling.

Fixed Dressings.—**Plaster-of-Paris Bandage.**—Cover the extremity with a cotton or flannel bandage or with a woolen stocking. Take a gauze roller infiltrated with plaster and place endwise in a basin of tepid water, the water covering the plaster. When bubbles cease to arise, squeeze the bandage and apply it *without much tension*, smoothing out each turn with a moistened hand. As each bandage is taken from the basin drop a fresh one into the water. Apply four thicknesses of bandage, and finish the dressing by sprinkling dry plaster over the bandage and smoothing it with wet hands. The ordinary plaster will set in from fifteen to thirty minutes. If it be desired to have it set more rapidly, put a tablespoonful of salt in each pint of water used; if, to have it set more slowly, pour stale beer into the water or add a solution of gelatin. The plaster bandage is removed by sawing it down the front or by moistening with dilute hydrochloric acid and then cutting through the moistened line with a strong knife. Gigli has devised a mode of application which enables us to remove the dressing with ease. A layer of cotton is placed around the limb. A piece of parchment paper which has been wet and shaken out is placed over the cotton. A cord greased with vaselin is laid upon the paper in a position corresponding to the line through which we shall saw when it is time to remove the plaster. Apply the plaster bandage and see that the ends of the cord project beyond the bandage. When desiring to remove the bandage take a steel wire, make nicks on one side of it by means of a file, and attach the string to the wire. Pull the wire under the bandage. Attach each end of the wire to a wooden handle and saw through the plaster.[1]

Silicate of Sodium Dressing.—Protect the part as is done for a plaster bandage. Bandage the limb *loosely* with an ordinary gauze bandage, paint this bandage with silicate of sodium, apply another bandage and paint it, and so on until six layers are applied. Gauze bandages are better than ordinary bandages to take up silicate of sodium. Silicate dressings require from twelve to eighteen hours to dry, and they are removed by softening with warm water and then cutting.

XXXVI. PLASTIC SURGERY

Plastic surgery includes operations for the repair of deficiencies, for the replacement of lost parts, for the restoration of function in parts tied down by scars, and for the correction of disfiguring projections. Many reparative operations have been devised. Among them are: cheiloplasty, or the construction of a new lip; the closure of a cleft in the palate, the lip, or the penis; the making of a new nose; skin-grafting; fascia transplantation; fat transplantation; bone-grafting; tendon-grafting; grafting of muscle or tendon; nerve-grafting; the introduction of celluloid or metal into the tissues to act as a support; the injection of paraffin into the tissues to amend a depression; the diminution in the size of a lip or a nose; the amendment of protuberant ears; the correction of distortion due to cicatrices; excision of scars; closure of congenital sinuses and of fistulæ; and removal of disfiguring growths.

Carrel has proved that autoplastic transplantation of organs can be accomplished successfully; that homoplastic transplantations succeed temporarily only and that heteroplastic transplantations always fail. The rapid destruction of the heteroplastic transplant as well as the destruction of the homoplastic transplant is due to the invincible tendency of the organism to destroy foreign tissue. Transplantation of organs is useless in human surgery because a homoplastic

[1] "La Semaine Méd.," Nov. 3, 1895.

transplant though an anatomical success does not functionate. (Carrel in "Med. Press and Circular," 1914, xcvii.) Lydston has apparently proved that a transplanted testicle may give out an internal secretion for a sufficient length of time to place an individual in the masculine groove and to remove him from the road to perversion.

The subject of plastic surgery is very extensive, and a treatise upon it should be consulted if one wishes to obtain detailed and comprehensive information.

A plastic operation can only be successful after lupus when the disease has been cured. It is useless to do a plastic operation during active syphilis, and a plastic operation for a syphilitic loss of substance is to be performed only after the patient has been thoroughly treated and the disease has been apparently cured. The first step of a plastic operation consists in making the surfaces which are to be brought together raw; the second step is the complete arrest of bleeding; the third step is the approximation of the surfaces without tension; the fourth step is to close any gap from which tissue may have been transplanted; and the final step is the application of the dressings.[1] The following are the methods used:[2]

Displacement is the method of stretching or of sliding: (1) Approximation after freshening the edges (as in harelip); (2) sliding into position after transferring tension to other localities (linear incisions to allow of stretching of the skin over large wounds). *Interpolation* is the method of borrowing material from an adjacent or a distant region or from another person: (1) *Transferring a flap with a pedicle*, in which the flap is put in place at once or gradually by a series of partial operations (as in rhinoplasty, when a flap is taken from the forehead); (2) *transplanting without a pedicle*, which is performed by placing in position and by fixing portions of tissue recently removed from the part, from another part of the same individual, or from a lower animal (as replacement of the button of bone after trephining, transplanting a piece of bone from a lower animal to remedy a bone defect in a human being, transplantation of fat or fascia, or the grafting of a piece of nerve from a lower animal or from an amputated human limb to remedy a loss of nerve in a human being). (See "Free Tissue Transplantations," by D. B. Phemister in a Collective Review in "Internat. Abstract of Surgery," Jan., 1914.) *Retrenchment* is the removal of redundant material and the production of cicatricial contraction.

Skin-grafting.—As long ago as 1847 Dr. Frank Hamilton partly covered an ulcer with a pediculated flap, and trusted that the uncovered portion would be healed by new skin from the flap. Beck's "Ahdesive plaster method for the rapid regeneration of skin over granulating wounds" will undoubtedly supersede some of the skin transplant operations. Beck applies "strips of plain or zinc oxide adhesive plaster along the edges of the granulating wound" and leaves these strips in place for twenty-four hours when he finds, along the skin margin, a bluish-gray border of epithelial cells. He now dresses the wound with dry gauze for twenty-four hours and then makes another application of adhesive plaster. This routine is followed until the whole granulating surface is covered with an epithelial growth which "serves practically the same purpose as a skin transplant" (Emil G. Beck, "Annals of Surgery," March, 1919). We may graft small pieces of epithelium taken from the patient, another person, or one of the lower animals, or may graft large pieces of epithelium. The grafts should, if possible, come from the person to be grafted. The epidermic scales may be scraped off the sound skin and grafted. Lusk has blistered the skin with cantharides and grafted portions of the epidermis. The shavings of a corn and fragments of hair roots have been used. The best plan is to cut off and transplant small bits of epidermis.

Grafts may come from another person or from a lower animal, but such

[1] "American Text-Book of Surgery." [2] Ibid.

grafts are not so apt to grow as those obtained from the individual, and even when they do grow, fail to furnish a secure cicatrix. The organism always strives to eliminate foreign matter. If a graft must be obtained from another person, the closer blood relation that person is, the better the chance of the graft growing. Before taking a graft from another person be certain that the donor is free from syphilis. Frog-skin furnishes unsatisfactory grafts. Some surgeons have used bits of sponge; others, the skin of rabbits, guinea-pigs, or pups. Arnot has employed the lining membrane of a hen's egg, cut in strips and applied upon the wound with the shell-surface uppermost. Small bits of epidermis taken from a recently amputated foreskin or leg have been used. Grafts of fetal membranes and of ovarian cysts have been used. Autoplastic grafts should be used whenever possible. Homoplastic grafts from stern necessity only. Heteroplastic grafts never.

Fig. 924.—Injury caused by crush and burn. Healed by granulation in eight months. Showing condition after removal of scar of the palm, which has been repaired by stitching in an autoplastic graft (free flap) from the thigh (George S. Brown).

Reverdin's Method.—This operation was devised by Reverdin in 1869. Small bits of epithelium are used, and they are taken, preferably, from the person himself. The surface to be grafted should possess healthy granulations level with the skin. Cleanse the skin from which the grafts are to come, the ulcer, and the skin about it, and, if corrosive sublimate be used, wash it away with a stream of warm normal salt solution. Thrust a sewing-needle under the epidermis to raise it, cut off the graft by a pair of scissors, and place the raw surface of the graft upon the ulcer. After applying a number of grafts, place thin pieces of gutta-percha tissue over them and extending beyond each side of the ulcer. These pieces of gutta-percha should be so arranged as to have distinct intervals between them, the gaps permitting drainage. The rubber tissue must be aseptic and moist with warm normal salt solution. Dress with a pad of aseptic gauze moistened with salt solution; place over this gauze a rubber-dam, and over the latter absorbent cotton and a bandage. In the case of a child apply a light silicate bandage. If the grafted area be very extensive or if it be in the lower extremity, put the patient in bed. In forty-eight hours remove all the dressings except the gutta-percha tissue, irrigate with normal salt solution, and reapply the dressings. All signs of the grafts will often have disappeared. In a day or two more, at the site of grafting, there should appear bluish-white spots, which are islands of epidermis. Each graft is capable of forming about ½ inch of cicatrix. Graft-

ing also stimulates the edges of the ulcer to cicatrize and contract. At the end of seven days the special dressings can be dispensed with. The spot from which the grafts have been taken is dressed antiseptically. Reverdin's method does not limit cicatricial contraction to any great degree, and the new skin is apt to break down.

The Ollier-Thiersch Method.—Ollier of Lyons, in 1872, succeeded in transferring large pieces of epidermis. In 1886 Thiersch, of Leipzig, set forth the technic practically as it is employed to-day. The Ollier-Thiersch method is performed as follows: Thoroughly asepticize the ulcer, the surrounding skin, and the site from which the graft is to come (the inner side of the arm or the thigh), and wash away the mercurial preparation with normal salt solution. Apply dressings wet with salt solution. On bringing the patient into the operating room remove the dressings from the ulcer, scrape the ulcer and its edges, irrigate with salt solution, and compress to arrest hemorrhage. Grafts are then obtained by putting the prepared skin upon the stretch and cutting strips with a razor. While the razor is being used the part is constantly irrigated with salt solution. Mixter's apparatus enables one to perform this operation with great neatness and speed. This apparatus consists of a knife and an open square with sharp points on the under surface. The square is forced down upon the front of the thigh, the epidermis mounts up in the opening to above the level of the metal sides and the grafts may be cut with ease. The graft contains the epidermis, the rete, and part of the true skin. In Halsted's clinic the skin of the thigh is made tense by pressing and drawing upon it with a piece of asepticized wood, the wood is drawn slowly along, and is followed closely by the sharp catlin, by which the surgeon cuts long grafts. The grafts are pressed into place upon the raw surface, and each graft overlaps a little the edges of the wound and the adjacent grafts. The skin wound is dressed antiseptically, and the grafted area may be dressed as in Reverdin's method. If a ring of aseptic gauze be made to encircle the limb below the grafted area, and another ring above the grafted area, and if on these pads little strips of wood wrapped in aseptic gauze be laid, a cage is made, and around this cage the dressings may be applied (moist chamber plan) (Fig. 926).

Fig. 925.—Claw-hand from burn. A flap with a pedicle was taken from the chest. The pedicle was cut on ninth day.

Wolfe's Method.—It was pointed out by Wolfe that a piece of skin, comprising the entire thickness of that structure, can be successfully transplanted without a pedicle. The ulcer is extirpated and asepticized and bleeding is arrested. The flap is cut one-sixth larger than the surface to be covered. Fat is kept out of the graft. This bit of tissue is laid upon the wound, the edges of the graft being brought against the edges of the raw area. It is not

necessary to employ sutures. The part is dressed in a moist chamber. If the graft perishes, remove it.

Subcutaneous Injection of Paraffin for Prosthetic Purposes.—The principle of injecting solidifying oils into tissues to obtain mechanical effects was first laid down by J. Leonard Corning in 1891. The use of paraffin was introduced by Gersuny to amend the deformity of a saddle-nose. It has been used to limit incontinence of feces, incontinence of urine in women, to prevent reunion of nerves after division, as a counterfeit testicle, to obliterate small-pox marks, to narrow a hernial ring, to correct sinking of the cheek after removal of the upper jaw, and for other purposes (Moszkowicz, in "Wien. klin. Woch.," June 20, 1901). Paraffin is not toxic. Its injection may produce some swelling and redness, but applications of cold usually control inflammation. In two or three months the paraffin becomes hard like cartilage and encapsuled. It is questionable whether or not it is subsequently destroyed and replaced by granulation tissue. Sometimes sloughing takes place in the skin above it.

Prepare the paraffin as follows: In Gersuny's clinic solid paraffin is mixed with liquid paraffin. The melting-point of the mixture should be about 104° F. It is rendered sterile by boiling, is injected by a warm syringe, and as a semisolid, the skin having been first warmed by a hot sponge. After injection it is molded into proper shape. It sets in half a minute. It is not wise to use a mixture with a much higher melting-point, because it would possibly cause thrombosis in veins. There are difficulties and even dangers

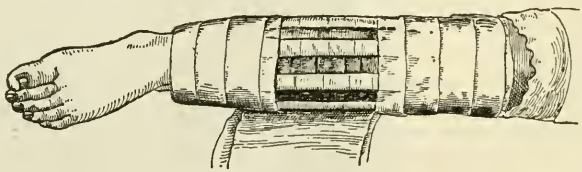

Fig. 926.—Mayer's dressing for Thiersch's method of skin-grafting ("Amer. Text-Book of Surg.").

in the use of paraffin for saddle-nose. It should only be used when the skin is loose and elastic. It should never be used if there be great deformity, because then the amount required would surely cause dangerous tension. It is difficult to prevent the injected material from passing down the sides of the nose and up into the forehead. Cases of embolism causing blindness have been reported. The skin may slough if the injection be too hot or if it produce much tension.

Paraffinoma.—This term, suggested by Delangre, means an inflammatory new formation which may arise in the submucous or subcutaneous tissues about a depot of injected paraffin. It may or may not ulcerate. It is particularly apt to form in a tuberculous person. The swelling is marked and the disfigurement great. The possibility of the formation of a paraffinoma is particularly great if paraffin be used in the subcutaneous tissue.

The only treatment is excision.

Correction of Saddle-nose by the Insertion of a Plate.—Saddle-nose is a condition in which the bones and cartilages have been destroyed by ulceration or collapsed by injury. It is useless to attempt correction by skin-flaps alone. Paraffin injections (see above) may be used in the less severe cases. In a bad case we must transplant bone-flaps or insert a plate for support. The bone-flap operation is seldom satisfactory and, of necessity, creates a hideous scar. The insertion of a plate may give an excellent result, although the future is always uncertain. In 2 cases I have seen sloughing occur over the plate months after the operation. In 1 of these cases the sloughing was due to a blow from a cow's tail.

The plate used may be of silver, gold, or celluloid. An incision is made to permit the insertion of the plate. I agree with Leonard Freeman ("Annals of Surgery," August, 1907) that the incision along the bridge and the incision in the septum below the tip are both objectionable. The first leaves an unsightly scar and does not allow for stretching of the skin. The incision at the tip gives unsatisfactory access to the tissues requiring separation and is liable to infection from the nostril.

The best incision is Freeman's. This is a short incision across the root of the nose between the eyes. The skin is undermined along the bridge to the tip and along the sides. The undermined skin can be stretched if necessary.

Rhinoplasty.—The complete operation may be performed by transferring a flap from the forehead. This is known as the Indian operation. It was employed for centuries in India, and interest in it was awakened in England about 1820 by Mr. Carpue. The edges of the defect are made raw. A model of the desired nose, made out of gutta-percha, has its outlines marked upon the forehead, and the cut is made ¼ inch outside of the outline, so as

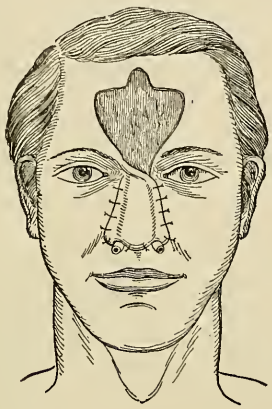

Fig. 927.—Indian method of rhinoplasty.

Fig. 928.—Italian method of rhinoplasty.

to allow room for retraction. The flap is turned down and sutured in place (Fig. 927), care being taken not to cut off the blood-supply from the pedicle. Plugs of gauze or tubes are inserted to support the flap.

The complete operation can be performed by the Italian method (Tagliacotian method). This method was first described in Tagliacozzi's book, which was published in 1597. In this operation the flap is marked out on the arm, is made twice the size of the desired nose, and is left attached by a broad pedicle. The nasal surface is rendered raw at proper regions, and the flap is sutured in place, the hand being held upon the head by a special apparatus (Fig. 928). The raw surface upon the arm is dressed. In about three weeks the flap is cut loose from the arm, and is pared and corrected as may be necessary.

The operations for harelip and cleft palate, and plastic operations on muscles, nerves, tendons, and bones are considered in other portions of this work.

XXXVII. DISEASES AND INJURIES OF THE GENITO-URINARY ORGANS

Hematuria.—By this term is meant the voiding of bloody urine or of pure blood, the blood arising from any portion of the urinary apparatus, and the condition being a symptom and not a disease. In hematuria the urine contains more than blood coloring-matter; it also contains blood-corpuscles. The condition in which there is coloring-matter only is called *hemoglobinuria*. Hemoglobinuria may arise after burns, etherization, and after taking urotropin, and during various fevers, especially in malaria (see page 1411). Hematuria may be a symptom of disease or of injury of some part of the urinary system (calculus, acute nephritis, pyelitis, renal tuberculosis, prostatic enlargement, morbid growth, wounds or contusions of the genito-urinary tract), of blood disorganizations (purpura, scurvy, variola, leukemia, or anemia), or of metallic poisoning (mercury, lead, or arsenic). It may arise during typhoid fever, in the beginning of an acute fever, (especially variola), in hemophilia, in nephralgia, in malarial fever, and in kidney infarction resulting from endocarditis. It may be caused by parasites (Filaria sanguinis hominis and Bilharzia hæmatobia). Some drugs are renal irritants and may cause hematuria (cantharides, oil of turpentine). Oxaluria is an occasional cause. The most usual cause of renal hematuria is stone. The color of the urine in hematuria may be anything between a light pink and a decided black, but these colors may be produced by agents other than blood. (See Sollmann's "Text-Book of Pharmacology.") Carbolic and salicylic acids make urine brown or greenish black; beet-root and sorrel, the color of blood; methylene-blue, green or blue. In melanosis and splenic fever the urine becomes brown. Senna and rhubarb make an acid urine yellowish brown and an alkaline urine purple. In jaundice the urine is yellow or green. Coal-tar products may make it blackish brown. Picric acid makes it yellow. Santonin makes an acid urine yellow and an alkaline urine pink. Logwood imparts no color to acid urine, but colors alkaline urine violet or reddish. Trional, sulfonal, tar, tannic acid, and gallic acid make urine brown. Renal hematuria may be bilateral or unilateral. The cystoscope and ureteral catheterization will demonstrate the existence of either. The commonest cause of unilateral hemorrhage is stone but it can be caused by pyelitis, infarction, a neoplasm, injury, parasites, nephritis, or tuberculosis. Unilateral pain associated with unilateral hematuria is very significant of an unilateral lesion.

Tests for Blood.—**Spectroscopic Test.**—Bloody urine, if fresh and diluted with water, shows the two absorption bands of oxyhemoglobin. The addition of ammonium sulphid causes the two bands to give place to the band of reduced hemoglobin. If bloody urine stands for some time the four bands of methemoglobin are discovered (von Jaksch).

Heller's Test.—Add potassium hydrate to the urine and boil; a red precipitate of earthy phosphates and hematin forms. Throw the precipitate upon a filter and treat it with acetic acid; a red solution is produced, which soon fades.

Rosenthal's Test.—Take the precipitate from caustic potash, dry it, and test it for hematin; put some of the dry sediment on a slide, add a crystal of common salt, apply a cover-glass, and cause a few drops of glacial acetic acid to flow under the glass; warm, but do not boil. Teichmann's crystals will appear on cooling.

Struve's Test.—Test the urine with hydrate of potassium and add acetic acid in excess; a dark precipitate forms, which will yield crystals of hematin when treated with sal ammoniac and glacial acetic acid.

Almen's Test (Guaiac Test).—Take 10 c.c. of urine and pour upon its surface a mixture of equal parts of tincture of guaiac and old oil of turpentine; at the

point of junction of this fluid with the urine there forms a white ring which turns to a striking blue. If a man is taking iodid of potash his urine shows blue in the guaiac test.

The Benzidin Test.—This is very delicate. If this reaction cannot be obtained the urine is certainly free of blood. Add 1 c.c. of glacial acetic acid to 10 c.c. of urine. Add to the mixture one-third of its volume of ether containing a few drops of alcohol, shake, and allow to stand. The ether rises to the top, is taken off by a pipet, and is put in a test-tube in which is the benzidin mixture (0.5 c.c. of a solution of benzidin in 2 c.c. of glacial acetic acid and 2 c.c. of hydrogen dioxid). Blood turns the reagent green or blue within two minutes. Later the color changes to purple. (See Holland's "Medical Chemistry and Toxicology.")

Microscopical Test.—The microscope shows numerous corpuscles except in a very alkaline urine, when but few corpuscles may be found.

In hemoglobinuria—a condition sometimes occurring after burns, as a result of large doses of urotropin, and during malaria, acute febrile maladies, metallic poisoning, acute alcoholism, poisoning by mushrooms, chlorate of potash, coal-tar products, pyrogallic acid, and naphthol—there is present blood coloring-matter, which is shown by Heller's test and by Almen's test. The spectroscope shows methemoglobin. The microscope shows no corpuscles or only a few, but discloses masses of pigment. Hemoglobinuria does not occur in diseases limited to the genito-urinary tract.

Determination of the Source of the Blood.—In a woman, be sure that the bloody urine is not due to a mixture with menstrual blood. If menstruation does exist, obtain the urine for examination by a catheter. The three-glass test may be of service. Blood may be thoroughly mixed with urine. Renal blood is sure to be mixed. Bladder blood may or may not be. Blood from the urethra comes out with the first urine. The source of blood may be determined certainly only by the urethroscope, cystoscope, or ureteral catheter.

Bleeding from the Kidney-substance.—Bleeding from the *pelvis* of the kidney and from the *ureter* may be due to inflammation, congestion, contusion, stone, vicarious menstruation, hemorrhagic diathesis, powerful diuretics, fevers, purpura, tumors, catheterization of the ureter, etc. Blood is thoroughly mixed with the urine and no sediment forms (smoky urine). The corpuscles are profoundly altered, are devoid of coloring-matter, and show pale-yellow rings. The severity of the hemorrhage is measured by the number of the corpuscles. Von Jaksch states that the diagnosis between renal and ureteral hemorrhage rests on the nature of the casts and epithelium present. From the pelvis of the kidney and from the ureter comes small epithelium, the cells from the superficial layers being polygonal or elliptical, those from the deeper layers being oval or irregular. In hemorrhage from the ureter the cells are few; in hemorrhage from the pelvis they are plentiful and rest upon one another like "tiles on a roof" (von Jaksch). Cells from the tubules of the kidney are small, granular, and polyhedral, have large nuclei, and are often so arranged as to form cylinders (epithelial casts). The urine during and immediately after a renal hemorrhage is apt to be acid unless alkalis have been administered, unless the bleeding has been severe, or unless pus is present in the urine. A very large renal hemorrhage may cause the passage of almost pure blood. In *renal* hematuria there are aching in the loin, numbness of the corresponding leg, and often renal colic. The use of the cystoscope enables the surgeon to determine if the hemorrhage is vesical or renal, and if it comes from one or both kidneys. If the bladder fluid is kept clear, the blood can be seen flowing out of the ureter of the damaged organ, or if both ureters are catheterized a sample of urine can be obtained from each kidney. Even when skilfully used the ureteral catheter is apt to cause slight hemorrhage. Hence, after catheterization, microscopical hemorrhage does not count in diagnosis.

Spontaneous Hemorrhage into the Kidney.—This may or may not cause hematuria. It may arise during nephritis or may depend on arterial disease. No lesion may be discoverable. If accompanied by hematuria it is classed as essential hematuria (see below). The bleeding may take place beneath the capsule or through a tear in the capsule into the perirenal tissue. In some cases bleeding begins in the perirenal tissue. A possible cause is aneurysm of the renal artery. There are 26 cases of this condition on record ("Lancet," Jan. 27, 1912). Spontaneous hemorrhage comes on suddenly with shock and pain in the loin. There may or may not be hematuria. A mass can be palpated. In some cases the skin becomes discolored. Always operate. If hemorrhage comes from perirenal tissue, excise the bleeding tissue. If blood comes from the kidney it is usually necessary to perform nephrectomy. In spontaneous hemorrhage blood may tear its way into the peritoneal cavity. (See Article by Russell S. Fowler, in "Annals of Surgery," Dec., 1911.)

Essential Hematuria.—In this condition the ureteral catheter reveals blood from one kidney only, there being no demonstrable lesion to account for the condition. Randall, in a very comprehensive article, draws the following conclusions regarding this condition ("Jour. Am. Med. Assoc.," Jan. 4, 1913.)

He divides essential hematurias into three groups: (1) Nephritis with congestion playing the leading rôle. (2) Varicosities of vessels of renal pelvis resulting from some extrinsic condition affecting the kidney circulation. (3) Hemorrhage due to rupture of capillaries or to diapedesis of red blood-corpuscles. In each of these conditions congestion probably exists.

I believe that some cases are due to unrecognized papilloma. Essential hematuria is sometimes called *unilateral hematuria*, an unfortunate name, as many cases of hematuria which do not belong to this group are unilateral.

Ureteral Catheterism.—Catheterization of the ureters may give information of the greatest value. It enables the surgeon to obtain the urine from one kidney unmixed with urine from the other kidney and uncontaminated by material from the bladder or urethra. By this method we can determine if pus, blood, bacilli, etc., come from the ureter or kidney, and from which ureter or kidney. A stricture of or a calculus in a ureter can be located; hydronephrosis and pyonephrosis can be diagnosticated; the presence of both kidneys, if either kidney is diseased or if both are diseased, and the secretory capacity of each kidney in a given time, can be ascertained. The method is also employed to treat various conditions of the ureter and kidney.

Kelly impressed upon the profession that the ureters in women could be catheterized when the patient by the knee-chest posture permitted the atmospherical distention of the bladder, so that the ureteral orifices could be inspected through a speculum. Light is reflected into the speculum, a forehead mirror and an electric light being employed. It may be necessary to dilate the urethra before inserting the speculum. It is rarely necessary to give a general anesthetic. Kelly moistens a bit of cotton wrapped on a metal rod in a 10 per cent. solution of cocain, introduces it just within the external urethral orifice, and holds it there for five minutes before beginning the operation. When the ureteral orifice of one side is found by inspection through the speculum, he introduces a sterile flexible silk catheter lubricated with boroglycerid and it is pushed up from 4 to 6 inches in the ureter. A similar tube is introduced into the other ureter and the separated urines are collected in test-tubes. (See Kelly's "Operative Gynecology.") The catheterization of the ureters by this method can be performed by a dextrous and experienced man only; but such an individual can do it with ease and celerity; as practised by Kelly himself it seems, until one tries it, the perfection of ease and simplicity.

Kelly has catheterized the ureter in man by inserting a straight speculum, placing the patient in the knee-chest position to inflate the bladder with air,

and introducing a metallic catheter. (For a discussion of the technic of catheterizing the ureters see Cystoscopy, page 1447.)

Segregation of urine is the method of obtaining urine separately from each ureter by segregating each ureter's supply into an artificial trough, from which it is drawn. The method is seldom used in the United States at the present time. It is painful, unreliable, and has been replaced by ureteral catheterization. In cases in which the ureters cannot be found, segregation may be employed. The three most practical segregators are Harris's, Luys's, and Cathelin's. Professor Harris, of Chicago, has devised an instrument (Fig. 929) which in some cases simplifies the problem of obtaining unmixed urine from each ureter. The double catheter is passed into the bladder. The lever is inserted in the rectum of the male and the vagina of the female. The lever is fastened to the perforated frame from the double catheter. The double catheter is now opened in the bladder, and the blades of the instrument are held in position by a spring. The end of the lever in the vagina or rectum humps up the floor of the bladder between the separated ends of the divided catheter, and forms a longitudinal septum or watershed between the ureteral orifices. The end of each catheter lies in the bottom of a pocket to the side

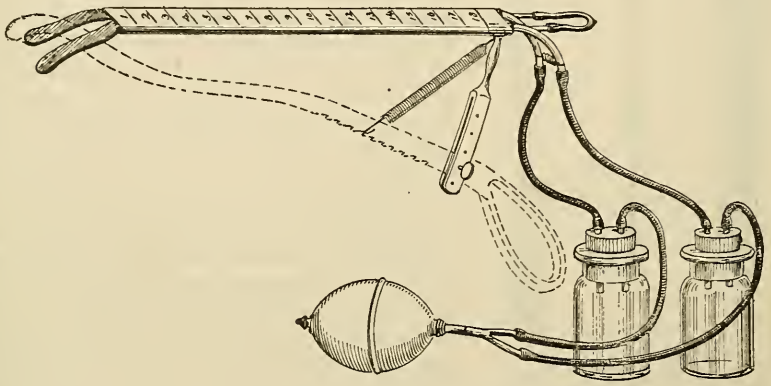

Fig. 929.—Harris's segregator fitted for use.

of the watershed. "By producing a very slight exhaustion of the air in the vials by means of the bulb the urine, as fast as it escapes from the ureters, drops directly into the ends of the catheters and flows at once into the vials, right and left respectively."[1]

In using this instrument place the patient flat on his back upon a table, the thighs and legs being flexed, and the feet, hips, and head being on the same level. Irrigate the bladder thoroughly with sterile water and have 150 c.c. of fluid in the bladder when the blades are opened. Leave the instrument in place for thirty minutes. It is rarely necessary to give an anesthetic. In some cases cocain must be used, and in some cases of painful cystitis ether should be given. Harris says the instrument should not be used if there be a growth of the bladder that bleeds easily, if the bladder be contracted, if there be a very large prostate or a vesical stone.[2]

In catheterization of the ureters there is always some danger of carrying infection upward from the bladder, and sometimes catheterization is impossible. It is impossible if great quantities of blood or pus make the urine opaque, or if inflammation of the bladder wall hides one or both ureteral orifices. The Harris method of segregation produces considerable pain, but is free from this

[1] "Jour. Cutan. and Gen.-Urin. Dis.," May, 1899.
[2] M. I. Harris, in "Medicine," April, 1898.

danger. As a matter of fact, however, Harris's method often possesses elements of uncertainty, because the septum may not be perfect and the urine from one side sometimes contaminates the urine from the other. The separator devised by Luys in 1901 finds some warm advocates (Fig. 930). It causes less pain and accomplishes more certain results than the instruments of Harris or Cathelin. Barringer ("Am. Jour. Med. Sciences," March, 1907) points out that "there are certain classes of cases in which the separator cannot be used. They are the following: (A) Those in which the bladder capacity is less than 20 c.c.; (B) those in which the urethra is not penetrable by the instrument; and (C) those in which the base or neck of the bladder is distorted by (*a*) marked prostatic hypertrophy; (*b*) extreme anteversion or anteflexion of the uterus; (*c*) certain uterine tumors; and (*d*) marked cystocele." Catheterization of the ureters is not so safe as separation, is far more difficult, but gives more certain results.

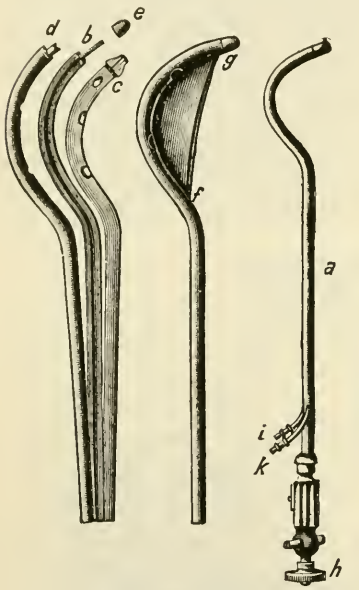

FIG. 930.—Luys's separator: *a*, The composite instrument ready for introduction; *i* and *k*, discharge tubes; *h*, screw to regulate the tension of the membrane; *b*, flat middle piece; *c* and *d*, grooved lateral portions; *e*, tip uniting the parts; *g–f*, rubber membrane, tense. The chain is not visible in the figure (Sahli).

Urethral Hemorrhage.—In urethral bleeding, blood appears independently of micturition, or blood comes out first and is followed by clear urine. Urethral hemorrhage may arise from acute urethritis, from an inflamed stricture, from the passage of an instrument, or from some other traumatism. It may be due to a polypus, to a stone in the prostatic urethra, to violent or prolonged sexual effort.

The source of urethral hemorrhage can be ascertained by the use of the endoscope or, better, by means of the cysto-urethroscope.

Vesical hemorrhage, including hemorrhage from the prostate, may follow the relief of retention of urine (hence do not draw off all the urine at once when a bladder is distended), may be due to stone, inflammation, tumors, etc., or may arise from traumatisms, instrumental or otherwise. The color of the urine is usually bright red, but if long retained in the bladder it becomes black and often tarry. The reaction is alkaline. The clots, when floated out, are large and without definite shape. In micturition the urine is clear or only a little colored at the beginning, but becomes darker and darker as micturition continues, and as it ends the flow may consist of almost pure blood. In very small vesical hemorrhages the urine may be smoky. Crystals of triple phosphate indicate bladder disorder. The microscope shows colorless and swollen corpuscles and many polygonal cells. Symptoms of bladder mischief usually exist, but cystoscopic examination or exploratory suprapubic cystotomy may be required for the diagnosis.

Pain in Genito-urinary Diseases.—Pain as a symptom of genito-urinary disease may be found at some point distant from the seat of lesion. A stone in the bladder causes pain in the head of the penis just back of the meatus; stone in the kidney induces pain in the loin, the groin, the thigh, and the testicle; inflammation of the testicle causes pain in the line of the cord in the groin. In other cases of genito-urinary disease pain is felt at the seat of lesion, as in urethritis and prostatitis. Pain felt before micturition, and being relieved by the act, is found in cystitis and in retention of urine. Pain is felt during mic-

turition in inflammation of the bladder, prostate and urethra, and in the passage of gravel or stone. Pain which is acute at the end of micturition is noted in stone in the bladder, in trigonitis or urethrocystitis (inflammation of the neck of the bladder), and in inflammation of the prostate gland. The pain caused by stone in the bladder, it may be observed, is ameliorated by rest and is aggravated by exercise unless the stone be encysted. The pain caused by acute prostatitis is intensified by defecation and the act is accompanied by the appearance at the meatus of a few drops of starch-like mucus.

Frequency of Micturition.—Frequent micturition arises from irritation of the sensory nerves, from phimosis, contracted meatus, inflammations, very acid urine, calculi, urethral stricture, and hyperesthesia of the urethra. Frequency of micturition may be due to spinal irritability from concussion or from sexual excess, from contraction of the bladder rendering the viscus unable to hold much, from worry, anxiety, fear, or from excessive urinary secretion, as in diabetes or in the first stage of contracted kidney. Frequent micturition exists in obstruction by enlarged prostate and in atony of the bladder walls. Hypersecretion of urine plus bladder intolerance is known as "nervousness of the bladder," and is found in hysteria. Frequency of micturition increased by *movement* is observed in stone and tumor of the bladder. Nocturnal frequency of micturition is present in cases of enlarged prostate and atony of the muscular walls of the bladder. Frequency of micturition with diminution of the diameter of the stream suggests a constriction of the urethral canal; frequency of micturition with diminished projectile force suggests a posterior stricture, enlarged prostate, or bladder atony. Slowness of micturition hints at enlarged prostate, atony, or urethral stricture.

Sir Henry Thompson's diagnostic questions are as follows:

"1. Have you any, and, if so, what, frequency in passing water? Is frequency more manifest during the night or the day? Is frequency more manifest during motion or rest? Does any other circumstance affect it?

"2. Is there pain on passing urine, and, if so, is it before, during, or after the act? What is its character—acute, smarting, dull, transitory, or continuous? What is its seat? Is it felt at other times, and is it produced or intensified by sudden movements?

"3. What is the character of the stream? Is it small or large; twisted or irregular; strong or weak; continuous, remitting, or intermitting? Does it come through the meatus, or partly or entirely through fistulæ?

"4. Is the character of the urine altered? What is its appearance, color, odor, reaction, and specific gravity? Is it clear or turbid, and, if turbid, is it so at the time of passing? Does it vary in quantity? Are the normal constituents increased or diminished? Does it contain abnormal elements, as albumin or sugar? What inorganic deposits are found? What organic materials are met with?

"5. Has the urine ever contained blood? If so, was the color brown or bright red; were the blood and urine thoroughly mixed; was the blood passed at the end or at the beginning of micturition, or did it come only with the last drops of urine; or was it passed independently of micturition?

"6. Inquire as to pain in the back, loins, and hips, permanent or transitory, and for the occurrence of severe paroxysms of pain in these regions."

The Determination of the Excretory Capacity of the Kidneys in Health and in Disease.—As a rule marked diminution in the excretory power of a kidney means anatomical changes but this inference is not always correct. Even a great diminution in excretion may be functional. Hence the surgeon must always gauge and weigh the functional findings in the light of clinical evidence. There are two types of cases in which the surgeon finds renal functional tests of the greatest value: (1) in cases in which kidney disease is secondary to disease of the lower genito-urinary tract and (2) in cases in which

such tests are applied with ureteral catheterization in unilateral and bilateral surgical maladies (J. T. Geraghty, in "Bull. Johns Hopkins Hospital," 1915, xxvi).

The Phloridzin Test.—This test is made with comparative ease and may aid the surgeon in determining whether he is justified in performing some operation of convenience. It enables him to estimate with a fair amount of accuracy the capacity for elimination possessed by the kidneys. The test depends on the fact that the healthy epithelium of the glomeruli and tubes, when stimulated to activity by phloridzin, forms sugar from that drug and thus produces temporary glycosuria. When the epithelium is diseased, little or no glycosuria occurs. The test is applied as follows: The dose is about 5 to 10 mg. of phloridzin, according to the body-weight of the patient. It is administered hypodermatically, the bladder having been emptied beforehand. If the eliminating powers of the kidney are at a healthy level, sugar should appear in the urine within half an hour of the injection. If at the end of this time only a small amount of sugar can be detected, one may assume that the kidneys are affected; and if no sugar can be found, a serious renal disease may be assumed to exist.

The actual standard that is to be considered as the normal amount of sugar which should be eliminated after the administration of phloridzin is a matter of some uncertainty. It is usually estimated at 0.3 per cent., a less amount of sugar than this being taken as an evidence of renal difficulty (Watson and Bailey, in "Report of Boston City Hospital for 1902"). The sugar is separated from the phloridzin in the epithelium of the glomeruli and tubules of the cortex of the kidney. The drug seems to be entirely harmless.

It is because phloridzin is acted upon by the kidney epithelium that this test is better than the methylene-blue test. The latter does not really measure the excretory power of the kidney epithelium; it merely shows to what degree the kidney is permeable in the mechanical sense. Personally, I should not be disposed to set aside older and more thorough methods of urinary analysis for the phloridzin test, although I believe that it has a range of distinct usefulness.

The Methylene-blue Test (*The Method of Achard and Castaign*).—When methylene-blue is injected hypodermatically it normally is changed into a chromogen, appears in the urine within half an hour, and disappears in from thirty-six to forty-eight hours. If the blue color is not manifest in the urine for an hour or more, there is impairment of renal permeability. Only 50 per cent. of the amount ingested is removed by the kidneys. Accuracy in the test is not possible unless the amount of the methylene-blue actually passing into the urine in a given time be determined. The dose given hypodermatically is 0.05 gm. in 1 c.c. of sterile water. The test is unreliable and the blue color may appear in the urine in half an hour in some cases of marked kidney disease. At its best the test only indicates the freedom of mechanical renal permeability.

The Indigo-carmin Test.—This drug should be largely excreted in a few minutes. It colors the urine. It is an unreliable method. It will show functional failure, but there may be no functional failure even in organic disease. In many cases the color appears as quickly in urine from a diseased kidney as in urine from the sound organ.

This method enables us to recognize functional incapacity. By it we may forecast uremia. If the urine be collected from each ureter separately we can tell the capacity of each kidney. In this test, if color does not appear until after twenty-five minutes, and if during the first hour less than 30 per cent. of the amount introduced is excreted, a contemplated surgical operation should be postponed or abandoned.

The Phenolsulphonephthalein Test.—This is the most reliable one. It shows the working capacity of each kidney. The drug is not toxic. It is given in an alkaline solution. A hypodermatic injection of 6 mg. is administered. It appears in the urine when the kidneys are normal in from six to twelve minutes,

and from 40 to 60 per cent. of the amount given is excreted during the first hour. It colors urine red and a quantitative estimation can be made by means of a colorimeter. When the color first appears, and how much of the drug is excreted in the first hour, must be noted.

Cryoscopy (*Korányi's Method*).—Cryoscopy is the determination of the freezing-point of a liquid and the comparison of this with the freezing-point of distilled water. It is applied particularly to blood and urine. This method is complex and difficult of application, requires a considerable amount of fluid, and is not regarded as very valuable. The freezing-point of a fluid depends upon the number of molecules it contains. The freezing-point goes hand in hand with molecular concentration—great concentration gives a low freezing-point; little concentration, a high freezing-point. Cryoscopy of the blood and urine is used to determine the adequacy of renal activity. Normal blood freezes at about −0.56° or −0.57° C. Healthy urine freezes between −0.9° and −2° C. In renal inadequacy the freezing-point of the blood is lower than normal and the freezing-point of the urine is higher. It is held that surgical operation is contra-indicated if there be such a degree of renal inactivity that the freezing-point of the blood is at or below −0.6° C. and if the freezing-point of the urine is at or above 1° C. The urine is obtained from each kidney separately and is compared with the blood's molecular composition.

Diseases and Injuries of the Kidney and Ureter

Infantile Kidney—This is a rare anomaly but a very dangerous one if a surgeon operates upon the other kidney. Even when ureteral catheterization is practised a clear and normal urine may be obtained from the ureter of the small kidney. The amount of urine is small, the percentage of urea is decreased and functional activity is impaired (Geraghty and Plaggemeyer, in "Jour. Am. Med. Assoc.," 1913, lxi). In some few persons who are thin the *x*-rays will demonstrate the kidney to be very small. Geraghty and Plaggemeyer point out that pyelography is of no help as the size of the renal pelvis is no certain index of the size of the kidney (Ibid.).

Cysts and Tumors of the Kidney.—Cysts are not uncommon. In a case of *congenital cystic kidney* both kidneys are involved. The condition is due to failure of fusion between the excretory and collecting tubes. The cysts are numerous and are separated by bands of atrophic renal structure. The cyst-fluid is usually clear and yellow and contains urinary salts. In some cases it is colored by blood. The congenital cystic kidney may attain a great size. It is a strange fact that these kidneys are functionally active and that a person who has them may live well into adult life although they are prone to strike work suddenly, a cessation which causes death (see Staehlin, in "Annals of Surg.," 1916, xxx). The bilateral nature of the condition forbids nephrectomy. Cysts, single or multiple, bilateral or unilateral may arise after birth. Obstruction of the renal tubules may result from acute parenchymatous nephritis or interstitial fibrosis, and obstruction may produce a retention cyst or retention cysts. The large solitary, serous retention cyst is an uncommon disease, most often encountered in males and in adult life (Cunningham, "Surgery, Gynecology, and Obstetrics," 1916, xxiii; Staehlin, Ibid.). Hydatid cysts may form in the kidney. Tumors, innocent or malignant, may arise in the kidney. Among the innocent tumors are fibroma, lipoma, angioma, and adenoma. Hypernephroma of the kidney arises from fragments of adrenal tissue included in the kidney. Hypernephromata were thought to be renal lipomata until 1883, when Grawitz showed they contained adrenal elements ("Virchow's Archiv.," xciii). The name "hypernephroma" was suggested by Birch-Hirschfeld in 1896. A hypernephroma may arise directly from the suprarenal gland or it may arise from an adrenal "rest" or aber-

rant gland. Such rests may be met with in the substance of the kidney, under the renal capsule, in the perirenal tissue, in the testicle, the ovary, the liver, the inguinal canal, the mesentery, among the spermatic vessels, in the broad ligament, in the renal plexus, or in the solar plexus (W. W. Keen). The term hypernephroma is applied to any growth which arises from adrenal cells "whether the growth be adenoma, carcinoma, or sarcoma in type" (Duffield, in "N. Y. Med. Jour.," May 1, 1909). The tissue of a hypernephroma is identical with the adrenal gland, and it contains fat and glycogen. The tumor may arise at any period of life from childhood to old age. The commonest decade is from 50 to 60. The exact nature of such a tumor is unsettled. It is probably an adenoma, but some consider it to be a sarcoma and others a carcinoma. Some tumors give no evidence of malignancy; some are very malignant. A malignant

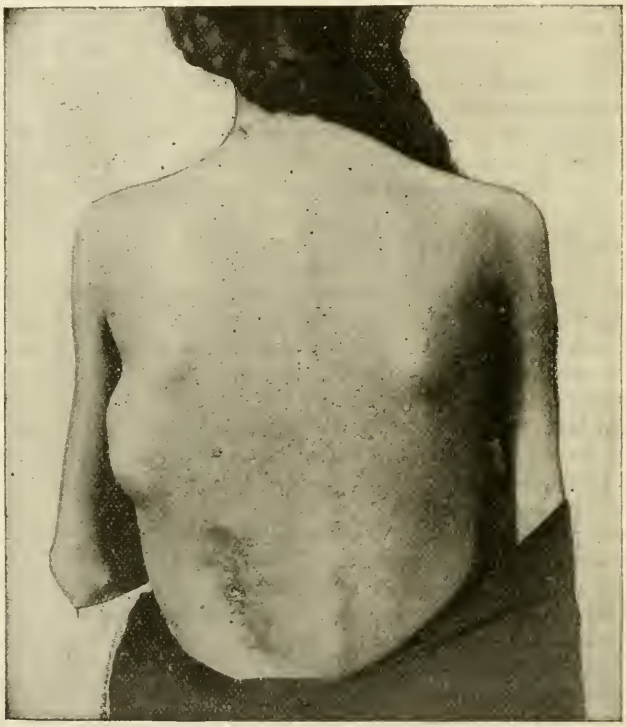

FIG. 931.—Sarcoma of kidney with metastasis (Horwitz).

hypernephroma grows rather rapidly, eventually attains a large size, and is sometimes painful. A patient in the Philadelphia Hospital from whom I removed a hypernephroma complained of tenderness in the left side and occasional attacks like renal colic during which he passed bloody urine. The tumor could be easily palpated in the left loin. The kidney was removed and resembled a huge kidney of nearly normal shape, but nodular in outline. Dr. Coplin found it to be hypernephroma. In this case there was no increase of arterial tension. The patient died. Another case was a woman of forty-five who was brought to the Jefferson Hospital. She had suffered from pain in the loin for months. It was paroxysmal, but lacked the radiation of renal colic. Hematuria appeared long after the pain had begun. It was persistent, but small in amount. Palpation detected a tumor and the *x*-rays showed enlarged kidney. There was no increase of arterial tension. Recovery followed nephrectomy. In a man, aged thirty-four, in the Philadelphia Hospital there were attacks of

severe pain referred to the groin, testicle, and loin. The bleeding was profuse. A mass was palpable in the right upper abdomen and loin. Examination of blood showed hemolysis, but there was no hypertension. The growth was exposed in the loin. Hemorrhage was so violent that it became necessary to open the abdomen and ligate the renal pedicle. The kidney was removed and the patient recovered.

Very malignant cases have proved fatal within six weeks after symptoms have been observed. Some patients have lived three years. A hypernephroma of malignant nature involves adjacent structures, and gives rise, after a time, to metastases, particularly by way of the blood. The bones are most liable to metastatic deposit, but such deposits may occur in the lungs, liver, and other regions. In a case upon which I operated for a supposed adenomatous goiter the condition was really metastatic hypernephroma. Hypernephromata are infinitely more common in the kidney than anywhere else. The treatment is nephrectomy. The operative mortality of hypernephroma of the kidney is from 12 to 15 per cent. The earlier the operation the better the prospect of cure. One-third of the cases will pass the three-year limit after nephrectomy. Sarcoma or carcinoma may arise in the kidney. They may be primary or secondary. Primary sarcoma is far more common than primary carcinoma. Primary sarcoma is most common in the young, and may reach an enormous size (Fig. 931). A malignant tumor of the kidney produces hematuria, the urine often containing blood-casts of the ureter, kidney, and pelvis, and sometimes, though rarely, characteristic cells. Pain is often present in the loin and thigh, and there may be colic-like attacks when clots are passing through the ureter. A tumor can usually be palpated. Emaciation is decided and rapid. Sarcoma of the kidney is a rapid growth and in this, as in all rapidly growing sarcomata, fever is not uncommon (Longhnane, in "Brit. Jour. Surgery," 1914, ii). In some few cases the growth is bilateral. Pyelography with a 10 per cent. solution of collargol may aid in the diagnosis (see page 1455). The only possible treatment for a malignant growth is early nephrectomy. In some few cases an innocent tumor can be removed by a partial nephrectomy. A malignant tumor requires a complete nephrectomy. The mortality is considerable (7 to 15 per cent.) and rapid recurrence is to be expected in 80 per cent. of the cases. A very few pass the three-year limit. In making a diagnosis of renal tumor use the cystoscope. If blood is coming from above the bladder, note if it is from one or from both ureters. Blood from both would contra-indicate nephrectomy. Before removing a kidney it is necessary to be sure that the patient is possessed of two kidneys. Note if urine flows from each ureter, or, if uncertain, catheterize the ureters.

Nephroptosis, Prolapse of the Kidney, or Mobile Kidney.—There are two forms of this condition: (1) *Movable kidney*, which is an organ freely moving back of the peritoneum, either within the cavity of its fibro-fatty capsule or entirely without its capsule (this condition is acquired); and (2) *floating* or *wandering kidney*, an organ having a mesonephron and lying within the peritoneal cavity (this rare condition is always congenital). Keen states that there may be drawn a clear theoretical distinction between movable and floating kidney, but practically there is no rigid line of demarcation, as a movable kidney may have as large a range of movement as a floating kidney. The kidney is normally somewhat mobile, and nephroptosis is considered to exist only when the range of movement exceeds distinctly what is normal. Normally, on inspiration the kidney descends about ½ inch. It is seldom that a normal kidney can be palpated in men, but in most women the right kidney can be palpated, and in some women the left organ can also be felt. Harris ("Jour. Amer. Med. Assoc.," June 1, 1901) describes three degrees of movable kidney. In cases of the first degree, one-half of the organ can be distinctly grasped and the kidney can be made to recede. In cases of the second degree both hands

can be brought together above the kidney. In cases of the third degree the kidney has descended as low as the pelvic brim or has moved to or beyond the umbilicus. The organ may drop below the brim of the pelvis, may cross the vertebral column, or may reach the anterior abdominal wall. When a movable kidney becomes fixed in an abnormal situation, the organ is spoken of as *dislocated*.

Women suffer from movable kidney more often than men. Küster estimates that 4.41 per cent. of women examined in general surgical practice have movable kidney. Edebohls finds it in 20 per cent., and Harris in 56 per cent., of cases in gynecological practice. In about one-half of the cases it gives rise to little or no trouble. A movable kidney is found in the great majority of cases upon the right side. In many cases it is bilateral, the right kidney being usually the most mobile. Splanchnoptosis may be associated with acquired nephroptosis. Floating kidney is always congenital. Movability of the kidney is occasionally, but rarely, found in children, though congenital cases occur. In a congenital case there is not splanchnoptosis. Tuffier has reported 3 cases in children six, nine, and ten years of age respectively, and J. Cromby reported 18 cases of floating kidney in children, the youngest patient being three months of age (quoted by Harris, Ibid.). Among the assigned causes of the movable condition are to be named traumatism; strains; abdominal-wall laxity from pregnancy, removal of a tumor, or tapping for ascites; absorption of peritoneal fat from wasting disease (Edebohls); tight lacing; uterine displacements; and enteroptosis leading to traction on the transverse mesocolon. The condition is certainly often associated with ptosis of the other abdominal viscera (enteroptosis, gastroptosis, etc.).

Traumatism is rarely the immediate and essential cause of a true movable kidney. In some cases patients assert that pain began immediately after a blow, an attack of coughing, violent vomiting, lifting, straining at stool, a fall, or in parturition. In such cases the kidney may have been mobile before the accident. Again, pain is not proof of the inauguration of movability. It is probable, however, that traumatism may loosen the kidney and that mobility may subsequently develop. Gutterbock says that a kidney in normal relations cannot be rendered mobile by a simple fall or a trivial force. Loosening can be induced only by rupturing surrounding tissues; and if this happens, symptoms of a distinct nature will indicate the seat of injury. Becher and Lennhoff claimed that there is a connection between movability of the kidney and the length and breadth of the body. They have laid down a formula, viz.: Measure the distance from the suprasternal notch to the crest of the pubes. Divide this by the smallest circumference of the abdomen. Multiply the product by 100. The result is the abdominal index. If the index is greater than 75 there is a tendency to movable kidney. If it is less than 75 there is no such tendency. Harris makes out a strong case for the view that the condition is due to the relation existing between the location of the kidney and the body form. He divides the body into three zones: The upper zone contains the lungs and heart. The middle contains the liver, stomach, spleen, pancreas, and the greater part of each kidney. The lower contains the intestinal canal and the lesser part of each kidney. When there is a naturally small or a diminished capacity of the middle zone, the kidney is displaced downward. The right kidney is pressed upon by the heavy liver, which drives it down; the left kidney is pressed upon by the comparatively small spleen. Hence movable kidney is more common on the right side than on the left. The upper pole of the kidney is first pushed forward and then the entire organ descends (M. L. Harris, in "Jour. Amer. Med. Assoc.," June 1, 1901). Harris maintains that the amount of mobility depends upon the degree of contraction of the middle zone and upon internal traumatisms (lifting, straining, coughing, etc.).

Symptoms of Both Forms.—There may be no discomfort whatever, or the patient may be a confirmed invalid. The usual symptoms are epigastric

pain (just to the left of the middle line), which disappears when the kidney is replaced, dragging pain in the loin, and paroxysms like nephritic colic. Sudden attacks of violent pain in the kidney or stomach may occur—attacks which are accompanied by nausea, vomiting, great weakness or collapse, vertigo, chills, and subsequently elevated temperature (*Dietl's crises*). Dietl's crises are due to kinking or twisting of the ureter or renal vessels or to inflammation of the kidney. They may be caused by physical exertion or indiscretion in diet and may be followed by hydronephrosis or strangulation of the renal vessels. A few years ago I operated upon a man suffering from a violent and prolonged crisis and found a twist of the vessels and ureter. In a Dietl's crisis there is congestion or strangulation or both. An incomplete or temporary twist of the renal pedicle may induce simply pain in the abdomen and loin, hematuria, albuminuria, and cylindruria.

The question as to whether or not abdominal pain is due to movable kidney is sometimes in doubt. The localization of the pain may lead us to suspect appendicitis. Some surgeons think that catarrhal appendicitis is often associated with movable kidney, but I do not think the association is common. "Dr. Kelly has shown us how to solve this doubtful question between appendicular pain and the pain of movable kidney. He catheterizes each ureter separately, and introduces into each catheter as much fluid as the renal pelvis will hold without causing pain. He then measures this fluid from each side, and determines whether it is in excess of an estimated average. If it is in excess, he is sure that dilatation has begun. He then injects the kidney again, with the deliberate purpose of producing pain: and if the patient recognizes this pain due to the distention as of the same character and in the same position as that which he has previously felt, Dr. Kelly assumes that the pain has been due to the kidney, and not to the appendix, and recommends an operation to fix the kidney" (the author, in "New York Med. Jour.," August 4, 1906). Usually in a case of movable kidney there is a sense of a moving body in the abdomen,

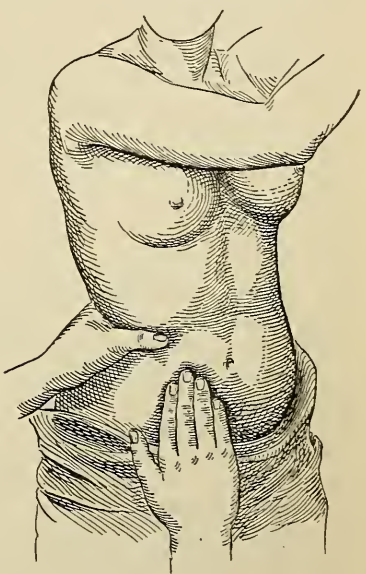

Fig. 932.—A. H. Goelet's method of palpation for the detection of a prolapsed kidney.

and the patient has aggravated indigestion, often accompanied by vomiting. Constipation is the rule, and violent attacks of cardiac palpitation are common. Most subjects of kidney mobility are extremely nervous—many of them hysterical or hypochondriacal. Persistent vasomotor paresis causes cold hands and feet and often albuminuria. Temporary jaundice is not uncommon. There is frequently irritability of the bladder. Vertigo and insomnia are present in many cases. The patient cannot sleep when lying on the sound side (Goelet). In women the sexual organs are almost invariably deranged, and menstruation aggravates the pain and discomfort. All the symptoms are intensified by exertion and are modified by rest. The urine is normal except after violent exercise, when it may contain blood. Splanchnoptosis may also exist, and if it does, the pulsations of the abdominal aorta are strongly noticeable because that structure is bared by gastroptosis. The proof of the existence of movable kidney is the finding of a mass, movable on respiration, change of position, and palpation, shaped like that organ, pressure upon which occasions

no sensation or causes pain or a sickening feeling. A "lumbar recess" (Morris) may sometimes be found, and percussion over the loin gives resonance. In some cases a movable kidney can be readily detected when the patient stands up but is difficult to find when he is recumbent. Franks' method of examination is very satisfactory in most cases (Fig. 932). The patient is placed recumbent. If dealing with a right kidney, the surgeon stands to the right side and pushes four fingers of his left hand in the loin below the twelfth rib, and rests the thumb lightly in front just below the ribs. The patient takes a full breath and holds it a moment, and just before he empties his lungs the surgeon presses his thumb up deeply below the ribs. During expiration the thumb follows the liver, and the fingers press toward the front. If with the right hand the kidney can be felt entirely below the left hand, the case is one of movable kidney. If such a condition is detected, press hard with the right hand, and gradually loosen the grasp of the left hand, and the kidney will slip between the fingers and ascend. A normally mobile kidney descends so that its lower end can be felt, but it moves back during expiration.[1] Goelet uses Kendal Franks's method of palpation, but has the patient stand, with the weight resting on the leg of the sound side and with the leg of the impaired side slightly flexed and resting on the toes. The body leans a little forward. A movable kidney must not be mistaken for a distended gall-bladder, a tumor of the mesentery, stomach, or omentum, a phantom tumor, an ovarian tumor, or a cancer of the pancreas. A distended gall-bladder can be pushed upward, but not backward, and not downward unless the liver be movable; it is extremely tender, and cannot be pushed out of reach. A kidney can be pushed upward and backward—in fact, in all directions. An enlarged gall-bladder can always be palpated. A movable kidney which is not enlarged can be felt at times and not at others (Henry Morris). A movable kidney may pass between the examiner's fingers, and if pushed into the loin, it tends to remain; but if a distended gall-bladder is pushed into the loin, it springs out as soon as pressure is relaxed (Henry Morris). The *x*-ray study of the kidney pelvis after injection with collargol is known as *pyelography* (see page 1456). The *x*-ray picture of a kidney so injected is a pyelogram. This method is of the highest diagnostic value. It will always show a displaced kidney, and it indicates hydronephrosis. One picture should be taken with the patient standing, another with the patient recumbent. It is important to remember that in about one-half of the cases of movable right kidney the left kidney is also movable, but to a less degree. Appendicitis is thought by some to be more frequent in individuals with movable right kidney than in those free from renal mobility. Sometimes a movable kidney endangers life, rupture of the kidney, twisting or rupture of the ureter, or strangulation of the renal vessels occurring, the ultimate cause of death being nephritis, uremia, or hydronephrosis.

Treatment.—Mobile kidney is treated as follows: If the kidney is but slightly mobile and there are no local symptoms, the treatment should be non-operative: (1) The *rest treatment of S. Weir Mitchell* may be tried; it often markedly mitigates the symptoms, but does not seem to cure. (2) *Mechanical support* should always be tried. The most satisfactory mode of applying it is by the corset recommended by Gallant ("Am. Jour. Obstet.," July, 1901). This corset is long and straight in front, and when applied, fits firmly over the hips and lower abdomen, less firmly at the waist, and least firmly above.

The patient lies down, a pillow being under the buttocks and the knees being drawn up. While in this attitude the corset is put on and it is laced in front from below up. If the attempt to apply the corset develops tenderness, keep the patient at rest in bed until it can be applied without pain. In some cases conservative treatment is not indicated; in others it fails.

In every case of very movable kidney, and in some cases in which movability is not great, operation is indicated.

[1] "Brit. Med. Jour.," Oct. 12, 1895.

"In a case in which the kidney exhibits trivial movability, but in which the range of mobility is found to be gradually and certainly increasing, or in any case of kidney movability in which there are distinct local symptoms, operation is indicated. The distinct local symptoms mean the beginning of actual harm to the kidney, and the progressive increase of movability means the ultimate attainment of a wide range of movement. A kidney which is widely movable may at any time twist upon the ureter and the renal vessels; and it is certain to suffer from partial or slight twists, probably many times repeated in the twenty-four hours, even if a severe twist does not occur. A deduction from the foregoing statements is that a patient suffering with nephroptosis, even when the mobility is slight, should be examined at regular intervals, to note whether the area of movement is extending, or whether local symptoms have arisen. Three local symptoms that should be regarded as indications for operation are severe pain in the renal region, distinct tenderness of the kidney, and enlargement of the kidney" (the author, in "New York Med. Jour.," August 4, 1906). Billington ("Brit. Med. Jour.," May 1, 1909) formulates the following indications for operation:

1. When renal pain is so severe or persistent as to cause serious inconvenience. The ordinary dragging pain in the loin is not an indication. Billington refers to severe pain due to perirenal inflammation, ureteral obstruction, or impeded venous return.

2. When there are harassing and depressing gastric and colonic troubles (gross lesions being absent).

3. Cases of spinal and cerebral neurasthenia.

4. Cases of lunacy. Personally I do not operate on groups 3 and 4 unless there are signs of grave renal disaster.

The usual operation chosen will be nephropexy, very seldom nephrectomy. (1) *Nephropexy* is the operation employed in most instances (see page 1443). It is the author's experience that if the patient has had marked nervous symptoms for a long time, nephropexy will rarely cause them to pass away permanently, even though the kidney remains firmly anchored. (2) *Nephrectomy* is necessary in very rare cases only; it may be done for dislocated kidney, when grave kidney disease exists, or when nephropexy has failed in a case of great severity.

In many cases of this trouble no operation should be performed, the use of Gallant's corset securing, perhaps, decided or complete relief. I do not operate if the kidney is only slightly movable and if there are no local symptoms or if there are merely the general symptoms of hysteria. If the mobility is slight and the hysterical and neurotic condition is pronounced, anchoring the kidney will not cure the nervous condition In these nervous cases, associated with prolapse of the kidney, there is usually also prolapse of the other abdominal viscera; and both kidneys are, as a rule, movable, the right, however, in most cases being decidedly more movable than the left.

If there is but slight mobility of the kidney, but the range of movement is, week by week and month by month, increasing, or if we find a case of movable kidney in which there are distinct symptoms, an operation should be performed. The existence of definite local symptoms means beginning harm to the kidney; and if we find the area of movement gradually increasing, we know that eventually it will become extensive. Any widely movable kidney may twist the ureter and the renal vessels, producing serious trouble or even disaster, and consequently should be fixed by operation. Even if a severe twist does not take place, the kidney is bound to suffer from partial or slight twists. Such kidneys will eventually become hydronephrotic. The meaning of the term "slight mobility" is indicated on a previous page (see page 1419).

One is not unusually in doubt in cases of movable kidney whether a pain indicates local trouble with the kidney or catarrhal appendicitis, because the

pain may be located in the appendix region. Kelly, of Johns Hopkins Hospital, has shown how to solve this problem (see page 1421).

There are many operations for movable kidney. In all of them the kidney is exposed in the loin. Some make a vertical and some an oblique incision. Edebohls makes a vertical incision, forces the kidney out of the wound, incises the fibrous capsule longitudinally, turns a cuff down on each side, and applies sutures. These sutures traverse the kidney substance and the fold of capsule on each side. The upper suture catches the periosteum of the last rib; the other sutures catch the lumbar fascia. Drainage is not required, and the suture material employed is kangaroo-tendon or chromicized catgut.

Some surgeons simply pass sutures through the uncut capsule and the kidney substance and thus fasten the kidney to the lumbar fascia. Others split the capsule and pass sutures through the edge of the capsule and the wound edges, but not through the kidney substance.

To promise success, an operation ought to restore the kidney nearly to its normal position and fix it permanently in place. It is undesirable to inflict damage on the kidney itself, and I do not believe in any operation that seeks to obtain fixation by passing sutures through the kidney substance. In cases in which decapsulation is performed the kidney will grow fast without any special method of suturing.

Most of the operations suggested do not place the kidney sufficiently high up to get it into a fair position. Kelly's operation gets it higher than most of them, and Goelet's operation gets it well into place. In many of the suture operations the sutures are placed in the convex surface of the kidney or the kidney capsule, and, on fixing the kidney by tying the sutures, there is a permanent quarter twist of the ureter—a condition that may be responsible for great pain. This may be obviated entirely by the ingenious method of Goelet ("Annals of Surgery," Dec., 1903). I believe, however, that the suture operations which do lift the kidney well up toward its proper place and in which the sutures are applied on the posterior surface and not the convexity, tilt the upper pole forward into a permanent and perhaps disastrous position. Such operations lift the kidney from below its midline and thus fix the lower half of the organ, but leave the upper half unfixed. I believe, too, that in many cases in which kidneys have been sutured they get loose again and that the best operation, after all, is that by the use of slings of iodoform gauze (see page 1442).

Injuries of the Kidney.—**Laceration** or **rupture** is caused by falls and by blows upon the back or the belly.

Symptoms.—In some cases the parenchymatous structure is torn, but the capsule is not torn, and in consequence urine and blood are not extravasated into the perirenal connective tissue or into the peritoneal cavity. In other cases the parenchyma and capsule are both torn and urine and blood are extravasated into the perirenal tissues, the peritoneal cavity, or both of these regions. The laceration may be trivial, may be considerable, or may tear the kidney apart. The symptoms depend on the gravity of the injury. A slight tear without involvement of the capsule may produce practically no symptoms at all. A more severe injury produces shock, and, if profuse bleeding occurs, the general symptoms of hemorrhage. In intraperitoneal rupture there is profuse and usually fatal hemorrhage. In laceration of the kidney there are lumbar tenderness and severe loin pain which shoots into the testicle. If there is considerable perirenal bleeding the loin will be full and dull on percussion, and if the hemorrhage is large, a palpable mass will form after a time and after some days the skin will become discolored. There is usually frequent and painful micturition, and in some cases suppression of urine. Hematuria occurs in renal laceration unless the rupture has been intraperitoneal or the ureter has been torn. If the rupture has been intraperitoneal there are evidences of profuse internal hemorrhage, abdominal rigidity, etc. (Daniel N.

Eisendrath," Jour. Amer. Med. Assoc.," Oct. 25, 1902). It is important to remember that hematuria can arise from simple renal contusion, and that even severe kidney damage does not of necessity cause bloody urine. If there be hematuria, the use of the cystoscope, catheterization of the ureters, or the employment of Harris's segregator will demonstrate from which kidney the blood comes. A kidney laceration may be followed by secondary hemorrhage, perirenal suppuration, hydronephrosis, or pyonephrosis. The force of the injury may have caused kidney displacement.

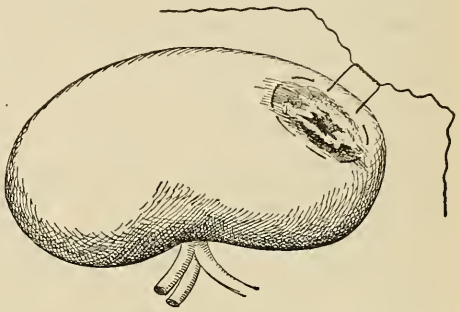

Fig. 933.—Purse-string suture applied to a perforation (after Schacher).

Treatment.—In an intraperitoneal rupture laparotomy should be performed. As a rule, nephrectomy is necessary, but it may be possible to arrest hemorrhage by packing. If the shock is pronounced and if there is increasing fulness in the loin, whether hematuria exists or not, or if blood comes profusely from the ureter, whether or not there is much shock or lumbar fulness, make an exploratory lumbar incision and stop the bleeding by packing or by a purse-string suture (Figs. 933, 934), or, if necessary, perform partial, or even complete, nephrectomy. Ordinarily, after a kidney injury, when there is not great shock, increasing lumbar swelling, or severe hematuria, treat by rest in bed and by feeding with liquid food or by nutritive enemata to prevent vomiting. Opium, tannic acid, or gallic acid may be used. Apply ice-bags to the loin and to the side of the abdomen, and after bleeding ceases strap the loin and apply a binder. If large blood-clots in the bladder cause pain or retention of urine, introduce a catheter and inject the bladder with boric acid, or use the tube and evacuator of a Bigelow apparatus. If this procedure fails, open the bladder by a suprapubic incision and drain.

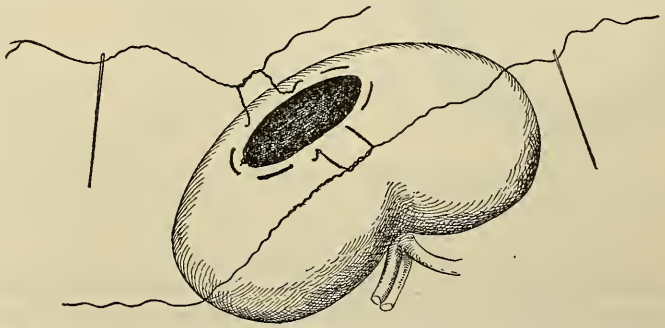

Fig. 934.—Showing the application of a double purse-string suture for the arrest of hemorrhage in large wound (after Schacher).

Results of Operation.—Up to 1894 there had never been a case of intraperitoneal rupture operated upon. During the following seven years 6 were operated upon and all recovered (Daniel N. Eisendrath, "Jour. Amer. Med. Assoc.," Oct. 25, 1902). Küster collected 47 cases of nephrectomy, and 83 per cent. recovered. Keen estimates the mortality of primary nephrectomy for rupture at 20 per cent., and of secondary nephrectomy at 38.5 per cent. Without operation intraperitoneal rupture is inevitably fatal. Of extraperitoneal ruptures, 70 per cent. recover without operation (Eisendrath). Francis

S. Watson ("Boston Med. and Surg. Jour.," July 16, 1903) has collected 660 cases of subparietal injury of the kidney. The following statistics are of interest: Treated expectantly: 273 cases with 81 deaths, a mortality of 29.6 per cent. Treated by operations other than nephrectomy: 99 cases with 7 deaths, a mortality of 7.7 per cent. Treated by nephrectomy: 115 cases with 25 deaths, a mortality of 21.7 per cent.

Perforating wounds of the kidney, if purely posterior, do not involve the peritoneum; if anterior, they do. The *symptoms* are escape of blood and urine from the wound; hematuria is usual, but not invariable; pain as in rupture; the patient may be unable to micturate; and nausea, vomiting, and constitutional signs of hemorrhage exist. Traumatic peritonitis, perinephric abscess, or general sepsis may ensue. Confirm the diagnosis by exploration with the finger after operative exposure. Extraperitoneal injuries give a good, and intraperitoneal a bad, prognosis.

Treatment.—If the wound of the kidney be extraperitoneal, enlarge the lumbar wound to permit of drainage, and arrest hemorrhage by packing and hot water or by a purse-string suture (Figs. 933, 934).

Suture of the Kidney.—The tendency of any suture material to cut through the kidney structure is great. The following simple procedure greatly lessens this danger: Cut the ordinary catgut roll into three or four

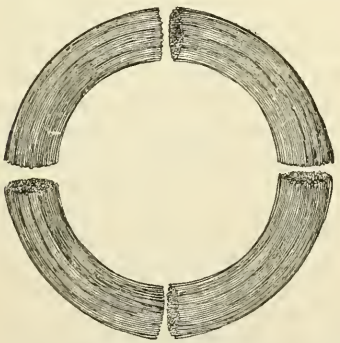

FIG. 935.—Catgut ring cut into quarters to be inserted under the suture as shown in Fig. 936.

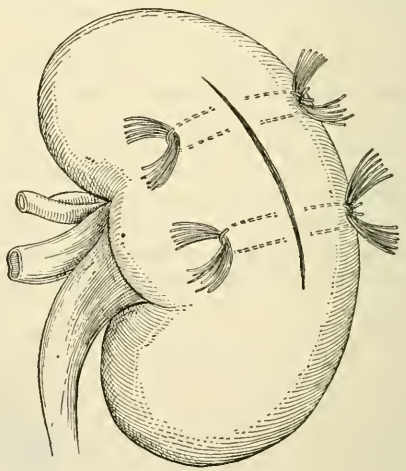

FIG. 936.—Stellwagen's suture of kidney to prevent cutting after tying.

parts, as shown in Fig. 935. Slip beneath the exposed loops of the purse-string suture, as shown in Fig. 936, a section of the catgut roll consisting of a series of short stiff strands. These permit fairly firm tying of the suture-ligature without cutting of the kidney structure by the suture. In nephrotomy the same procedure can be used in closing the kidney wound.

Asepticize the wound, insert a drainage-tube down to the kidney, dress with sterile gauze and make frequent changes of dressings, keep the patient in bed and on a low diet, and give gallic acid and opium. In some cases nephrectomy, partial or complete, will be required. In intraperitoneal wounds perform an abdominal section and, as a rule, remove the damaged organ (see Nephrectomy).

Wounds of the Ureters.—Rupture from external violence is an extremely rare accident. Eisendrath ("Jour. Amer. Med. Assoc.," Oct. 25, 1902) found only 3 undoubted cases on record. A rupture or wound from accidental violence is almost invariably associated with other serious injuries. The ureter may be wounded accidentally by the surgeon during the performance of an abdominal operation, or it may be wounded intentionally, as in Morris's

case, in which the ureter was incorporated in a malignant growth. There is particular danger of injuring the ureter in operations upon intraligamentary growths, because the ureter is displaced and often resembles an adhesion. The rule of surgery is that when working about the ureter the surgeon neither clamps nor cuts any structure without a careful preliminary examination to identify the exact position of this organ. Rupture causes severe shock and extravasation of urine around the kidney or into the peritoneal cavity. In extraperitoneal rupture a palpable mass forms in the loin. When the ureter is divided in an operation, a flow of urine is seen.

Treatment.—The upper three-fourths of the ureter can be reached by an extraperitoneal incision, which is a prolongation of the incision for lumbar nephrectomy, running from the twelfth rib downward, and forward to 1 inch anterior to the anterior superior spine of the ilium, and then parallel to Poupart's ligament until a point is reached above the latter's center (Fenger). Israel's incision begins at the anterior edge of the erector spinæ mass, one finger's breadth below the twelfth rib, is taken forward parallel with the rib until it reaches the line of the rib's tip, and is then carried toward the middle of Poupart's ligament until the line for ligation of the common iliac artery is reached, and is then taken toward the middle line as far as the outer border of the rectus muscle. The lower one-fourth of the ureter can be reached by abdominal section, by sacral resection, or by an incision like that for extraperitoneal ligation of the iliac vessels. The best operation to reach the lower ureter is Gibson's (see page 1445). If it seems probable that the ureter is wounded or ruptured, explore, and if a breach in the ureter is found, endeavor to restore the continuity of the tube. A longitudinal cut can be sutured with fine catgut. If the ureter is cut across near the bladder, implant the proximal end into the bladder and ligate the distal end (Van Hook, Penrose, Kelly). If it is cut above the bladder portion, perform lateral implantation by Van Hook's method (see page 1447).

A longitudinal wound of the ureter inflicted during an abdominal operation should be sutured, but if the duct cannot be readily reached, simply make a posterior incision and drain with rubber tissue, as the longitudinal wound will heal by granulation if no sutures are inserted (Van Hook). In a case of transverse division perform uretero-ureterostomy or vesical implantation; or, if neither of these methods be feasible, make a urinary fistula in the loin or perform nephrectomy.

Renal Calculus (Nephrolithiasis).—A stone in the kidney is formed by the precipitation of urinary salts upon the renal epithelial cells and the gluing together of these salts and cells by material from mucus or blood-clot, this mass serving as a nucleus on which accretion takes place. Most calculi escape when small, as *gravel*. The **cause** is said to be highly acid urine, which induces catarrh of the renal tubes. Such high concentration of urine is favored by a sedentary life, by the ingestion of much alcohol or nitrogenous food, by constipation, by an inactive skin, and by a torpid liver. Infection is certainly a cause in some cases. Any obstruction to the ureter favors stone formation by producing stasis and stasis leads to precipitation and favors infection. O. S. Fowler ("Jour. Am. Med. Assoc.," 1914, lxii) points out that stones tend particularly to form in the lower pole and cites this as evidence that renal drainage is deficient from that portion of the organ. The slaves of poverty are particularly liable to calculi because of the use of unsuitable foods and the formation of great amounts of nitrogenous waste. Males suffer more often than females; certain locations favor the development of the malady, and a family tendency sometimes exists.

The **symptoms** of stone in the kidney may not appear for years after the stone forms, but generally they are manifested early. There may be no pain. There had been none in 13 cases out of 23 which came to autopsy and were

reported by Clark. Usually there is pain; the severity of the pain depending upon the roughness and movability rather than upon the size of the stone. A fixed stone in the kidney and a smooth stone in the pelvis may cause little or no pain. A rough stone in the pelvis causes severe pain The patient usually complains of pain in the loin, and sometimes of pain in the iliac region. Deep percussion over the kidney causes pain in the loin, even when pressure is painless (Jordan Lloyd's symptom). Pain is aggravated by exercise and pressure, and the kidney is, in most cases, enlarged. The urine is often somewhat albuminous, and may from time to time contain blood. Frequency of micturition is noted during the day, but seldom when at rest at night. The urine may be purulent. *Nephritic colic* is due to the washing of

Fig. 937.—Stone in kidney.

a calculus into the orifice of the ureter, which it blocks, tears, or distends. The pain is either sudden or gradual in onset, is fearful in intensity and runs from the lumbar region down the corresponding thigh and spermatic cord (the testicle being retracted), and into the abdomen and back. There are nausea, vomiting, collapse, sometimes unconsciousness or convulsions. Frequent attempts at micturition are productive of pain, but of little urine. Rectal tenesmus is common. The urine is often, but by no means always, smoky from blood. Blood may be found by the microscope when it cannot be detected by the naked eye. In rare cases fatal hemorrhage occurs. Blood is present in about one-half the cases. After a time the pain vanishes, the stone having passed into the bladder or having fallen back into the pelvis of the kidney. Slight attacks of colic occur from the passage of small stones or plugs of mucus. A calculus retained in the kidney eventually excites pyelitis, pus appears in the urine, and

soreness or pain exists in the loin. Kelly says: Even if pus is found, we are not always sure from which kidney it came. Pain or swelling may point to one side, but we are not sure that the other organ is not also affected. The cystoscope must be used. Bloody or purulent urine may be seen coming from one ureter. If able to pass the renal catheter into one ureter, attach a syringe, and by making suction draw out any pus which may be present. In renal calculi cases this fluid is apt to contain fragments of uric acid. By using a renal bougie coated with dental wax it may be possible to make scratches on the instrument when it comes in contact with a concretion.[1] When a stone is impacted in the renal pelvis the point of greatest tenderness on pressure is below the last rib, at the edge of the erector spinæ muscle. In septic cases there may be chills and irregular fever, and often there is leukocytosis. In most cases a stone in the kidney or ureter can be skiagraphed. Nephrolithiasis may cause death by exhaustion, by sepsis, by rupture of a hydronephrosis, or by amyloid degeneration.

Treatment.—For the gravel of the uric-acid diathesis use alkalis, especially the liquor potassii citratis, and reduce the amount of nitrogen in the diet to a minimum, at the same time washing out the organs by copious drafts of water. Citrate of lithia, given in the water, is supposed to add to the therapeutic effect. Some surgeons prescribe natural lithia water. Piperazin, in doses of 5 to 8 gr. three times a day, is highly commended by some. Exercise is to be insisted on. When gravel is phosphatic, order strychnin, the mineral acids, and rest at the seaside. When oxalate of lime is found, restrict the diet, use the mineral acids, recommend travel or rest amid new surroundings, and give an occasional course of sodii phosphas, ½ dram three times a day, taken in a natural lithia water. Nephritic colic is relieved by hypodermatic injection of morphin and atropin, a hot bath, diluent drinks, and possibly the inhalation of ether. After an attack watch all the urine passed to see if a stone appears. If one does not soon appear, use the cystoscope, and if a stone is found in the bladder, wash out that viscus with an evacuator. This is very important, as the vesical stone may fail to pass, and if it remains in the bladder it will progressively enlarge. Further, finding it proves the diagnosis of renal colic. If a stone impacts in the ureter, perform the operation of *ureterolithotomy*. The diagnosis of this impaction is in many cases aided by the *x*-ray, but is sometimes possible only after exploratory laparotomy. If the symptoms point to stone in the kidney, always take a skiagraph. Take a skiagraph of both kidneys for comparison. If this shows a stone on the affected side, if medical treatment fails, or has failed, and if the other kidney is not organically diseased, operate and operate early. Delay may mean disastrous or fatal sepsis. The danger of delay is greater than the danger of operation. If in doubt in spite of the skiagraph, make an exploratory lumbar incision; feel the surface of the kidney with the finger, sound the inside of the organ with a needle, or open the organ for exploration, and if a stone be detected, incise the kidney and remove the stone. Keen is of the opinion that operation should not be performed if the urea is below 1 per cent. If, after nephrolithotomy, suppression of urine occurs, cut into the other kidney, as in one-half of all cases a stone will be found lodged there. I agree with Brewer ("Med. Record," March 20, 1909) that "a kidney containing one or more calculi, and also the seat of an advanced septic process, should be removed if the opposite organ is healthy. To leave such a kidney is to invite subsequent trouble from recurrence of stone, pyonephrosis, or long continued sepsis." I agree with him when he says: "It is also often safer to remove a kidney with multiple calculi embedded in its substance than to inflict the trauma necessary to remove them, as alarming primary or secondary hemorrhage is apt to occur." In a case of my own a most persistent postoperative hemorrhage forced me to perform nephrectomy to save life. If each kidney contains a stone or stones operation is perilous. The mor-

[1] Howard Kelly, in "Med. News," Nov. 30, 1895.

tality of operation in this condition is at least 30 per cent. and fistula is apt to result. If there is little or no infection operation is inadvisable, otherwise it must be done in spite of the risk.

Calculus Impacted in the Ureter.—A ureteral calculus comes from the kidney, sometimes dropping, but more often being forced, into the tube. A stone may be arrested at any one of the points of constriction. There are three points of constriction in the ureter: one point is about 2 inches below the renal pelvis, another is at the pelvic brim, another is about ½ inch from the bladder orifice of the ureter. The highest point has a diameter of about 1/7 inch, the middle point a diameter of about ¼ inch, the lower point a diameter of about 1/10 inch. A small stone may completely block the ureter. A large stone may fail to block it completely because the ureter dilates above, the stone acts as a ball-valve, and urine trickles by.

Symptoms.—Attacks of violent pain of the nature of renal colic occur, and not unusually there are rigor with the attack and fever after it. Such an attack may be followed by hematuria. The urine should be examined microscopically during several days after a colic to see if it contains blood-cells. Tenderness can be developed at the point of impaction, the point of greatest tenderness being in the loin *below* the level of the kidney or in the iliac region (Perkins). In stone in the ureter pain is not developed by pressure in the loin at the level of the kidney. If a stone partly obstructs the ureter, the urine is pale, of low specific gravity, and free from albumin. Impaction near the bladder causes symptoms similar to stone in the bladder (Jordan Lloyd). These symptoms are frequent micturition, pain at the seat of impaction, pain in the head of the penis, and bloody urine. If a stone is impacted in the lower end of the ureter a finger in the vagina or rectum will find tenderness and perhaps will feel the stone. In a woman, a stone lodged in front of the broad ligament may be felt by a finger in the vagina. Back of this region and up to the pelvic brim a stone may be felt by a finger in the rectum. A cystoscopic examination, in unusual cases, may show a portion of stone projecting from a ureter (Kelly). Impaction near the kidney is accompanied by hematuria and pyuria, lumbar pain, pain radiating into the groin, thigh, or testicle, and retraction of the testicle. These symptoms are identical in character with the symptoms caused by stone in the renal pelvis. Complete obstruction of the ureter causes hydronephrosis. Pyonephrosis results from infection of a hydronephrosis. In some cases a stone acts as a ball-valve, plugs the ureter for a time, during which a lumbar mass develops, and then allows the urine to flow. A copious flow of urine is accompanied by disappearance of the lumbar mass. Complete urinary suppression may follow blocking of a ureter by a calculus. If a ureteral catheter tipped with wax be introduced, a calculus will make distinct scratches upon it (Kelly). The Cunningham catheter (see Fig. 948, *e*) may assist in detecting a stone. It has not been successful in our hands when the stone has been impacted more than 6 c.c. above the ureteral outlet. This catheter may also be of assistance in dislodging the stone.

The *x*-rays are very valuable in diagnosis. A pyelographic study of the ureter and pelvis may give material assistance.

Treatment.—During a painful paroxysm give morphin and use hot packs. Belladonna is useful by inducing relaxation of spasm. The ozonized oil of turpentine, given in capsules in 10-min. doses, is often valuable. It was employed by the elder Gross. For the pain Bransford Lewis ("Jour. Am. Med. Assoc.," Jan. 29, 1910) catheterizes the ureter and injects into the renal pelvis 20 min. of a 1 per cent. solution of alypin (monohydrochlorid of benzoyl). Alypin is a powder. It is soluble in water and is to be sterilized by boiling for not over five minutes. The attack may terminate and not return, because the calculus passes. If such an attack does pass away, the urine should be examined after every act of micturition to see if the stone has been voided from the

bladder. After a day or two, if the stone does not appear, use the cystoscope, perhaps catheterize the ureter, and thus discover if the stone is in the bladder or if it is impacted. If the stone is in the bladder, use the Bigelow evacuator to effect removal, or crush the stone by the small forceps of Bransford Lewis or by the forceps of Leo Buerger. The stone must never be allowed to remain, as it will surely enlarge and cause subsequent trouble. If a stone is found impacted in the ureter have the patient drink water freely. Sterile olive oil may be injected into the ureter through a ureteral catheter, or the ureteral orifice may be dilated by a suitable bougie. If the impacted stone is very near the bladder the ureteral orifice may be slit. Simple catheterization of the ureter may be followed by expulsion of the stone. If in spite of these procedures the stone remains impacted in the ureter, the question of operation presents itself. An impacted stone is certainly a peril, but how immediate the danger is it is often impossible to say. In some cases stones have remained impacted for many years without doing obvious harm. In other cases the kidney has been rapidly destroyed. The stone may pass after having been retained for a long time, and drinking freely of water favors its expulsion. One of my cases had long carried a retained stone, came to the hospital for operation, and passed the stone. Sooner or later a retained stone will lead to disaster and it ought to be removed by operation and it should be removed early. The danger of delay exceeds the danger of operation. It will cause, if retained, thickening or ulceration of the ureter, dilatation of the ureter above it, and kidney trouble from blocking or sepsis. A lodged stone increases gradually in size and other stones may form above it. The extraperitoneal operation is to be chosen in most cases. Even when the stone is impacted below the pelvic brim, it is usually better to do the extraperitoneal operation (see Ureterolithotomy).

Infections of the Kidney.—Bacteria may reach the kidney by the blood, by the lymph and by any of the lymphatics. Mechanical obstruction favors infection greatly. So does inflammation. Blocking of the ureter may result from stone or from pressure without. The gravid uterus may obstruct the ureter and this may be an explanation of that common lesion, the pyelitis of pregnancy. In the male, enlargement of the prostate and urethral stricture interfere with kidney drainage.

Intestinal inflammation or stasis is not unusually followed by kidney inflammation. In any general infection the kidneys may suffer.

In over 90 per cent. of renal infections the colon bacillus is responsible (Koll, "A Collective Review" in "Internat. Abstract of Surgery," April, 1915). According to Koll (Ibid.), next in order of frequency is the Staphylococcus pyogenes albus, rarely the aureus; the Streptococcus pyogenes; the typhoid bacillus; the gonococcus; the Bacillus fæcalis alkaligenes; and the pneumococcus.

Gonococcus infection is so rare as to be a surgical curiosity.

Staphylococcic infection comes from the urethra. These bacteria can be found in one-fifth of healthy male urethras (Koll, Ibid.). In scarlatina or tonsillitis streptococci may reach the kidney by the blood and cause acute nephritis.

One-fourth of all typhoid patients have typhoid bacilli in the urine after the third week of the disease. These organisms may continue in the urine for weeks, months or several years.

Abscess of the kidney may be caused by traumatism, by calculus, by stricture of the ureter, by disease of the bladder, by the union of miliary abscesses (tuberculosis), by pyemia, and by certain parasites.

The **symptoms** are pus in the urine (this is usual, but not invariable), hematuria in traumatic cases, and pain running into the groin. The urine in most cases is alkaline. Constitutional symptoms of suppuration exist, the fever being far higher than that generally encountered in renal tuberculosis. The bladder should be examined with a cystoscope to determine whether or

not the turbid urine is flowing from the ureter and to identify the diseased side. It is well, if possible, to catheterize the ureters.

The **treatment** in the early stage is rest, morphin, purgation, anodynes, and hot fomentations. In some cases repeated lavage through the ureter may cure. When the diagnosis is clear, and lavage fails or is not thought desirable, incise the loin, open the kidney and stitch it to the abdominal wall, or, if the organ be badly damaged, remove it.

Pyelitis.—Pyelitis is inflammation of the pelvis of the kidney. It may be unilateral but is usually bilateral. It may arise by a descending process from nephritis, by an ascending process from a ureteritis, or, in very rare instances, by spread from a perinephric inflammation.

The pelvis of the kidney is predisposed to inflammation by irritation and congestion. Among the irritants are large doses of sandalwood oil and urotropin. Cold may cause congestion. Highly concentrated urine and calculi cause irritation. Interference with drainage of urine strongly favors infection and aggravates existing infection. Interference with urinary drainage may be caused by a stone in the kidney, ureter or bladder, by a blood-clot in or stricture of the ureter, by pressure upon the ureter from without (by an abdominal tumor or a pregnant uterus), by kinking of the ureter (in movable kidney), by vesical paralysis, by urethral stricture, by prostatic enlargement, by ascending tuberculous infection, and by growths in the calices. In rare cases trauma is responsible. Nephritis, especially the chronic interstitial nephritis of the gouty, and heart disease predispose. Perinephric abscess, malignant disease or parasites may be responsible. Intestinal stasis is blamed in some cases. The organisms chiefly responsible for infection are pus bacteria and colon bacilli. In nine-tenths of the cases arising secondarily to bacterial nephritis colon bacilli are responsible. In most ascending infections staphylococci are to blame. Gonococcal infection almost never occurs. Pyelitis is not uncommonly caused by the exanthemata. If infection be mild a catarrhal inflammation may arise, but it is rare and most inflammations are suppurative. A pyelitis is greatly aggravated if the ureter becomes blocked with pus (pyonephrosis or pyelonephritis follows).

Pyelitis may lead to ulceration and ascending pyelitis frequently causes parenchymatous and more frequently interstitial nephritis.

Symptoms.—Pain in the loin, which may be severe and is apt to have acute exacerbations; which may radiate into the penis, the testicle or even the corresponding shoulder, and which is associated with tenderness of the kidney. The pain is increased by motion (especially by cough). The output of urine may be, but seldom is, diminished. The urine is acid, and contains hyaline casts, albumin and in most cases numbers of pus-cells or even obvious pus. It may contain blood. In catarrhal cases fever may be slight or absent but in purulent cases there is certain to be fever. Chills and sweats occur in many cases. In an acute case the kidney is seldom enlarged. If pyonephrosis occurs the kidney of course enlarges.

In acute Bright's disease there is edema, the skin is dry, the urine is scanty and contains blood and there may be convulsions. In pyelitis the urine is usually plentiful, contains pus, albumin and bacteria, seldom contains blood, there is no edema, the skin is moist and convulsions do not occur.

In grave cases a chill is followed by fever, with headache, stupor, dry tongue and usually scanty urine. The prognosis in catarrhal cases is of the best but in severe infections is extremely grave. Pyelitis may at any time originate kidney inflammation (pyelonephritis). When, during the existence of pyelitis, the ureter becomes blocked the condition is known as *pyonephrosis* (page 1435).

Treatment depends upon the course or the severity of the infection. Trivial inflammations, such as may arise during an exanthematous fever, require merely rest in bed, liquid diet and the use of diluent drinks. In a more severe case give morphia if the pain be severe.

In colon infections the kidney is certainly involved, the urine almost never sterile, and some practitioners use an autogenous vaccine.

If the urine be acid, give liquor potassi citratis; if alkaline, give benzoate of ammonium and boric acid or urotropin. Gallic acid, eucalyptol, and small doses of copaiba or cubebs are recommended. Venice turpentine, camphor, and opium may be given in pill form. Quinin is used to stimulate the patient. If cystitis exists the bladder is to be washed out every day with boric acid solution (3 grains to the ounce of water) and at intervals with a solution of nitrate of silver (1 to 8000). In some cases a catheter is inserted and retained. Cups, dry or moist, and hot sand-bags or bran-bags are to be applied to the loin. Alcohol may be sparingly administered. Urotropin is a useful drug if the urine be alkaline. Lavage of the pelvis by means of the hydrostatic apparatus shown in Fig. 956 may be practised and is often most useful. For lavage, use a return flow catheter; first wash the pelvis gently with normal salt solution or sterile distilled water. Silver nitrate in solution, of a strength of $\frac{1}{10000}$, may be used.

S. B. Dudgeon and A. Ross, of London ("Annals of Surgery," March, 1910), give small doses of autogenous vaccine—100,000,000 to 200,000,000 administered every five days. Relapses are apt to occur. If pyonephrosis develops perform nephrostomy.

Pyelonephritis.—This is a septic inflammation of the kidney which is associated with or secondary to pyelitis. In a hematogenous infection (for instance with colon bacilli) the nephritis precedes the pyelitis (E. G. Crabtree and Hugh Cabot, in "Jour. Am. Med. Assoc.," Feb. 24, 1917). In an ascending infection the pyelitis precedes the nephritis.

Some restrict the term pyelonephritis to the ascending form of renal suppuration and call the descending form suppurative nephritis. The causes of pyelitis and pyonephrosis are the causes of pyelonephritis. The calices, the uriniferous tubules and the renal parenchyma are involved in suppuration.

Symptoms.—In the acute form the symptoms arise suddenly. There is a chill. High fever follows. Delirium is common. Loin pain is severe. In a short time the patient becomes dull and drowsy, stupor comes on and finally in most cases, death. Death is the rule in from one to two weeks. A few cases recover. The symptoms "are due in part to septic intoxication, in part to renal insufficiency" ("Genito-urinary Surgery and Venereal Disease," by Martin, Thomas, and Moorhead). In chronic pyelonephritis the chief symptoms may be indicative of irritation of the gastro-intestinal tract, in fact there may be no sign pointing to the urinary organs. A urinary examination and a bladder study are of course imperative. The patient suffers from indigestion, flatulence, dry mouth, loss of flesh and strength and from attacks of violent diarrhea.

Treatment.—A liquid diet, diuretics, diluent drinks, laxatives. In acute cases dry cup over the kidneys. Alcoholic stimulation is required. Martin gives salol. If pyonephrosis develops open the kidney and drain (nephrostomy).

Spontaneous Perirenal Hematoma.—Traumatism is the common cause of a hematoma in the perirenal tissues (page 1424). Spontaneous hematoma is a rare but recognized affection. It was described by Wunderlich in 1856 under the name of spontaneous apoplexy of the capsule of the kidney. In most of these cases acute or chronic nephritis exists. In some cases the hematoma is under an unruptured capsule. In some, the capsule is ruptured and a mass is palpable. This mass may reach up to the diaphragm and down into the pelvis and even to the median line of the body. In a case of perirenal hematoma a cyst may form (*perirenal hygroma*).

Lippens ("Jour. de Clin.," 1913, xi, 1) collected 23 cases of perirenal hematoma. He found records of two bilateral cases. The condition is much more common in the young than in the elderly and is more frequent in men than in women. It causes sudden and violent pain in the loin, with symptoms of concealed bleeding, and the formation of a palpable mass, which is immovable,

tender and dull on percussion. In some cases violent attacks of colic occur during a number of months. The temperature is usually elevated, after reaction from the initial hemorrhage. Without operation the condition will be fatal sooner or later.

The **treatment** in some cases is incision and packing with gauze; in some, is nephrectomy. The earlier the operation the better the prognosis.

Perinephritis is an inflammation of the perinephric fatty tissue produced by cold, febrile disease, slight traumatism, or the spread of inflammation from another part.

The **symptoms** of this condition are rigidity of the spine, the inclination being toward the affected side, flexion of the thigh, pain in the loin and iliac region, and often pain in the knee. The symptoms resemble those of hip-joint disease in the second stage. Suppuration may or may not take place. In some suppurative cases the condition strongly suggests woody phlegmon (see page 147). I have seen one case in which there was severe, unilateral abdominal pain, rapid pulse, elevated temperature, abdominal distention, a mass in the loin, and compression of the iliac veins. After incision and drainage necrosis of the kidney was found to exist and the kidney was removed.

In another case the kidney sloughed away without hemorrhage. There is a chronic form in which masses of fibrous tissue develop.

The **treatment** is wet cups and heat to the loin, rest, purgation by saline, morphin for pain, and, after the acute stage, potassium iodid internally. In a lingering case an incision should be made. It will frequently be followed by cure. Decapsulation has advocates. If suppuration occurs it is necessary to incise and drain. Necrosis of the kidney calls for nephrectomy.

Perinephric or Perirenal Abscesses.—An abscess in the perinephric fat is known as a perinephric or perirenal abscess. There may or may not be renal involvement. *Primary abscess* may follow a chill, may develop during or after an acute febrile disturbance, or may be caused by pus flowing from some other part, as from the spine. Slight traumatisms, by producing hemorrhage, make the perinephric region a point of least resistance and lead to abscess of hematogenous or renal origin. The causative injury may be produced by digging, stamping, coughing, falling, carrying a burden, lifting a weight, or riding on a horse or on a jolting wagon. *Consecutive abscess* is secondary to kidney inflammation, suppuration, calculus, tuberculosis, or cyst. Some cases follow furunculosis. The staphylococcus is the organism usually found. In the consecutive form the symptoms may be masked by the malady to which perinephric abscess is secondary. As a rule, in a case of perinephric abscess there are found the constitutional symptoms of suppuration. As Dr. Morris Miller has shown, there is high leukocytosis. The chief local symptom is a deep aching and paroxysmal pain in the loin, intensified by lumbar pressure. There may be pain in the iliac region and pain in the knee. Edema of the corresponding foot and lameness are not unusual. The thigh is often drawn up. The spine is rigid and inclined toward the diseased side. Edema of the skin is usual, but fluctuation is not. An exploratory incision will settle a doubtful diagnosis.

The **treatment** is to lay open the abscess, wash it out, and drain. The mortality is over 10 per cent.

Stricture of the Ureter.—This is usually at or near the termination of the ureter. It is due to gonococcic inflammation, pyogenic inflammation, or tuberculosis. The symptoms, as Howard Kelly says, are at first those of a vesical or renal inflammation. The diagnosis is made by the ureteral catheter. We may be unable to introduce it; we may introduce it with difficulty and find that the pelvis of the kidney is distended and that the urine obtained is slightly acid or even alkaline, much lower in urea than the urine from the other kidney, and perhaps contains pus. Stricture of the ureter causes hydronephrosis, pyelitis, pyelonephritis and pyonephrosis. Great care must be exercised in

the examination of the ureter for stricture, and we know of cases diagnosticated as stricture that were simply spastic contractions or deviations in the course of the tube resembling stricture. Some urologists have regarded the condition as quite common, but we do not believe it is so; in several of the cases so diagnosticated a pyelographic study of the ureter has revealed tortuosities due to a descended kidney. These cases will often have greatly enlarged pelves and many of them suffer from mild attacks of kidney colic. Before arriving at a diagnosis the Blasucci catheter should be used and a pyelographic study be made.

Treatment.—Dilatation with bougies, resection of the diseased portion and anastomosis, resection of the diseased portion and implantation of the sound end into the bladder, or division of the stricture and suture. In tuberculosis the diseased kidney and ureter may be removed.

Hydronephrosis is a condition of the kidney resulting from an impediment to the outflow of urine by obstruction in the ureter, the bladder, or the urethra, the calices of the kidney becoming overdistended with urine and the glandular tissue being absorbed by pressure. It has been asserted by Albarran that secretion of urine ceases in a kidney whose ureter is completely blocked, distention being due purely to congestion. Hydronephrosis may be congenital, due usually to twisting of the ureter or to valve-formation obstructing the ureter at its point of junction with the pelvis of the kidney, the valve having been produced because the ureter passed into the kidney pelvis at an unnatural angle. Occasionally, imperforate urinary meatus produces hydronephrosis of both kidneys.

The causes of the acquired form are the pressure of pelvic growths or pregnancy, inflammation or tumor of the bladder, stone in the bladder, kidney, or ureter, twisting or kinking or stricture of the ureter of a movable kidney, enlargement of the prostate gland, and stricture of the urethra. Acquired hydronephrosis may involve both kidneys, all of one kidney, or only a part of a single gland.

Symptoms.—Hydronephrosis is most frequent in females. When a lumbar tumor is absent there may be no symptoms, or there may be pain in the back and abdomen, frequent micturition, a persistent or intermittent diminution in urine, or even occasional anuria. In the loin may be found a mass which is dull on percussion, which shrinks and enlarges, and which may disappear with a large urinary flow. Hydronephrosis may last a long while if only one kidney be involved, but death is not far distant if both glands suffer. Death occurs from uremia, from pressure on adjacent organs, or from rupture into the peritoneal cavity. The diagnosis is aided by the use of the cystoscope, by catheterizing the ureters, and by pyelographic study.

Treatment by aspiration may possibly cure, but the operation will have to be done repeatedly. Tapping on the left side is performed just below the last intercostal space; on the right side the tap is made midway between the last rib and the crest of the ilium. Some few cases have been cured by catheterizing the ureter (Pawlik). The proper operation in most cases is nephrotomy, stitching the edges of the cut kidney to the surface. After the kidney has been opened, explore the ureter by means of a uterine sound or an elastic bougie. A healthy ureter will permit the passage of an instrument of the size of from No. 9 to No. 12 of the French scale (Fenger). If the opening of the ureter into the pelvis cannot be found, open the pelvis or open the ureter. A valve should be slit longitudinally and sutured transversely (Fenger). If a permanent suppurating fistula ensues or if the organ is found extensively damaged, nephrectomy is to be performed, provided the other kidney is in reasonably good condition.

Pyonephrosis or **surgical kidney** is a condition in which the pelvis and the calices of the kidney are distended with pus or with pus and urine.

The whole kidney may be destroyed. This condition has the same causes as hydronephrosis, for it is, in reality, usually an infected hydronephrosis. In some cases the inaugural malady is pyelitis, which causes blocking of a ureter. Watson, of Boston, has reported 2 cases associated with obliteration of the ureter by a mass of fibrous tissue (stricture of the ureter).

The **symptoms** are those due to the obstructing cause plus pyelitis. Pus may be constant in the urine in incomplete obstruction, or it may intermittently appear. Bacilluria, and especially colon bacillus infection of the urine, has a strong tendency, unless speedily controlled, to cause pyonephrosis. Constitutional symptoms of suppuration are soon manifest. A mass like the tumor of hydronephrosis may appear in the loin. If only one kidney be involved, and if the disease be due to blocking of a ureter, recovery is to be expected. The diagnosis is rendered more certain by the use of the cystoscope and by catheterizing the ureters.

The **treatment** in the early stages comprises removal, if possible, of the cause of obstruction, and the employment of measures directed to the cure of the pyelitis. If obstruction is not complete, palliative measures may be employed for the tumor. If fever continues; if there is great visceral derangement; if pain is severe and constant, and if the mass continually enlarges, perform nephrostomy, stitching the organ to the surface if possible, or removing it if it be hopelessly disorganized and the other kidney be in good or fairly good condition.

Chronic Tuberculosis of the Kidney.—This condition may begin in one kidney, no other area of infection existing in the body. In such cases the bacteria have been deposited from the blood in the renal tubules. "From these they reach the surface of the papillæ or calyx recess, where they are amassed in sufficient number to bring about a tuberculous lesion" (Leo Buerger, in "Interstate Med. Jour.," 1914, No. 11). Even when the bacteria are deposited from the blood there is, in most cases, an initial focus of tuberculosis somewhere else in the body. Primary renal tuberculosis remains for a long time a local disease, but, unfortunately, the other kidney, sooner or later, is very apt to become involved, the process in the first kidney affecting the bladder and secondarily the other kidney. The important point is that tuberculosis of the kidney arising in this manner is at first a unilateral disease.

Tuberculosis of the kidney is seldom a primary disease and usually arises secondarily to tuberculosis of the prostate, bladder, or epididymis. In such a condition the kidney disease is always bilateral. Renal tuberculosis is particularly common in the third and fourth decades of life, and is more frequent in males than in females.

Symptoms.—Renal tuberculosis of arterial origin may exhibit no symptoms until the disease is far advanced. As long as a tuberculous kidney drains pain is absent. When the urinary passages are blocked suddenly, tension ensues and renal colic occurs. If the blocking be gradual pain may never occur. Renal tuberculosis secondary to disease of the bladder or prostate always presents symptoms.[1] A very common symptom of renal tuberculosis is the sudden onset of polyuria and frequent micturition. The patient is annoyed day and night, and in some cases micturition is distinctly painful. Paroxysms of renal pain are not unusual. As stated above there may be no pain. Tenderness may be absent. The urine is acid and may contain pus or blood. Tubercle bacilli may be found in the urine or in the sediment of centrifuged urine, but they may be absent. Repeated examination should be made before it can be stated certainly that bacilli are absent. The presence of bacilli proves the diagnosis, but their absence does not negative it (Willy Meyer). If bacilli are not found, inject some of the urinary sediment into a guinea-pig, and note if tuberculosis arises in the animal. Czerny has shown that in cases of tuberculous kidney in which

[1] F. Tilden Brown, "New York Med. Jour.," April 10, 1897.

bacilli are not found in the urine the administration of tuberculin will cause great numbers to appear. This agent will also cause a marked febrile reaction if tuberculosis exists. The urine may or may not be albuminous.

In many cases the kidney is obviously enlarged, and the renal area is frequently tender and occasionally painful. When pain and tenderness are absent (*silent renal tuberculosis*) the diagnosis is often missed. The patient loses flesh, and there is nocturnal fever followed by sweating. The use of the cystoscope furnishes important information. It shows from which ureter turbid urine is coming. Catheterization of the ureters should be practised by some one who is expert. Always examine carefully to determine if one or both kidneys are involved, if the bladder is diseased, and if the prostate gland or seminal vesicles are tuberculous.

Treatment.—Lumbar nephrectomy is not justifiable in the very beginning of a case, because such a patient may be cured by a combination of medical and hygienic treatment, and the weakening effect of the operation of nephrectomy may cause the other kidney to develop tuberculosis rapidly. Tell such a patient to lead an outdoor life. Brown recommends camp-life in the Adirondacks during the summer, and sends such patients south during the winter. If a patient cannot go to another climate, urge upon him the necessity of practically living out-of-doors (see page 255). Insist upon the taking of plenty of nutritious food. Full antituberculous treatment is indicated (see page 257).

If the kidney is markedly enlarged; if there is profuse hematuria; if the fever is high and persistent; if only one kidney is involved, if the other kidney has a satisfactory functional capacity, and if the bladder and prostate are free from disease, perform nephrectomy. After nephrectomy for tuberculous kidney a tuberculous sinus not uncommonly forms. If a diseased ureter is removed as far as possible at the operation, if an open ureteral stump is injected with 5–10 minims of a 95 per cent. solution of carbolic acid (Mayo), and if the fatty capsule is removed with the kidney, a tuberculous sinus will seldom form. In cases with involvement of the other kidney or of the genito-urinary tract lower down, or in which the functional capacity of the other kidney is not satisfactory, nephrectomy is not justifiable, although nephrotomy for drainage may, for a time, greatly benefit the patient.

Operations on the Kidney and Ureter.—**Operations for Chronic Nephritis.**—In 1897 Mr. Reginald Harrison advocated puncture of the kidney to relieve tension in cases of albuminuria, and in 1901 advocated incision of the true capsule of the kidney and puncture of the gland to accomplish the same purpose ("Brit. Med. Jour.," Oct. 19, 1901). Alexander Hugh Ferguson in March, 1899, reported 2 cases of interstitial nephritis cured symptomatically by decapsulation and multiple punctures ("Jour. Am. Med. Assoc.," March 11, 1899). Dr. Geo. M. Edebohls observed, between 1892 and 1897, that in certain cases of movable kidney with albuminuria the albumin and casts disappeared after nephropexy. Rose, Wolff, and Ferguson have observed the same fact. Harrison believes that renipuncture removes the symptoms by abating tension, but Edebohls concludes that nephropexy relieves the condition and possibly cures it by establishing vascular adhesions which carry on additional supply of blood. He proposed to operate for Bright's disease in 1899 ("Med. News," April 22, 1899). Edebohls deliberately operated for chronic nephritis and claimed 8 complete recoveries from chronic Bright's disease ("Med. Record," Dec. 21, 1901). There can be no doubt whatever that operation is sometimes followed by polyuria, disappearance of edema and other symptoms, and apparent cure. But in some cases the disappearance of symptoms has been too rapid to permit of the assumption that new vessels have caused it. In such cases it seems much more probable that relief of tension is the real curative factor. The capsule of the kidney is only slightly elastic, and tension may be brought about by an increase in the blood-supply, by edema, and by cell pro-

liferation. Increased tension causes pain and perhaps hematuria, and tension is relieved by Harrison's plan of incising the capsule. Simple incision is easier, safer, and probably just as useful as stripping the capsule off of the kidney. Edebohls advocates decapsulation and says that the polyuria begins about the tenth day after operation; that improvement begins in one month and is gradual; that the cure is due to vascular adhesions; that the adhesions contain more arteries than veins; that the free blood-supply absorbs exudate and products of inflammation, frees the tubes and glomeruli from pressure and constriction, causes the reëstablishment of a normal circulation and the regeneration of epithelium (Ibid.).

The exact status of the operation is not as yet determined. It does, however, seem to be proved that operation is in some cases followed by apparent cure or great amelioration of the condition. Whether permanent cure is ever thus obtained is doubtful, and the part played by rest in bed and drugs in effecting an improvement must not be lost sight of. I have seen no case of genuine cure. I doubt if cure is ever obtained. Albumin has always continued present in the urine. It is certain that the operation is unjustifiable unless medical treatment has been tried and failed, unless the symptoms are growing worse, and unless they indicate danger. James Tyson ("Med. Record," July 8, 1911) sets forth dangerous symptoms as follows: Persistent dropsy, uremia (violent headache, convulsions, or coma), excessive amount of albumin causing anemia and weakness, anuria. The best results are obtained in chronic parenchymatous nephritis associated with marked anasarca. Pain and bloody urine are often much improved by incising the capsule. Postoperative suppression and the anuria of acute infectious diseases may be favorably influenced by the operation. In perinephritis it may prove curative.* An important fact which Rovsing maintains and Edebohls proves is that chronic nephritis may be for some time a unilateral disease. (Read the views of Schmidt, in "Med. Record," Sept. 13, 1902; of Rovsing, of Copenhagen, in "Mittheilungen aus den Grenzegebieten der Medicin und Chirurgie," vol. x, 1902, and editorial in "Jour. Am. Med. Assoc.," Jan. 11, 1902; James Tyson, in "Trans. of Amer. Physicians," 1911, and "Med. Record," July 8, 1911.) Personally, I would not operate in the presence of grave and advanced cardiovascular disease. Tyson believes that albuminuric retinitis, very irregular heart, and valvular disease forbid operation, and that in patients over fifty the operation is of slight value. I believe the operation has its highest indication in an acute congestion arising in the course of chronic nephritis.

The operation as practised by Edebohls may be done on both kidneys either at one sitting or in two séances. In some cases only one kidney is subjected to operation. Edebohls takes a very radical view and would operate on any case free from incurable complications, if an anesthetic can be given and if the life-expectancy without operation is not less than one month ("Med. Record," Dec. 21, 1901). Ether is given or nitrous oxid and oxygen. Lay the patient prone with an air-cushion under the belly and expose the kidney by a vertical incision at the edge of the erector spinæ mass. This incision does not open the sheath of the muscle. Remove the fatty capsule from the true capsule, continuing the dissection around each pole until the pelvis of the kidney is reached. The kidney is extruded from the wound, the true capsule is incised along the convex border and around each pole, is separated from the kidney, and is cut away close to its junction with the kidney pelvis. The kidney is then returned to its bed of fat and the wound is closed (Ibid.). Edebohls does not drain unless there is considerable edema. He reported 18 operations without a death. In 9 of the cases the operation had been done more than one year, and 8 of them were said to be cured. Personally, I do not believe that the operation can really cure Bright's disease. It cannot restore altered connective tissue and epithelial cells. The new blood-supply must be through scar tissue, and

we have yet to learn that such a blood-supply can be efficient. The operation should be restricted to acute nephritis, to acute exacerbations in chronic cases, to conditions with severe renal pain, hematuria, anasarca, very high albumin percentage, or persistent, and notable diminution in the amount of urine voided (Ertzbischoff, in "Archiv. générales de Chirurgie," April, 1908).

Nephrotomy means incision into a kidney, but the term is sometimes, though wrongly, applied to the exploratory exposure of the kidney without incision into the organ. When the kidney wound is left open as it almost invariably is, the operation should be called *nephrostomy*. The operation is employed to evacuate infectious material, relieve tension, permit of the removal of a calculus or exploration of the ureter, and for diagnosis of renal disease. The patient lies upon the sound side, a sand-pillow or a cylindrical air-bag being placed under the flank. The *incision* is made ½ inch below the last rib and close to the outer border of the erector spinæ mass, and runs obliquely downward and forward toward the iliac crest for 3 inches, the incision being enlarged later if required. Divide the skin, the superficial fascia, the fat, the external oblique, the posterior border of the internal oblique, and the outer edge of the latissimus dorsi. This incision exposes the lumbar fascia. Push aside the last dorsal nerve and incise the lumbar fascia, when the perirenal fat will bulge into the wound. Two distinct layers of fat exist. Tear through this fat with dissecting forceps to expose the kidney, which can now be opened while it is forced into the wound by the hand of an assistant making abdominal pressure. In some cases the kidney can be brought out of the wound for exploration and operation. In others it cannot. When it cannot be drawn out it is brought into the wound and supported by means of a pad of gauze under each pole.

Kocher's incision for nephrotomy is begun in the angle between the sacrolumbalis muscle and the twelfth rib, and is carried downward, forward, and outward to the axillary line (see Fig. 285). This incision divides the skin, subcutaneous tissues, lumbar fascia, the latissimus dorsi, and the serratus posticus inferior muscles. If possible, the kidney is brought out of the wound.

Edebohls's method enables the surgeon to explore the kidney thoroughly because this organ is brought outside of the body. It is not suited to cases in which the organ is much enlarged or when it has a short pedicle. Its best field is in operations for movable kidney. The patient lies prone, with a large cylindrical inflated rubber pad beneath his abdomen. A vertical incision is made close to the border of the erector spinæ muscle, from just below the last rib to just above the iliac crest. The sheath of the muscle is not opened. The fibers of the latissimus dorsi are separated by blunt dissection. The iliohypogastric nerve is found and retracted. The transversalis fascia is incised and the fatty capsule reached. The two layers of the fatty capsule are torn through and the kidney exposed. The fatty capsule is *well separated* from the kidney front and back. The patient is pulled by the legs toward the foot of the table, the pad remaining stationary. This change of position brings the pad beneath the chest, abdominal respiration takes place, the kidney is forced into the wound, and can be easily withdrawn and thoroughly examined. In many cases the lumbar incision does not expose the kidney pedicle enough to make the surgeon feel that he can readily clamp it should nephrectomy become necessary, and in any operation upon the kidney nephrectomy may at any minute become necessary. Cutting the twelfth rib adds to the exposure, but in cutting it the pleura may be opened. Wm. J. Mayo ("Annals of Surgery," Jan., 1912) in 203 lumbar operations divided the twelfth rib 51 times, and in 13 of the operations accidentally opened the pleural cavity. In not a case did the lung collapse (probably because the patients lay upon the abdomen with the hips somewhat elevated, the chest being fixed by the position). In each case the torn pleura was sutured, the stitches including tissue of the diaphragm.

Mayo discovered that after division of the quadratus lumborum muscle

and the lateral arcuate ligament (which binds the twelfth rib to the transverse process of the first lumbar vertebra) the rib can be lifted out of the way and does not need to be divided. Mayo now operates as follows: Beginning over the eleventh rib 2½ inches external to the spines of the dorsal vertebræ make a longitudinal incision 3 inches in length. From this point carry the incision downward and forward along the anterior margin of the quadratus lumborum to 1 inch above the crest of the ilium; then carried it forward parallel to the crest. The twelfth rib is cleared nearly to its articulation; the pleura is pushed up out of the way. The erector spinæ mass is retracted toward the spine. The costal margin is raised by retraction. A wide area for operation is exposed, the kidney can be brought out of the wound, and the pedicle can be seen and reached.

A common method of opening the kidney is to make a longitudinal incision through its convexity sufficiently large to admit the finger into the renal pelvis. This incision may be enlarged if necessary until the kidney is split in half. When the operation is finished close the kidney wound completely by means of a round needle and catgut, unless drainage is necessary or packing is required. Another popular incision is placed longitudinally a little posterior to the convex border. This goes through the bloodless zone of Hyrtl, and causes less hemorrhage than the incision along the convexity. Marwedel's incision is a transverse cut at the middle of the convex border of the kindey into the renal pelvis. It is doubtful if this incision is accompained by less bleeding than longitudinal incision of the convexity. After the completion of our work on the kidney the lumbar wound is closed completely or is partially closed to permit of drainage.

Operation for Stone in the Kidney by Pyelotomy or Nephrotomy (Pyelolithotomy, Nephrolithotomy).—It used to be held that incision of the pelvis of the kidney is far more apt to be followed by fistula than incision of the substance of the kidney. The Mayos, Bevan, and others have proved that this conviction is untrue. In many cases of stone pyelotomy is preferred to nephrotomy. It is used for single stones of moderate size in the pelvis and unaccompanied by suppuration. When we have a large branched stone, coral-shaped stones, multiple stones, and stones accompained by distinct and gross evidences of infection, then nephrotomy should be preferred to pyelotomy (Bevan and Smith, in paper read before the American Surg. Assoc. in 1908). In both operations the patient is placed on the sound side with a sand-pillow or cylindrical air-bag under the flank. In both cases the incision recommended for nephrotomy is used. In both cases the kidney is lifted into the wound or brought out of the wound so that it may be satisfactorily palpated. In both cases bleeding is controlled by having an assistant, if possible, grasp the pedicle with his fingers or with a pair of forceps, each blade of which has been covered with a bit of rubber tube, while the surgeon opens the pelvis or the kidney tissue, removes the stone, and explores with the finger.

Pyelolithotomy.—Remove the fat from the posterior surface of the pelvis of the kidney. We may then be sure that no aberrant vessel is in our way. The normal vessels are all in front of the pelvis. The posterior wall of the pelvis is now opened, the stone is extracted, the pelvis explored, the cut in the pelvis is sutured with fine catgut sutures, the kidney is restored to place, a cigarette drain is introduced, and the wound in the loin is closed. A gauze drain should not be used as it might lead to the formation of a fistula.

Nephrolithotomy.—The methods of incision, exposure, and opening the kidney are described on page 1439, under Nephrotomy. When the kidney has been opened, loosen the calculus with the nail, and remove it with the finger, with a scoop, or with forceps. After removing the stone, suture the incision with catgut, and release the pressure on the pedicle. Hemorrhage will usually be controlled, but sometimes violent bleeding occurs. If in spite

of this plan bleeding occurs, take out the stitches and apply pressure and hot water, compress the bleeding points by suture-ligatures, and close again by Stellwagen's stitches (see Figs. 935, 936). In some cases plug with iodoform gauze, suturing the gauze in place within the kidney by fine catgut and leaving it until it loosens. When hemorrhage ceases, put a large drainage-tube down to the kidney. Close the wound in the muscles and integument and dress antiseptically. The dressings must be changed frequently and the tube should be shortened daily. In some cases nephrectomy is necessary (see page 1429). Formerly in these cases I always drained for a time and removed the kidney secondarily, believing that the patient would gain strength in the interval and stand the severe operation of nephrectomy better. I am satisfied that in most cases this view is wrong, because removal of a kidney bound down by adhesions is one of the most perilous and difficult operations of surgery.

Nephrectomy is the removal of a kidney. There are two methods of nephrectomy—the *lumbar* and the *abdominal*. The first nephrectomy (according to Watson) was performed in 1861 by an American, Walcott. The operation was transperitoneal and was for the removal of a cancerous kidney. Simon, in 1869, performed the first lumbar nephrectomy and the first successful nephrectomy. Before performing nephrectomy ascertain the competence of the kidneys. If at least 1 per cent. of urea is not being excreted, it is very unsafe to operate. Be sure that the patient possesses two kidneys. Examination of the bladder by the cystoscope will show the ureteral orifices, a strong indication that both kidneys are present. Nevertheless, when we reflect that a horseshoe kidney has two ureters, the proof is not absolute. Catheterization of the ureters is advisable if it can be performed, but it will probably require a specialist to perform it. Proof absolute of the presence of two kidneys consists in feeling both of them. If in doubt as to the question, and if uncertain as to the ability of the organ which is to be left, feel each kidney during the operation before removing either, or perform a preliminary exploratory laparotomy.

Lumbar Nephrectomy.—The patient is placed on the sound side and a pillow is placed under the loin. Several incisions have been proposed. In many cases the oblique incision is first made to permit of exploration. This incision is begun ½ inch below the last rib and at the edge of the erector spinæ muscle, and is carried downward and forward toward the iliac crest. In some cases a kidney can be removed through this cut. In other cases the cut must be enlarged. It can be enlarged by extending the cut downward. Morris enlarges it by adding to it a vertical incision, which begins 1 inch below the origin of the oblique cut. König's incision for nephrectomy consists of a vertical cut at the edge of the erector spinæ, carried almost to the iliac crest, from which point it is curved forward toward the umbilicus, and is carried to or even through the rectus muscle. After thorough exposure lift the kidney and separate it from the peritoneum, if possible, with the finger; clamp the pedicle; pass an armed aneurysm needle between the vessels of the pedicle; ligate in two places; cut between the threads, and arrest hemorrhage permanently by ligation of each vessel. If the ureter be healthy, ligate it with silk and drop it back; if it be foul and purulent, scrape it with a sharp spoon, and inject it with 5–10 minims of a 95 per cent. solution of carbolic acid (Mayo), and then either ligate it with catgut and drop it back or sew it into the wound. If hemorrhage persists from the wound, plug with gauze. Insert a drainage-tube and close the wound. If the peritoneum be accidentally opened, close it with Lembert sutures. Kocher's method is excellent, and enables the surgeon to feel the opposite kidney before removing the one which is known to be diseased. The incision is begun as described on page 1439, and is carried forward so as to expose the reflection of the peritoneum on to the colon in the posterior axillary line (see Fig. 285).[1] At this point the peritoneum is opened,

[1] Kocher's "Text-book of Operative Surgery."

and the surgeon's hand is inserted into the abdominal cavity to feel the other kidney. If another kidney exists and it is found to be healthy, the diseased organ may be removed. Brewer's personal statistics show 53 cases of nephrectomy with 2 deaths, a mortality of 3.8 per cent. ("Med. Record," March 20, 1909).

Abdominal nephrectomy is more dangerous than the lumbar operation. The position is supine. The incision is that of Langenbeck—4 inches in length in the linea semilunaris, its center corresponding to the umbilicus. Open the abdomen, introduce a hand, feel the kidneys, and if both show serious disease, do not perform nephrectomy. If we decide to remove one kidney, keep the small intestine away by pads, push the colon toward the umbilicus, incise the outer layer of the mesocolon, and bare the kidney. Strip off the peritoneum from the kidney and its vessels, and ligate the vessels by passing strong slik through the center of the pedicle with an aneurysm needle. Ligate the ureter if healthy, and divide it. If the ureter be septic, fasten it in an open-

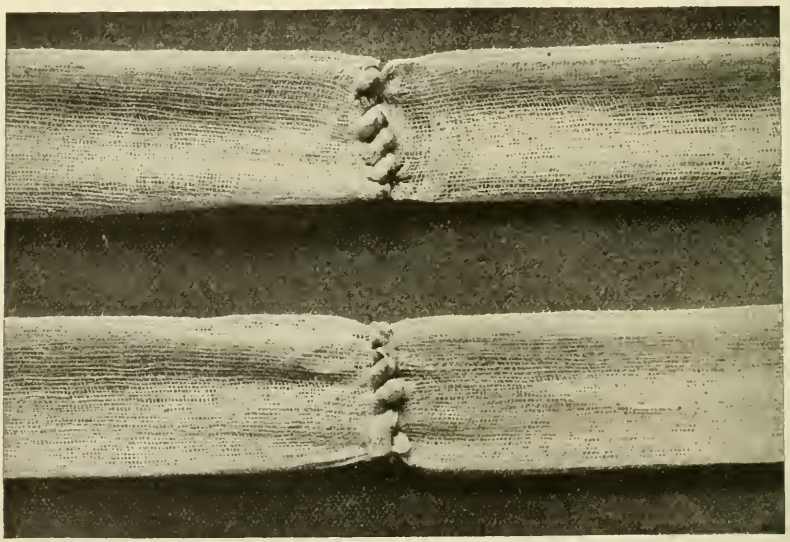

FIG. 938.—Gauze slings, each composed of two pieces sutured together with fine plain catgut.

ing made in the loin by cutting down upon forceps pushed to the outer edge of the quadratus lumborum. Stop bleeding, irrigate the belly cavity, and dress as usual, employing drainage only when septic matter has passed into the peritoneal cavity or when oozing of blood is persistent.

Nephrectomy in Children.—The operation is proper in certain non-malignant troubles. William Jepson (Jour. A. M. A., Sept. 28, 1910) did a successful nephrectomy for a congenital cystic kidney on a patient four months and fourteen days of age. Rovsing did it successfully for congenital hydronephrosis, the patient being nine months old. Roswell Park did a successful nephrectomy for congenital cystic kidney on a child twenty-three months of age. The value of nephrectomy for sarcoma is certainly doubtful. The operation never really cures, and if an operative recovery is obtained the disease appears after a time in the other kidney. Jessup performed nephrectomy in 11 children and every case died within two and one-half years of the operation. The operation often prolongs life and relieves discomfort, but does not cure.

Partial Nephrectomy.—This operation may be performed in some cases for wounds, cysts, and innocent tumors. After removing the damaged or

diseased part, bleeding points are ligated with catgut. The wound surfaces are approximated as well as possible by catgut sutures. Drainage is introduced. The value of partial nephrectomy in some cases seems certain, and we should perform it when possible instead of the complete operation,[1] except in cases of malignant disease.

Renipuncture.—This is an operation devised by Reginald Harrison for the relief of albuminuria due to elevated tension. The kidney is exposed in the loin, the capsule is incised, and punctures are made in the kidney. Simple incision of the capsule will usually relieve nephralgia. (See Operation for Chronic Nephritis, page 1437).

Nephropexy is fixation of a movable kidney. The term "nephrorrhaphy," so long used for the operation, really means suturing a wound in the kidney.

The Author's Modification of the Elder Senn's Operation.—Many surgeons feel that it is not desirable to pass sutures through the kidney substance, and I have entirely abandoned the use of them in operations for movable kidney. Urinary fistula has followed suturing. Again, the value of such sutures is very doubtful. The kidney is a very soft

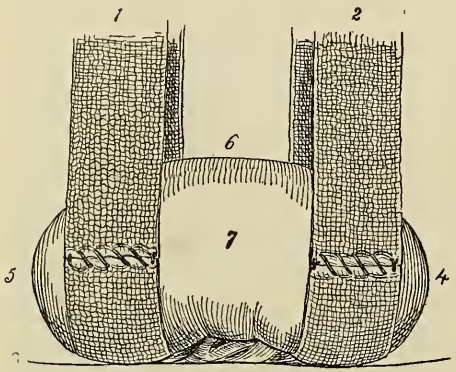

Fig. 939.—Right kidney projecting from wound. Observer standing on right side of patient: 1 and 2, Slings in place, with sutures external; 3, skin of the back; 4, upper renal pole; 5, lower renal pole; 6, convex border of kidney; 7, external surface of kidney. (Slings should be broader than those shown in illustration.)

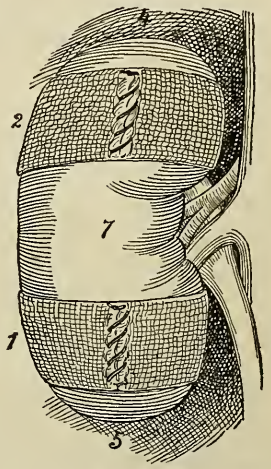

Fig. 940.—Right kidney restored to place, seen from in front: 1 and 2, Slings in place, sutures anterior; 4, upper renal pole; 5, lower renal pole; 7, anterior surface of kidney. (Slings should be broader than those shown in illustration.)

organ, and if it be suspended by sutures, they are certain to cut through. In most suture operations the kidney when restored is not placed sufficiently high and has its ureter and vessels looking forward; in other words, there is a one-fourth twist in the ureter. In operations like Goelet's and Kelly's, which raise the kidney much nearer its proper level and which do not twist the ureter and renal vessels, the upper pole is not anchored and tends to tilt forward (see page 1424). The operation herein described fixes the kidney without using sutures.

The patient lies upon his abdomen, Edebohls' bag being placed directly beneath the lower abdomen. A vertical or slightly oblique lumbar incision is made, the perirenal fat is exposed, and its two layers are torn through until the kidney is reached. The fatty capsule is thoroughly stripped from the entire organ. The kidney is brought out of the wound. This is accomplished by pulling the patient toward the foot of the bed, so that the pad gets under the

[1] See Oscar Bloch, in "Brit. Med. Jour.," Oct. 17, 1896; also reports of Czerny, Bardenheuer, Tuffier, and Kümmell.

ribs, when traction on the fibrofatty capsule will cause the kidney to emerge from the wound. The posterior fatty capsule is cut away, and also the anterior fatty capsule up to the hilum. The true capsule of the kidney is scarified. I always have packing prepared by suturing together with the finest plain catgut the ends of two pieces of iodoform gauze. Two such strands are prepared (Fig. 938). One piece of iodoform gauze is placed under the upper end of the kidney, and another piece under the lower end, the sling in each instance being directly under the kidney with the suture line external and not in front, as the kidney protrudes from the wound in the back (Fig. 939). When the kidney is replaced the suture line will lie in front (Fig. 940). The kidney is replaced and will then lie in a sling composed of two pieces of gauze, the ends of which protrude from the wound. Another piece is placed below the lower renal pole to fill up the space which always exists there and to stimulate granulation. This space below the kidney is a frequent cause of subsequent loosening in most

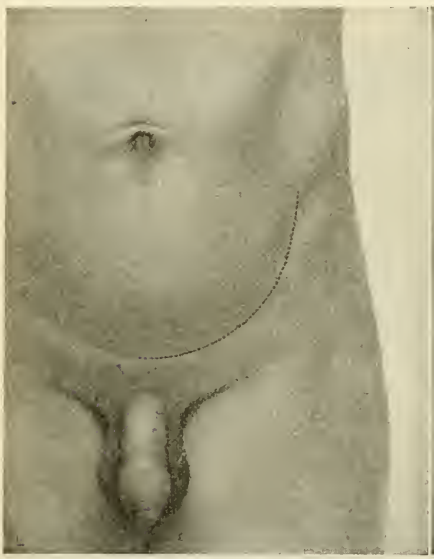

FIG. 941.—Gibson's incision for operations on the lower ureter. The superficial incision (C. L. Gibson).

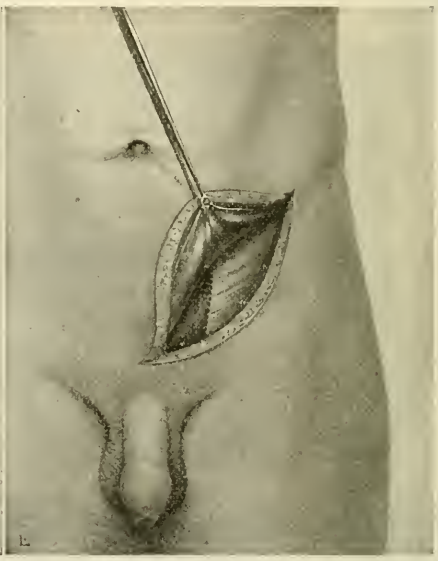

FIG. 942.—Gibson's incision for operations on the lower ureter. The upper flap, consisting of skin, external and internal oblique muscles, is retracted. The dotted line represents the line of incision in the transversalis fascia (C. L. Gibson).

suture operations, because the kidney hangs in it unsupported, as a bucket hangs in a well. Harris recognizes this, and in his operation closes the space by sutures. Gauze is packed in over and about the kidney, and over this the two long slings are tied. Several sutures of silkworm-gut are inserted to close the superficial parts and the lumbar aponeurosis; some are tied and some are left untied. A large gauze pad is placed upon the abdomen over the anterior surface of the kidney, and the lumbar wound is dressed with gauze. The dressing and gauze pad are held in place by a binder. In about eight or ten days the gauze should be soaked with dripping salt solution during half an hour and the packing removed. At this time the catgut is destroyed and the gauze can be easily pulled out. The tied sutures are cut and removed, the sutures left unfastened are tied, and a small piece of gauze is inserted as a drain between the granulating surfaces. If a continuous piece of gauze has been used, ether must be given before removal is attempted. Further, in the old operation, a large

wound was left to granulate and weeks were often required to obtain healing. In this operation the wound is usually entirely healed in from eighteen to twenty-one days. After the performance of nephropexy the patient remains in bed for three weeks. By this operation the kidney is placed in a proper situation, is surrounded with granulations which are converted into scar-tissue, and the organ becomes encased in a box of fibrous tissue. I believe that a kidney so treated will probably remain fixed.

If a kidney has been decapsulated, gauze slings should not be placed around it, because removal of them might lacerate the kidney. After decapsulation the surgeon rests content when he has filled the space below the kidney with a support of gauze.

Ureterolithotomy.—If the stone be impacted in the upper two-thirds or three-fourths of the tube it may be reached by an incision from the twelfth rib downward and forward to just anterior to the anterosuperior spine of

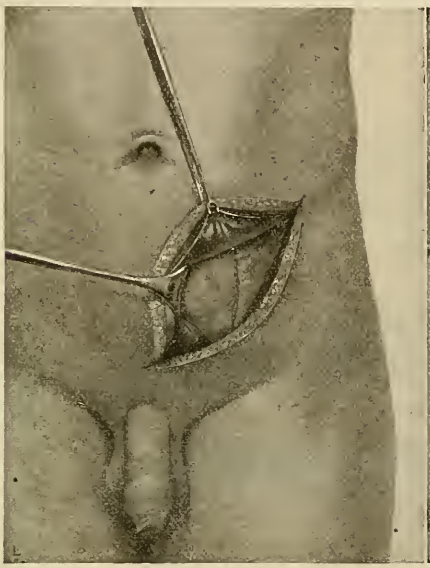

Fig. 943.—Gibson's incision for operations on the lower ureter. The edge of the rectus muscle is strongly retracted inward; between it and the cut edge of the transversalis fascia the peritoneum is exposed (C. L. Gibson).

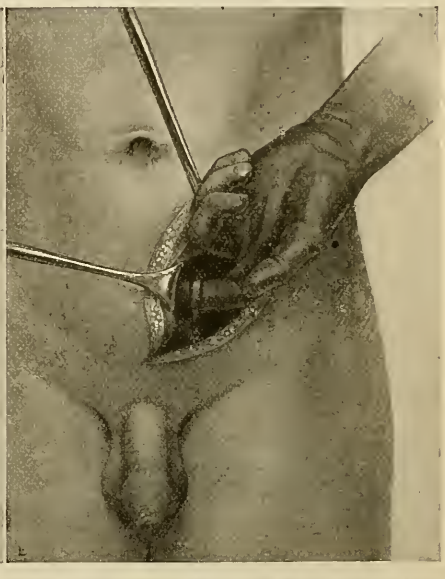

Fig. 944.—Gibson's incision for operations on the lower ureter. The peritoneum has been pushed upward. The ureter is lifted out of the pelvis and brought to the level of the external wound (C. L. Gibson).

the ilium and then parallel to Poupart's ligament to above its middle. The peritoneum is stripped up as in extraperitoneal ligation of the iliac vessels. The ureter adheres to the peritoneum. The operation is strictly extraperitoneal.

Gibson's incision for operations on the lower ureter ("Amer. Jour. Med. Sciences," Jan., 1910) is the most useful for reaching and amply exposing the lower ureter. Further, it enables us to feel and accurately to operate upon the tube, the entire operation being extraperitoneal. Gibson thus describes his operation:

"The skin incision runs from the midline about a finger's breadth above the pubes, horizontally outward nearly parallel to Poupart's ligament at first (Fig. 941), and curves rather sharply upward at its midpoint to end about opposite the anterior superior spine of the ilium. This incision is deepened in the same line through the aponeurosis of the external oblique and the internal oblique muscle—the latter is the only structure which suffers any real damage, and only to a slight degree, for the lower part of the incision runs

about parallel to its fibers, cutting only the ascending leg across a small part of these fibers. The incision stops short of the transversalis, which is not disturbed at all. With efficient retraction of the upper flap the external border of the rectus muscle is identified (Fig. 942) and the *fascia* of the transversalis is now divided by a vertical incision close to and parallel to the rectus—that is, at *right angles* to the original incision. Two retractors are now inserted, the outer one retracts the cut edge of the transversalis outward, the other (Fig. 943) pulls the rectus muscle well toward the midline. A generous space is thus obtained, situated well toward the midline (the lower part of the ureter is practically in the midline and difficult of access by other extraperitoneal exposures). The floor of this space is occupied by the peritoneum. The patient being in a complete Trendelenburg position, the peritoneum is easily and gently pushed away, and a free access to the pelvis is secured. So ample is the space and view that the whole hand can be introduced under the control of the eye. The ureter is released from its surroundings and easily brought to the level of the wound" (Fig. 944).

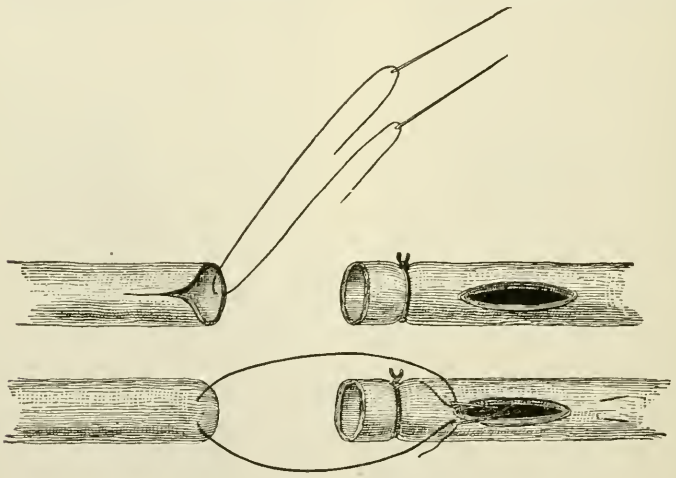

Fig. 945.—Van Hook's method of ureteral anastomosis.

When the tube has been exposed it is opened by a longitudinal incision. The stone is removed. The ureter is explored by means of a sound to see if it be patulous. After removing the stone, close the wound in the ureter with sutures of very fine chromic gut. Deep sutures pass through all the coats and are tied. Over this a layer of superficial sutures is inserted. Close the tissues about the ureter and drain by rubber tissue. Never drain by gauze. To do so will cause a urinary fistula. In a woman a stone near the vesical opening can be reached by a vaginal incision. Stone in the vesical portion of the ureter may perhaps be removed by aid of an operating cystoscope or by forceps after the performance of a suprapubic cystotomy.

Judd exposes the lower two or three inches of the ureter by making a median incision from the umbilicus to the symphysis, by retracting but not opening the peritoneum and by drawing the bladder toward the median line ("Annals of Surgery," 1914, lix).

My colleague, Prof. John H. Gibbon, advocates a combined intra- and extraperitoneal route for stones anywhere in the lower two-thirds of the ureter. The peritoneal incision permits of exploration and exact localization of the stone, allows the surgeon to push the calculus from an inaccessible into an easily reachable position, and makes the removal vastly easier. The stone

is removed by extraperitoneal incision of the ureter, and the peritoneum is closed. (Gibbon, in "Annals of Surg., Gynec., and Obstet.," May, 1908).

Uretero-ureterostomy (*Van Hook's Operation*).—In this operation ligate the lower end of the divided ureter with silk or catgut. About ¼ inch below the ligature make an incision in the long axis of the tube. This incision is in length equal to twice the diameter of the tube. Each end of a piece of fine catgut is threaded to a fine needle. This thread is passed through the upper end of the ureter (Fig. 945). The needles are made to enter the lower end of the tube through the door made by the surgeon. They are pushed through the wall of the ureter ½ inch below the door (Fig. 945). Traction upon the strings causes invagination, and the ligature ends are tied. If the operation be intraperitoneal the ureter is wrapped about with peritoneum.

Intestinal Implantation of the Ureters.—This operation may be employed in exstrophy of the bladder and in vesical cancer in which it is necessary to remove the bladder. After this operation there is danger of infection of the ureters and consequent ascending ureteritis and pyelonephritis, and the presence of urine in the bowel usually causes inflammation of the rectum and incontinence of urine may take place.

Maydl asserts that a piece of the bas-fond should be removed with the ureter, and implanted with it into the intestine, the flange hanging free in the lumen of the gut. If this be done, the relations of the ureter to the muscular coat of the bladder are not interfered with, stricture is less likely to occur, ascending infection is antagonized, and suppurative conditions arise at the margin of the flange rather than, as in other methods, directly in the cut ureter. Maydl has collected the records of 14 cases operated upon by this method, with 2 deaths.[1] I performed it twice, with 1 death. In vesical exstrophy Peterson transplants a vesical flap containing both ureteral orifices into the descending colon.

Cystoscopy is the employment of the cystoscope for the study of the interior of the bladder, the prostate, the ureteral orifices, and the appearance of the fluid from each kidney.

The cystoscope is an instrument of great value in the hands of a skilful and experienced man, but is practically useless when employed by a novice. All of my cystoscopic examinations are made for me by Dr. Stellwagen or some other expert. In using a cystoscope the mucous membrane may be burned with a hot lamp. This causes inflammation, and if an eschar forms, it will be cast off, exposing a granulating surface. Schmidt, in calling attention to this injury, speaks of the condition as *ulcus cystoscopicum* and says that it is in the fundus, has the shape of the instrument, and heals in from fourteen to twenty-one days ("Jour. Amer. Med. Assoc.," July 19, 1902).

Cystoscopic examination of the bladder owes its present position to Messrs. Max Nitze and Joseph Leiter, who were the first to introduce practical instruments: Nitze in 1876 and Leiter in 1879. The great obstacle in former years was the danger of burning the mucous membrane by overheating of the lamp. The invention of the cold lamp by E. C. Preston eliminated that danger, and was a great step forward. Nitze was the first to recognize the futility of examination by reflected light and constructed an instrument with the light on the end which to-day is copied by all of the modern instruments.

Cystoscopes may be divided into several types: (1) The examining instrument; (2) the instrument carrying ureteral catheters or the catheterizing cystoscope; (3) the operating cystoscope. They all have certain mechanical features in common, but differ in their construction and lens arrangement.

The examining instruments are of two fundamental types—the direct and the indirect. In the direct there is a straight telescope with a series of wide angle lenses that give the picture of the bladder in front and slightly to the side.

[1] Editorial in "Jour. Amer. Med. Assoc.," May 6, 1899.

In the indirect the lens is so ground and set as to enable the operator to look toward the prostate.

Catheterizing cystoscopes are also of two kinds—the direct catheterizing and the indirect. In the direct catheterizing cystoscope the catheters are passed directly from the carrying tubes into the ureters. In the indirect catheterizing cystoscope the catheter is bent or directed by a lever on the end of the instrument operated by a thumb-screw on the penile end. By raising or lowering the lever the angle of the catheter is altered to facilitate its introduction into the ureteral orifice.

It is obvious that the bladder should be distended in order to permit of cystoscopic examination. For this purpose air and water have been utilized.

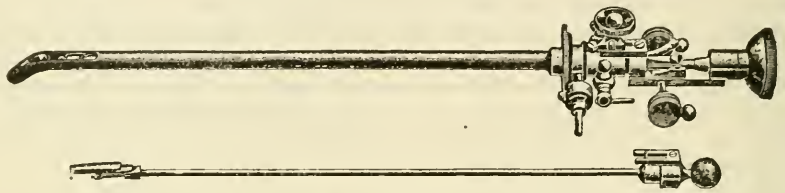

Fig. 946.—The A. C. M. I. double catheterizing cystoscope.

The modern tendency is in favor of water distention. Some of the operating instruments, notably that of Prof. Lewis, require air.

Water as a dilating medium is superior to air, unless operative work is to be done through the instrument, in which case the inevitable hemorrhage precludes the use of water. The air instruments show but a small field, the distention causes pain and is often followed by mild cystitis.

From the foregoing it is plain that one type of instrument is not suited to all cases, and each has its claim to practical utility. Some cases can be most readily catheterized by the direct, while others are only reached by the indirect, plan. It is my conviction that if the ureteral orifices are normally placed, the direct method is quicker and more readily learned by the beginner.

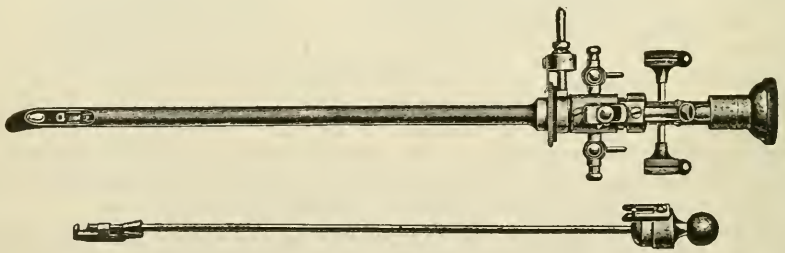

Fig. 947.—The A. C. M. I. operating cystoscope.

Men who have had training had best use the A. C. M. I. cystoscope (Figs. 946, 947). It is an indirect or oblique cystoscope, but has a corrected image field which enables the operator to work as he sees and not the reverse (as in necessary with the uncorrected image field). These new instruments cause less pain than direct instruments, and give a very wide field. When from any cause the ureteral orifice turns backward (which only happens in a very small percentage of cases) the indirect cystoscope is indispensable, it being practically impossible to reach the ureteral orifice by the direct instrument.

There are at present many different forms of cystoscopes on the market, notable among them being the Nitze, Casper, Tilden Brown, Cabot's modification of the Tilden Brown, Buerger, Albarran, Bransford Lewis, and the so-called Universal. The universal instruments of Bransford Lewis and Tilden Brown possess features of great practical utility.

Sterilization of Cystoscopes and Ureteral Catheters.—In order to sterilize the cystoscope before using, place it for five minutes in a solution of mercury oxycyanid (1 : 1000) or formaldehyd (1 : 500). The sterilizing power of formaldehyd gas is not to be relied on. Some operators use a 5 per cent. solution of phenol, in which the instrument is immersed for twenty-four hours, after which it is dipped into glycerin, which both neutralizes the phenol and lubricates the tube. The mercury oxycyanid solution is easily used and is thoroughly satisfactory. Should formaldehyd solution or formalin gas be used, always wash the instrument thoroughly with salt solution before using to prevent irritation by the sterilizing medium.

Dr. M. P. Willard, of San Francisco, in "Jour. Amer. Med. Assoc.," October 4, 1913, advocates the following method for sterilizing ureteral catheters: The ureteral catheter is placed in a muslin bag 2 cm. wide by 75 cm. long. The bag is enclosed, with the catheter in it, in paraffin paper, and secured by encircling strips of adhesive plaster. As many may be prepared as is thought necessary. The package is placed for twenty minutes in an autoclave with a pressure of 8 to 10 pounds. When the catheter is to be used the paper is removed and the end of the instrument is exposed by pulling back the linen bag and the tip of the catheter is engaged in the carrying tube of the cystoscope. As the catheter is fed through the cystoscope the linen bag is pulled back; in this way the fingers do not come in contact with the catheter.

Ureteral catheters can be sterilized by placing them in an open shallow dish containing a saturated solution of ammonium sulphate or sodium chlorid and boiling them for five or ten minutes. The following precautions must be observed: Each catheter should be wrapped in gauze and the bottom of the pan covered with gauze. If the catheters are allowed to touch each other or curl upon themselves the shellac coating will melt and ruin the instruments. They may also be sterilized in the same manner as the cystoscope, care being taken if formalin has been used to wash away carefully the germicide, especially from the lumen of the catheter.

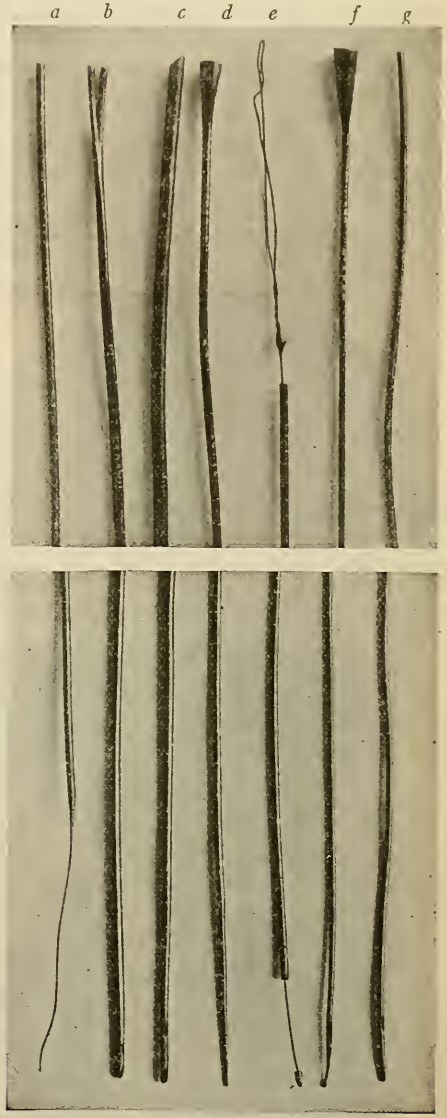

FIG. 948.—Different types of ureteral catheters: *a*, Blasucci; *b*, return flow for irrigation; *c*, Garceau; *d*, another type of Blasucci; *e*, Cunningham; *f*, olivary tipped; *g*, *x*-ray whistle tip.

Contra-indications to Cystoscopy.—The bladder must hold at the very least 50 c.c. of fluid. If it holds less cystoscopy is useless. Examination is either

impossible or unsatisfactory if the prostate be greatly enlarged. Contracted meatus urinarius and stricture of less caliber than No. 24 of the French scale are correctible contra-indications. Papillomata and other tumors and foreign bodies of the urethra are impediments. In acute Bright's disease instrumentation is dangerous, because it may be followed by suppression of urine. The

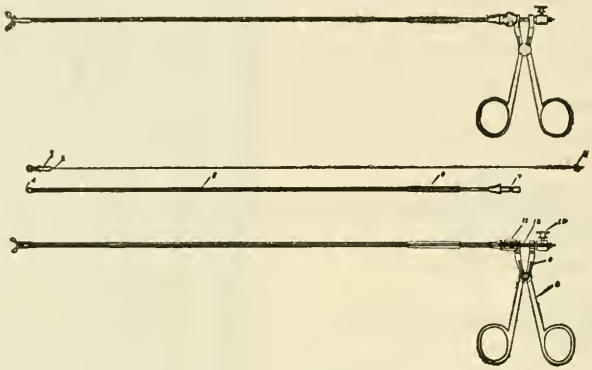

Fig. 949.—Buerger's rongeur forceps with flexible shank for use with Buerger's operating cystoscope.

following are further contra-indications, as suggested by Follen Cabot and Henry G. Spooner, in "Med. Record," July 11, 1903: When it is obvious that operative intervention would be useless; when there is a large tumor; in acute cystitis; in tuberculosis in which the diagnosis is evident without the cystoscope. In women, pelvic adhesions and large exudates may interfere with cystoscopy.

Fig. 950.—Tilden Brown's cystoscopic table with patient in position for examination.

Technic of Cystoscopy.—The patient should, if possible, be carefully sounded once a day for several days previous to the cystoscopic examination; this establishes tolerance of the urethra. He should be placed upon a suitable table, such as that devised by Tilden Brown or Bransford Lewis, as shown in Fig. 950.

The urethra is cleaned by irrigation with salt solution. General anesthesia is rarely necessary provided the operator is gentle in his manipulations. There are, however, some hypersensitive urethras which it is necessary to anesthetize. Cocainization of the urethra will usually suffice. This is carried out by instillation through the Keyes-Ultzmann syringe or, better, through a soft-rubber catheter into the posterior portion of the canal of 1 dram of a 4 per cent. solution of cocain. Alypin, placed in the canal at the points of greatest tenderness by means of Dr. Lewis's repositor, answers very well. These tablets are allowed to dissolve in the urethral mucus. The points of greatest tenderness are the fossa navicularis, the bulbo-membranous junction, and the prostatic urethra about the verumontanum. In cases complicated by cystitis preliminary lavage of the bladder should be practised. This may be given through the cystoscope sheath or through a soft-rubber catheter. If the bladder be not diseased, it is merely necessary to draw off the urine. After the urine has been withdrawn, the cystoscope sheath should be firmly but gently held in place. The thumb of the left hand presses downward while the index-finger presses upward on the under surface of the sheath. This procedure raises the beak of the instrument from the sensitive trigone, where most of the pain and hemorrhage are produced by vesical tenesmus.

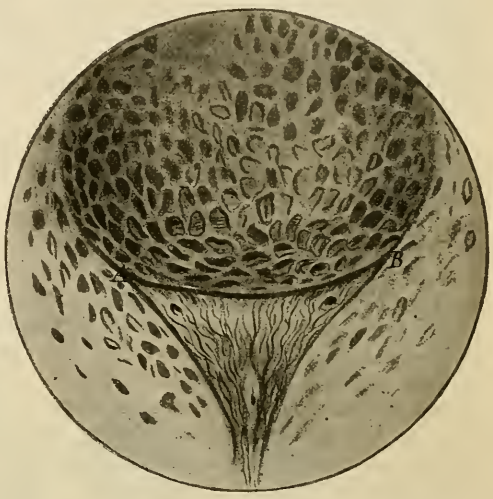

Fig. 951.—The interior of the bladder, showing arrangement of the vessels of the trigone: *A*, *B*, interureteral bar.

In regard to the selection of the distending medium, the operator may use sterile water, normal salt solution, boric acid solution, or mercury oxycyanid solution (1 : 5000). The bladder should be moderately distended and, if possible, from 8 to 10 ounces of fluid are allowed to remain in the viscus. In contracted or hypersensitive bladders it is well to elevate the hips and so relieve the pressure on the sensitive vesical neck and trigone.

The temperature of the distending fluid is of great importance, particularly if there be difficulty in finding the ureteral outlet. If this is the case, the temperature of the fluid should be about 60° F. This enables the operator to see a so-called swirl when the warm jet of urine mixes with the cold water in the bladder. It is sometimes advisable to give methylene-blue before examining for the same reason. The blue stream from the ureter at once identifies the tube.

After the bladder has been filled the telescope containing the catheters is inserted and the light is turned on. The instrument, then held in the median line, is pushed gently back, well into the bladder, pressure being always made to keep the beak from impinging upon the floor of the viscus. The cystoscope is now slowly withdrawn, a careful watch being mantained through the telescope for the *interureteral bar* (Fig. 951). This structure (there has been much argument as to whether this structure really exists) marks the posterior border of the trigone. The examiner has still another guide to the trigone in the blood-vessels, which in a general way run anteroposteriorly. There is a distinct line of demarcation between the fish-net loop arrangement of the mucous membrane of the sides and base of the bladder and the mucous membrane

in the trigone. Fig. 951 gives a general idea of the vascular arrangement. When the interureteral bar or posterior border of the trigone has been located, the instrument is gently and slowly moved laterally, so that the border of the cystoscope is kept in the field until the end of the bar is reached. The instrument is then held stationary for a moment and a sharp lookout is kept for the jet of urine or the swirl. The ureteral orifice is thus indicated. Should the field become blurred by blood on the lens, or should the solution in the bladder become mixed with blood, continuous irrigation must be kept up through the cystoscope.

The Ureteral Orifices.—As before mentioned, the ureteral orifices are usually located at the terminations of the interureteral bar, and occupy the basal angles of a triangle formed by the vesical outlet and the base of the trigone. They are usually about 1 to 1½ cm. from the median line and about 2½ cm. from the vesical end of the urethra. They are recognized as small slits or as tubercles on the surface of the mucous membrane. Their position is not always the same. Some of the abnormal positions more commonly met with are as follows: one ureter closer to or further removed from the median line, both ureters emptying into the bladder close to the median line, generally about one-quarter or one-half the length of the bar. Malposition is toward the vesical outlet and in some very rare instances both ureters empty on the same side. Sacculation and pocketing of the bladder with swelling of the mucous membrane often make localization of the ureteral orifices difficult. It is then that the administration of methylene-blue or indigo-carmin may enable the investigator to locate the ureters more readily.

After locating a ureteral orifice the vesical end of the cystoscope is carried directly over the opening and the catheter is projected against the opening, where it is allowed to remain for a moment in order to overcome the spasm of the sphincteric muscular fibers. The patient is instructed to hold his breath and the opening is carefully watched until a jet of urine is forced through, during which act the catheter is gently inserted into the ureter. The passing of the urine is accompanied by dilatation of the opening and greatly facilitates the passage of the instrument. After the catheter has passed the sphincter muscle it should be carried up the canal by *very gentle* pressure. The practice of passing the instrument quickly, so commonly resorted to by the novice in order to gain time, is pernicious, and almost invariably causes laceration and hemorrhage. Before inserting the catheter some operators prefer to coat it with paraffin in order to render it absolutely smooth and further to assist in the detection of calculus. This is not necessary. Any instrument with an imperfect eye should be discarded.

The round-pointed catheter should be used wherever possible, as with it there is less danger of injuring the delicate mucous lining of the canal. The sharp-pointed olivary tipped instrument often causes blood to appear. If possible, insert the catheter into the renal pelvis, for then hemorrhage from trauma is less likely to invalidate the examination, and spasm of the ureter, with sucking of the mucous membrane into the eye of the catheter, will not occur. Having finished the catheterization of one side, the catheter is left in place, the instrument handle is swung to the opposite side and a similar procedure is carried out. Always have a distinguishing mark upon the catheters. A very good method is to use different colored instruments, so that there may be no confusion after withdrawal of the cystoscope. In some cases only one ureter can be catheterized. In such a case the bladder should be thoroughly washed, and the other catheter, left on the floor of the bladder, will collect the urine from the uncatheterized side and give a fair idea of the condition of that kidney.

Removal of the Cystoscope.—The light should be turned off and a small amount of fluid allowed to escape through the barrel. The lens system carry-

ing the catheter is then loosened and gently rotated from side to side to free the catheters. During this procedure the catheters are drawn gently backward, but not with sufficient force to cause kinking, and the lens system is removed. Next the sheath is withdrawn by carrying it straight up over the abdomen.

Collection of the Urine.—The protruding catheters are carefully wiped with sterile gauze and are permitted to drain into separate bottles or test-tubes, marked respectively right and left. The orifices of the receivers should be plugged with sterile absorbent cotton, which will collect and prevent any admixture of urine or water coming from the bladder by capillary drainage. The bottles should also be held in such position as to prevent such capillary drainage reaching them. With regard to the collection of the samples, there are certain precautions that should be observed: (1) The samples should, if possible, be collected in three separate bottles from each side, allowing each set to remain in position a definite time, generally one-half hour. These should be carefully watched and marked first, second, and third half-hours. They should each be examined separately, and by a summation of the examinations the opinion should be reached. Almost invariably microscopical blood can be found in the urine drawn by catheterization of the ureters. In a study of 15 cases of normal

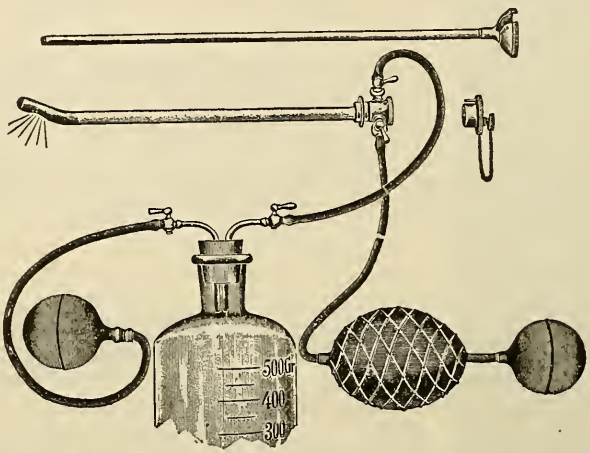

Fig. 952.—Bulbs and bottle for distending bladder and collecting washings.

ureters, blood not being present before catheterization after catheterizing with the greatest care, microscopical blood was present in all but 3. The erythrocytes are usually most numerous in the first bottle, gradually diminishing, until in the third there are very few or none. Should the blood increase in amount in the second or third bottle, it is an important clinical fact.

In some instances one or both catheters fail to drain. This may be due to a bubble of air in the instrument, impinging of the mucous membrane upon the eye, plugging by blood-clot, mucus, pus, or particles of gravel. A syringe is then essential. The blunt hollow needle should be inserted into the catheter and suction applied; should this fail, not over 4 c.c. of sterile normal salt solution may be injected through the catheter. This procedure, however, must be carried out very gently, because of the danger of overdilating the renal pelvis and thus producing colic.

The carrying capacity of the pelvis of the kidney is uncertain. Careful observations indicate that there is no definite carrying capacity that may be called normal. The range of difference is great and even differs at certain times in the same kidney. In many kidneys it is about 8 to 10 c.c., but, on the other hand, it may be as high as 20 c.c. and still be normal. It would seem as though the blood-supply of the organ had something to do with the pelvic

capacity, for a congested circulation means distended vessels, and they probably impinge upon the pelvis. Again, the question of producing renal colic by overdilatation of the pelvis is a very uncertain guide as to the capacity, for in many instances the ureteral and pelvic musculature is sufficient to force the fluid down the ureter with the catheter *in situ* and yet produce no evidence of

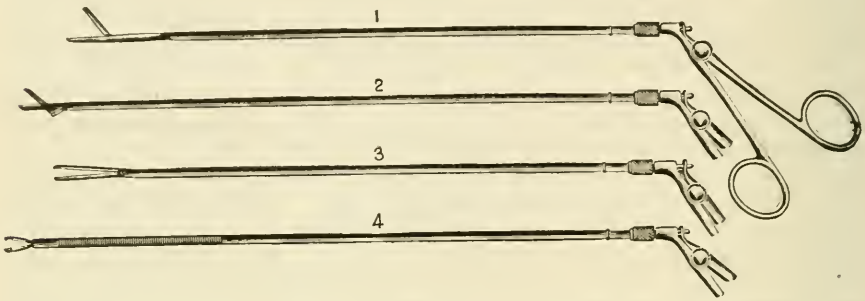

Fig. 953.—1, Scissors; 2, tweezers; 3, forceps; and 4, punch for use with the Lewis's cystoscope.

colic. This has been seen in many instances in making a pyelographic study by means of a solution of collargol, which is much thicker than urine or water.

A uropyknometer is used for taking the specific gravity of small quantities of urine removed by the ureteral catheter.

The Operating Cystoscope.—The most practical operating cystoscopes are Bransford Lewis's and the A. C. M. I. instrument (see Fig. 947). These instru-

Fig. 954.—"Universal" cystoscope with wire snare.

ments greatly facilitate the removal of small portions of stone and foreign bodies from the bladder and the ureteral orifices. They are also useful for making applications to ulcerated areas. It is not wise to remove papillomatous tumors by them, as most villous papillomatous growths sooner or later exhibit the elements of malignancy and should have their pedicles removed with a portion of the vesical wall, which can only be safely done after suprapubic cystotomy.

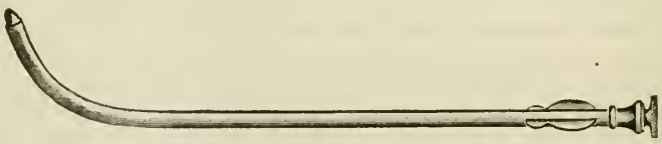

Fig. 955.—Lewis's repositor.

We have succeeded in fulguration of intravesical papillomata of a benign type by means of the high-frequency current, and Prof. Hiram R. Loux has had several such cases that have remained well for over two years.

Practical Value of Cystoscopy and Ureteral Catheterization.—The cystoscope has attained a very important position in the surgeon's armamentarium. It undoubtedly affords the best method of establishing an accurate diagnosis founded on pathological findings. By it one is enabled to determine the pres-

ence and character of cystitis, stone, foreign bodies, and malformations. Without it the presence of ulcerations could merely be guessed at by the clinical history. Its greatest field is in the early diagnosis of the cause of renal and vesical hemorrhages. In the detection of renal neoplasms it may be said to have revolutionized surgery. It makes possible the early removal of such growths before malignancy has signed the patient's death warrant. Cases of prostatic hypertrophy, in which the lobes project backward, cannot be accurately diagnosticated without the cystoscope; with it the parts can be seen and the clinical diagnosis positively confirmed. It makes possible the removal of small foreign bodies, such as stone, pieces of cotton, or filiform bougie through the urethra, thus saving formidable cutting operations. It is needless to mention the great difficulty found by surgeons in former years in determining the source of symptomless hemorrhage, a problem which is now comparatively easy of solution.

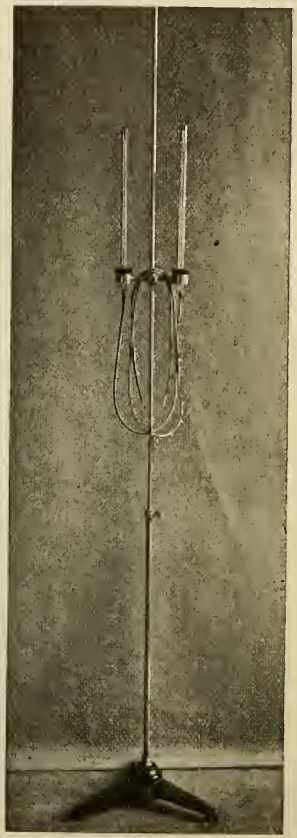

Fig. 956.—Apparatus for filling pelves in pyelography; also for doing lavage of ureters and pelves.

Ureteral catheterization makes possible the irrigation of the ureter and pelvis of the kidney in cases of ureteritis and pyelitis.

The technic of lavage is as follows: The gravity tubes for instilling fluid, shown in Fig. 956, are carefully sterilized and the metal nozzles arranged so as to fit correctly the lumen of the ureteral catheters. It is always necessary to make certain that the nozzles will fit and that they and the catheters are free. This should never be neglected. It has been found on several occasions that one or the other was blocked, and, again, any particles of catheter or other material that might form a nidus for stone formation should be washed out. We advise the irrigation to be done by means of gravity in preference to a syringe, as the fluid may be delivered more evenly and, so to speak, may be "sneaked" into the pelvis of the kidney. This gentle trickle of warmed fluid does not seem to excite acutely the musculature of the ureter and pelvis; in consequence there is not so much colic, and if colic occurs it does not persist so long. About this point there has been some difference of opinion, but the evidence is in favor of the gravity method both for lavage and pyelography.

There are several solutions that may be used. We believe that normal salt solution is the best for mere cleansing purposes. Saturated solution of boric acid may be used if a mild antiseptic be needed. Either of these solutions may be followed by the different silver solutions in strengths calculated to suit the case in hand. The nitrate of silver is generally used in a strength of 1: 8000, but a much stronger solution may be resorted to. In the clinic of Prof. Loux excellent results have been obtained from a 10 per cent. solution of argyrol.

The catheters are passed into one or both ureters and the fluid is permitted to pass very slowly into the pelvis or ureter, as the case may be. Overdistention must be guarded against, and a safe rule is not to allow over 8 c.c. to be used at any one time.

The type of catheter to be used may be according to the fancy of the operator. There is at present a very excellent two-way pelvic irigating ureteral catheter,

or the single tube instrument may be used and the fluid allowed to escape after filling the pelvis. This procedure should be repeated until the return fluid is clear. Should hemorrhage complicate the procedure, an irrigation of adrenalin may be used. (This has been known apparently to cure essential renal hematuria.)

After completion of the irrigation the bladder should be thoroughly washed and the patient put upon some mild genito-urinary antiseptic, of which there are several. Urotropin is the one usually given.

It would seem a wise plan to irrigate thoroughly the kidney, pelvis, and ureter before certain surgical operations. When a surgeon is about to open the kidney in the presence of pus or infected urine, before cutting down upon the kidney it is well to wash away as much as possible of the purulent matter through a ureteral catheter and then instil some nitrate of silver or collargol, which is the silver preparation used in making pyelographic studies.

FIG. 957.—*A*, Dilated kidney pelvis filled with collargol solution; *B*, kink in ureter; *C*, dilated ureter filled with collargol solution; *D*, constriction of ureter; *E*, ureteral catheter. (Taken by Dr. W. F. Manges.)

Irrigation of the pelvis and ureter has become a rational surgical procedure and in many cases is followed by a marked improvement in the general health of the individual, making operative procedure safer and not complicated by so marked a toxemia. In all cases when operative work is to be done on a kidney with a large pus sac of other than tuberculous origin, irrigation of the pelvis by means of one of the milder antiseptic silver solutions would seem to be a proper surgical procedure. It is especially so when the necessity may arise for opening the peritoneal cavity.

A differential diagnosis must sometimes be made between gall-bladder disease, appendicitis, and movable kidney with dilated pelvis. This is done by determining the carrying capacity of the pelvis by means of the injection of salt solution and by making a pyelograph (Fig. 957). If the trouble is in the kidney, pain caused by injection of salt solution will be similar in character and

situation to the pain of the attacks. As a rule, in movable kidney producing marked symptoms the renal pelvis is dilated. When the trouble is due to the kidney the pain induced by the distention is similar to that from which the patient has suffered (Howard A. Kelly). If a stone be present in the ureter the *x*-ray picture will usually reveal it, but here again there may arise doubt as to the exact course of the canal. Catheters passed into the ureters, each catheter with a lead wire in it, can be skiagraphed, and the radiographer will be able to determine the exact course of the ureters. Instead of a catheter containing a wire the *x*-ray catheter of Eynard may be used. Fig. 958 shows the practical utility of such manipulation. Phleboliths, fecal masses, appendoliths, concretions, and calcified lymph-nodes have been mistaken for ureteral stone even after a study of skiagraphs (page 1618). Appendices have been removed when the source of trouble has been impacted stone in the right ureter. In 3 cases seen by Stellwagen appendectomy had failed to cure. In each case a stone was subsequently removed from the ureter and the patient cured. An impacted

Fig. 958.—*X*-ray photograph, showing the course of the ureters by wires in the catheters. (Taken by Dr. W. F. Manges.)

stone in the ureter may often be dislodged by passing a catheter into the ureter and, if possible, beyond the stone. Through the catheter are then injected a few minims of sterile olive oil which act as a lubricant and assist in the passage of the stone. Dilatation of the ureteral orifice, by leaving the catheter *in situ* or by passing a second instrument alongside of the first, will often cause the stone to pass into the bladder.

Disinfection of Urethral Catheters.—Metallic instruments are cleansed by boiling. Soft-rubber and elastic catheters can be sterilized by mechanical cleansing with soap and water and by boiling for five minutes. The common custom of immersing a soft-rubber or elastic catheter for five minutes in a 1:2000 solution of corrosive sublimate is a useless waste of time, as such a procedure will not sterilize an infected instrument. Formalin vapor is not reliable. A catheter coated with varnish or resin cannot be placed in steam, and cannot be boiled in water if it be allowed to touch the metal of the boiler or

another catheter. Woven and varnished instruments can be boiled in salt water (3 drams of salt to 1 pint of water), provided each instrument be wrapped in a piece of gauze so that it cannot touch another instrument or the side or bottom of the metal sterilizer. This plan secures the most certain sterilization. Catheters, after being cleansed mechanically and disinfected, may be kept ready for use in a glass cylinder containing calcium chlorid (R. W. Frank, in "Berliner klin. Woch.," No. 44, 1895). By this plan the catheters can be kept straight. Some prefer to keep them in a glass cylinder containing a few formalin tablets.

An excellent way to keep sterile catheters clean is to place each catheter in an individual bag of linen or waxed paper. Stellwagen boils a number of rubber condoms at the time he boils the catheters. When the instruments and condoms are dry he encloses a curled up instrument in each condom. Before using catheters which have been in formalin vapor they must be washed in sterile water or salt solution.

Diseases and Injuries of the Bladder

Retention of Urine in the Male.—Retention of urine is not, of course, a disease; it is rather a result of one of a number of different diseases. By this term is meant an absolute inability to micturate voluntarily. The retention may be *complete*, not a drop emerging, or it may have been complete, a dribbling setting in after a time, due to paralysis of the bladder, which becomes unable to contain more fluid, expulsion of the overflow from the ureters being produced by atmospherical pressure. This condition is known as *the engorgement*, *the overflow*, or *the incontinence of retention*. There may be *retained* urine in a man with enlarged prostate, a portion only of the urine being voided. This is not retention, and the urine so retained is called *residual urine*. Of course, true retention may arise in a person with enlarged prostate. Retention may be caused by: (1) *Obstruction*, resulting from urethral stricture, hypertrophied prostate, inflamed prostate, occluded meatus, impacted calculus or foreign body, urethral tumor, rupture of the urethra, perineal abscess, imperforate prepuce, congenital phimosis, tumor of the penis, tumor of the prostate, prostatic abscess, abscess of the penis, ischiorectal abscess, and pressure from a large pelvic tumor. The commonest obstructive cause is spasm of the membranous urethra arising during the existence of stricture, acute gonorrhea, or gleet. In some cases of chronic retention there is a spastic sphincter. This condition is not uncommon in children and is due to disease of the sacral portion of the spinal cord. (2) *Defective expulsion*, resulting from impairment of the nervous apparatus for inducing micturition. Hysteria is a rare cause in men. We see retention without obstruction after vertebral fractures or spinal concussion, in certain diseases of the spinal cord, sometimes in shock and peritonitis, often in the continued fevers and diseases characterized by muscular wasting, from the action of certain drugs (belladonna, opium, or cantharides), and after certain surgical operations upon or about the rectum. The last-named form of retention is due either to reflex inhibition of the expulsor muscle or to reflex stimulation of the sphincter vesicæ, causing it to remain firmly contracted. *Acute retention* comes on suddenly and is sometimes the first thing that causes a sufferer from urethral stricture to seek a surgeon.

Symptoms.—In *acute retention* there is an agony of desire to urinate, the patient making acutely painful straining efforts, during which feces are often passed. There are severe pain and aching in the abdomen, thighs, perineum, and penis. All the symptoms rapidly increase, a typhoid state is inaugurated eventually, and death closes the scene unless relief be given. If retention is from time to time alleviated by the passage of a little water, the symptoms are slower in evolution and are less intense, and the case is said to be *chronic*. Some cases of gradual onset due to atony are very insidious, the patient feeling

no particular pain and complaining only of the dribbling, which is really the overflow of retention, and is not a sign that the bladder is successfully emptying itself. In any case of retention the bladder rises above the pubes, and there is found a pyriform, elastic, fluctuating mass in the hypogastrium, and this mass is dull on percussion and gradually enlarges until the bladder is evacuated or incontinence sets in. The flanks give a clear percussion-note, and the tumor is more prominent when the patient is erect than when he is recumbent. Long continuation of obstructive disease, producing partial retention with or without attacks of complete retention, disorganizes the kidneys. Acute and complete retention may induce rupture of the urethra or urinary suppression.

Treatment of Retention of Urine.—Place the patient upon his back and, if possible, upon a hard mattress. If the bed be so soft that the hips sink down in it, put an ironing board or some other support beneath the mattress at the level of the buttocks. This will facilitate catheterization. Never attempt to use a catheter when the patient is erect; to do so may cause serious or even fatal shock. Always keep the patient protected from cold. Obtain a full history of the case and always make a gentle rectal examination of the prostate; also examine the external genitalia. Failute is often traceable to a lack of thorough examination. It is evident that retention due to prostatic disturbance is not to be dealt with in the same manner as retention due to stricture, impacted stone, etc. If instrumentation does not rapidly succeed, give an anesthetic. Be sure that every instrument is aseptic, and irrigate the urethra before and after instrumentation. Grease the instruments with liquid cosmolin. Prolonged attempts to introduce a catheter and excessive instrumentation are highly dangerous, especially in prostatic cases. Dreadful damage may be inflicted. There is no operation in surgery that requires a gentler touch. Haste, eagerness, carelessness, roughness are, alike, taboo. If a non-medical person knew the facts he would give more thought in the selection of a surgeon to relieve him of retention of urine than of a surgeon to amputate his leg. A surgeon with retention would give grave thought to the question. When the instrument enters the bladder, draw off but half of the urine, withdraw the instrument, wait a few hours, insert it again, and then empty the bladder and wash out the viscus with warm boric acid solution. To draw off all of the urine at once is dangerous, because the sudden relief of the pressure upon distended veins leads to bleeding from the mucous membrane and hemorrhage into the bladder walls. After the bladder has been emptied the patient is wrapped in blankets, a bag of hot water is placed against the perineum, and a hot-water bag is laid upon the hypogastric region. If no anesthetic has been used, he is given, at once after the operation, a suppository of opium and belladonna. If an anesthetic has been used, he is given the suppository when he recovers from the effect of the anesthetic. Tablets of salol and boric acid are administered during the several days which immediately follow the operation. If the cause of retention is organic stricture, try to pass an elastic, olivary pointed catheter (Fig. 959, *a*). Do not use any force until the neck of the elastic catheter is well engaged in the stricture. Then an experienced operator may warily use a certain amount of force, but never an amount which much exceeds the slightest. If it is found impossible to pass an elastic instrument, make an attempt to carry a filiform

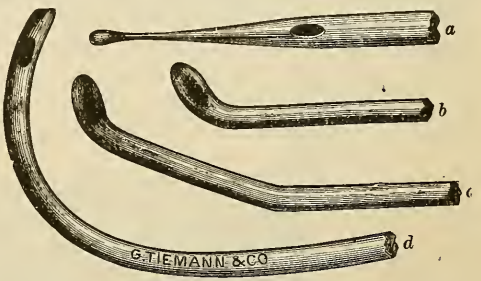

Fig. 959.—*a*, French olivary gum catheter; *b*, Mercier's elbowed catheter (coudé); *c*, Mercier's double-elbowed catheter (bicoudé); *d*, curved gum catheter.

whalebone bougie into the bladder. Fig. 960 shows filiform bougies. If the history shows that the man has long had an organic stricture, do not waste time with the gum catheter, but at once proceed to use the filiform bougie. On this bougie, after it has been inserted, Gouley's tunnelled catheter can perhaps be threaded (Fig. 961) and carried into the bladder. Instead of carrying in the catheter, we can simply leave the filiform bougie in place and fasten

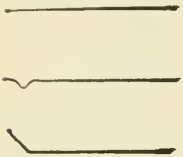

Fig. 960.—Points of Gouley's whalebone guides (filiform bougies).

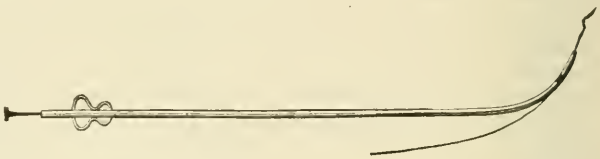

Fig. 961.—Gouley's tunnelled catheter threaded on a filiform bougie.

it. The filiform bougie will act as a capillary drain, and in a few hours will empty the bladder and will also dilate the stricture. Then insert another bougie beside the first and so on for several days, using also opium, ordering rest in bed, and making no attempt to dilate the stricture forcibly until retention has ceased and inflammation has subsided. Perhaps Phillips's catheter (Fig. 965) can be passed. If no instrument can be passed, aspirate above the pubes or perform cystotomy (suprapubic or perineal). In *spasmodic stric-*

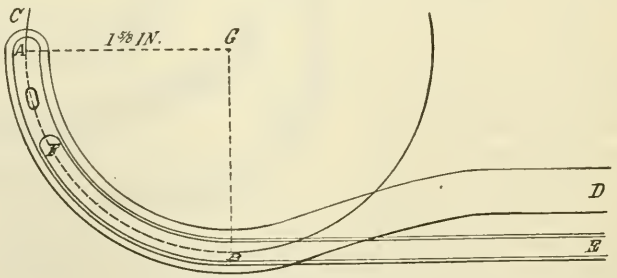

Fig. 962.—*A-B-E* shows the proper curve (reduced in size) for unyielding male urethral instruments; *C-B-D* shows an improper curve.

ture hold a good-sized metal catheter firmly against the area in spasm; relaxation will occur and the instrument will eventally pass. Fig. 962 shows the proper curve of a metal instrument. An individual who has an organic stricture which has given but little trouble may develop attacks of retention because of inflammatory edema of the mucous membrane and spasm of the urethral muscles. These attacks are temporary, and an instrument can usually be inserted when employed as above directed. In *inflammation*

Fig. 963.—English silk-web catheter.

give a hot hip-bath and suppositories of opium and belladonna, and then use a hot sand-bag to the perineum and a hot-water bag over the hypogastrium. If these fail or if the symptoms are urgent, pass a soft catheter. In the *occluded meatus of the newborn* incise with a tenotome. In a *congenital cyst of the sinus pocularis* pass a steel bougie, which will rupture the cyst. In *complete phimosis* split up the prepuce. In *impacted stone* try to pull out the calculus with urethral forceps; if this fails, cut the urethra or, in rare cases, push the stone back into

the bladder. In *fecal impaction* scrape out the rectum with a spoon. In *enlarged prostate* the rectal examination gives information as to the type of enlargement. If there be moderate enlargement of the middle lobe the coudé (Fig. 959, *b*) or the bicoudé catheter (Fig. 959, *c*) will probably pass. If these instruments fail, try the overcurved silver catheter of Sir Benjamin Brodie. This metal instrument has a large curve and will probably succeed, but it is a dangerous tool and one capable of inflicting grave injury. In enlargement of one lateral lobe with possible deflection of the urethra and valve formation try, in order, the woven silk catheter (Fig. 963), the Nélaton catheter (Fig. 964),

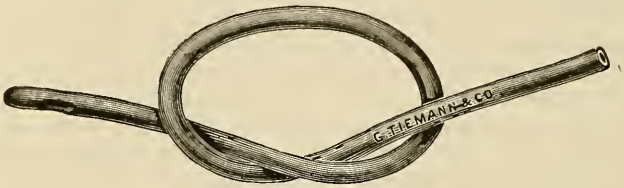

Fig. 964.—Nélaton's catheter.

strengthened by having a filiform passed in its lumen nearly to the beak, and the rat-tailed silk instrument. In enlargement of both lobes and the middle lobe try the coudé, then the bicoudé, then a coudé and a bicoudé with olivary or rat-tailed tips. If all of these fail, the overcurved metal catheter of Brodie must be used gently. In *retention from expulsive defect* use a soft catheter (Fig. 964). Cases of retention after catheterization require warmth, confinement to bed, the administration of laxatives, free action of the skin, and the use of such drugs as salol, boric acid, urotropin, and quinin to asepticize the urine.

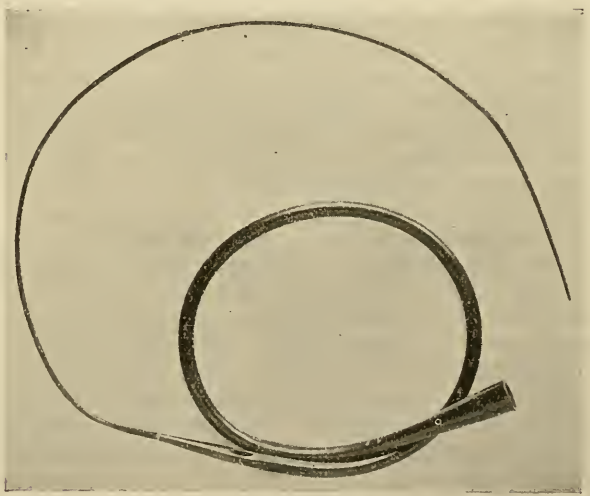

Fig. 965.—Phillips's catheter.

In some few cases no instrument can be inserted in the bladder. In most of such cases aspirate—which may be done several times if necessary—and in a day or two, when swelling and congestion abate, an instrument can be passed. The parts are asepticized. A small aseptic trocar or aspirator needle is pushed into the bladder, the trocar or needle being inserted in the median line, just above the pubes, and taking a course downward and backward. After the completion of the operation the puncture is dressed with iodoform and collodion. Only half the urine is withdrawn at a first aspiration. Rectal puncture is now

obsolete. If incision be necessary in retention, the perineal route is usually chosen. In some cases the operation is done with, in some without, a guide. In prostatic retention not relievable by a catheter, make suprapubic drainage or do prostatectomy.

Congenital Defects of the Bladder.—**Exstrophy of the bladder** (*ectopia vesicæ*) is a condition of defective development commoner in males than in females. The anterior abdominal wall has failed to close, the anterior wall of the bladder is absent, the arch of the pubes has not developed, epispadias exists, and in many cases the testicles have not descended into the scrotum. In this condition the posterior wall of the bladder projects into or beyond the gap in the abdominal wall; the urine constantly flows and renders the condition of the patient dreadful. The condition shortens life and only 30 per cent. of the victims live beyond the twentieth year, death being due to pyelonephritis.

The only treatment which offers hope is operation, and operation often fails. If possible, operate when the patient is about five years of age, and over rather than under five. Before operation the ureters should be catheterized and the urine from each side examined. Pyelonephritis of both sides forbids operation. Various operations have been suggested for this condition, viz.: covering with skin-flaps; implanting the ureters into the bowel (Maydl, Albert, Roux, Simon, and others); division of the posterior ligaments of the sacro-iliac joints, bringing the arch of the pubes forcibly together, the patient wearing a support until the parts become firm, when the greatly narrowed defect is closed in by integumentary flaps and by suturing the bladder edges (*Trendelenburg's operation* or *synchondroseotomy*); osteotomy through one ilium or both ilia instead of separation of the sacro-iliac joints (*Berg's operation*), or after extirpating the bladder, loosening the ureters from the bladder, drawing them down and attaching them to the end of the penis (*Sonnenberg's operation*).

A bladder closed in by autoplasty, by Trendelenburg's operation, or by Berg's operation is never really continent, although when the patient is erect and wears a light compress he may perhaps be able to hold water two or three hours. The above methods are suited to young children and are far safer than ureteral transplantation. Tuffier showed, nearly twenty years ago, that transplantation of the cut ureters into the bowel was certain to be followed by fatal infection of the kidney, and that the only way to prevent this was to retain the ureteral orifices which contain valves.

Maydl introduced his operation in 1892. He implanted the trigone with the ureters into the sigmoid flexure, extirpating the rest of the bladder. I have twice performed a modified Maydl's operation, with one death and one recovery. Buchanan ("Surg., Gynecol., and Obstet.," Feb., 1909) has collected 80 cases. In this collection there were 23 deaths (28.7 per cent.); 7 died of peritonitis and 9 of pyelonephritis. Bregenhem in 1894 devised extraperitoneal implantation of the ureters and a portion of bladder through two separate openings into the rectum. The Makka's operation employs the cecum as a bladder and uses the appendix as a ureter. Of course it cannot be done if the appendix has been removed, if it is blocked by inflammation, or if the cecum is anchored by adhesions.

Diverticula of the Bladder.—A diverticulum is a sac-like protrusion of a part of the bladder-wall or of the mucous membrane alone. During recent years the cystoscope has taught us that diverticula are much more common than we once thought. Some diverticula are congenital. These contain a muscular coat. Among congenital conditions is the hour-glass bladder and the double bladder (G. J. Thomas, in "Surgery, Gynecology and Obstetrics," Oct., 1916). An acquired diverticulum consists of mucous membrane. It may be of intrauterine origin (due to temporary obstruction), traumatism, and most commonly to urinary obstruction. One diverticulum, several, or many, may exist. The form most commonly seen is the pocketed bladder from chronic urinary ob-

struction. The mucous membrane of the bladder bulges out between layers of hypertrophied vesical muscle. The diagnosis of diverticulum is made by the *x*-rays and the cystoscope.

In most cases the best treatment is excision. The bladder is exposed, stripped of peritoneum, opened, the diverticulum packed with gauze, dissected free and excised and the wound in the bladder is sutured (Lower, in "Jour. Am. Med. Assoc.," 1914, lxiii). The various operations which have been performed for diverticula are set forth by G. J. Thomas (Ibid.).

Diseases and Injuries of the Bladder.—This viscus is so deeply situated, and the abdominal walls are so elastic, that it is rarely injured when empty. If the bladder be full and the abdomen tense—which is common in alcoholic intoxication—force applied to the abdomen may injure the bladder.

Contusion of the Bladder.—In this condition there are noted vesical hematuria, tenesmus, severe cystitis, and an impediment to the flow of water because of clots. Hemorrhage may be very severe and sepsis may arise, even causing death. When contusion exists retention is relieved by means of a clean soft catheter; if this fails because of occlusion of the eye of the catheter with blood-clot, at intervals there must be passed through the catheter from a fountain-syringe a solution of sodium bicarbonate in cooled boiled water. Gross's blood-catheter can be used or the evacuator of Bigelow may be employed. The patient is put to bed, a hot-water bag is applied to the hypogastrium, morphin is administered in moderate doses, the bladder is washed out several times a day with boric acid solution or a solution of bicarbonate of sodium to disintegrate and remove blood-clots, and the urine is diluted and rendered aseptic by the gastric administration of salol, boric acid, and the free use of bland fluids. Hemorrhage usually ceases on relieving distention; if it does not, some more radical measure must be employed (see Hematuria).

Wounds of the Bladder.—Besides being contused, the bladder may be injured by bullets; by stabs or punctures through the abdomen, the vagina, or the uterus; or by penetration by a fragment of a fractured pelvic bone. A gunshot wound may or may not damage bone. The greatest danger from a gunshot wound of the bladder is injury to the peritoneum. The next danger is urinary infiltration. Infection is common and may come from the wound or from bacterial urine. Bazy points out that in wounds from rifle bullets there is usually urinary retention but in wounds from shell fragments there is a free flow of urine from the wound ("Bull. et Mem. Soc. de chir. de Paris," 1916, xlii). The symptoms of such conditions are those of rupture of the bladder (*q. v.*). The diagnosis is made by palpation, the *x*-rays and the cystoscope. In an intraperitoneal wound at once open the abdomen, suture the wound in the bladder wall, irrigate and drain the peritoneal cavity, and drain the bladder by means of a retained catheter, perineal section, or suprapubic cystotomy. In an extraperitoneal wound drain the wound by a tube, and drain the bladder by a retained catheter, perineal section, or suprapubic opening.

Fistulæ may follow the injury. The wound itself may become fistulous or a collection of extravasated urine may break and form a fistula. The fistula may open upon the abdominal wall, the perineum, the scrotum, the buttock, the thigh or into the intestine. The mortality of gunshot wounds is said to be 25 per cent.

Rupture of the bladder occurs in three forms: (1) intraperitoneal—a rupture involving the peritoneal coat; (2) extraperitoneal—a rupture of a portion of the bladder not covered by peritoneum; and (3) subperitoneal—a rupture of the mucous and muscular coats, the urine diffusing under the peritoneal investment. The *causes* are of two kinds, predisposing and exciting. *Predisposing* causes are: distention of the bladder; drunkenness; cystitis; ulceration; degeneration or atony of the bladder-coats; prostatic enlargement, and urethral stricture. Distention of the bladder is the great predisposing cause.

It causes the bladder to rise from the pelvis and so become exposed to a direct blow, it places the organ under tension, and force tends to rupture the weakest point. In about one-third of the cases collected by Bartels the individual was intoxicated at the time of the accident. Drunkenness predisposes because a drunken man is very liable to injury and is apt to have a distended bladder and a rigid belly wall. Males are much more liable to rupture then females (10 to 1). Most cases are between the ages of twenty and forty. Of Besley's 25 cases, 1 was a child of three, 1 a man of forty-nine, 3 were in the first and second decades, 5 were between twenty and thirty, 7 between thirty and forty, 6 between forty and fifty, and in 2 the age is not given (paper before Chicago Surg. Soc., Feb., 1907). The condition is very rare in children, but 1 of Besley's cases was three years of age, and King recorded the accident in a fetus with imperforate urethra.

Exciting causes are: obstruction to the outflow of urine (by stricture or enlarged prostate); external violence; falls upon the feet or the buttocks, as well as upon the abdomen; lifting; straining at stool, in micturition, or during parturition; and the forcing of injections into the bladder. A distended bladder may be ruptured by a concussion. The most usual cause of the injury is a crush. The mechanism of the injury is in dispute. It is certain that the bladder must have lost its elasticity by distention. When force is applied to fluid (fluid is incompressible) the bladder tears at its weakest point. The weakest point is not identical in all individuals. It may be weak anywhere from disease. The most common site of the tear is at the postero-superior aspect, but it may be in front, at either side, or at the pubic or prostatic ligament (Staubenranch). The mucous membrane or the peritoneum may give way first and the tear may be anteroposterior, oblique, or longitudinal. Alexander maintains that the most usual cause of the injury is a crush which forces the distended bladder against the sacral promontory, but Besley's (Ibid.) experiments do not indicate that this is correct. A common complication, especially of extraperitoneal rupture, is fracture of the pelvis, due to the same force that ruptured the bladder.

Symptoms, Diagnosis, and Treatment.—The symptoms are not always definite, and every characteristic one may be for a time absent, the patient seeming in some rare instances of extraperitoneal and intraperitoneal rupture to possess the power of retaining his urine and of voiding it. As a rule, however, there are found some or all of the following symptoms, following an accident or occurring during the progress of a causative disease: severe pain in the bladder and in the suprapubic region, collapse; inability to walk or great difficulty in walking; excessive desire to micturate, but inability to do so (sometimes a little pure blood or bloody water is squeezed out by painful effort); a catheter, when used, brings away pure blood or a very little bloody urine; the catheter occasionally slips through the tear into the cavity, and more bloody water comes away. In some reported cases clear water has been withdrawn. If a measured amount of boric acid solution is injected, it is improbable that all of it can be withdrawn by the catheter, although in some cases it may all come away (Alexander in "Annals of Surgery," August, 1901). Injecting fluid fails to lift the bladder into the hypogastric region so as to be recognizable on percussion. In a patient suffering from retention of urine in whom rupture occurs there is first a temporary sense of relief from retention, but very soon severe hypogastric pain and rectal tenesmus. In intraperitoneal rupture reaction may be obtained after a few hours or a number of hours. The evidences of peritonitis will be noted soon (rapid pulse, perhaps vomiting, rigidity, distention, obstruction of the bowel, elevated temperature, etc.). Shock in vesical rupture is so severe that death may ensue; if reaction follows, there may be delirium and often septicemia; extensive infiltrations of urine may occur. In *intraperitoneal rupture* general peritonitis is certain to arise, but its appearance may be postponed for several days if the urine be healthy. In these cases

the extravasation is noted as a simple swelling, probably on one side only. In *extraperitoneal rupture* the urine may infiltrate the perineum, the scrotum, the thighs, and under the integuments of the abdomen and the back, and may soon induce sloughing. In *subperitoneal rupture* peritonitis is apt to arise.

In doubtful cases some surgeons pump air or hydrogen into the bladder. To insert air a bicycle pump can be used (Brown) or a Davidson syringe (Keen). Keen's directions are to insert a catheter, empty the bladder of urine, and connect to the catheter a disinfected Davidson's syringe, a mass of absorbent cotton being fastened over the distal end of the syringe. Air after it has filtered through the cotton is pumped into the bladder; an unruptured bladder will rise above the pubes as a pyriform tumor, tympanitic on percussion. A ruptured bladder will not so rise. In intraperitoneal rupture the air will pass into the general peritoneal cavity and distention will occur. In extraperitoneal rupture injection will produce emphysema of the extravesical connective tissue. On removing the syringe the air rushes out again if the bladder be unruptured, but little if any comes away if it be ruptured. Alexander considers gaseous distention unreliable, and claims that it adds to shock and disseminates infection. His rule is the wisest to follow; that is, in a case of suspected rupture of the bladder, make a suprapubic incision and inspect the prevesical space for signs of extraperitoneal rupture. If extraperitoneal rupture is not found, open the belly and explore.

Treatment.—In extraperitoneal rupture, after incision down to the bladder insert a drainage-tube. In intraperitoneal rupture, place the patient in the Trendelenburg position, expose the tear in the bladder by abdominal incision, and suture the opening in the viscus.

Results.—Baron Larrey was the first surgeon to state that a wound through all the coats of the bladder might be followed by recovery. In intraperitoneal ruptures, if operation is not performed, the mortality is 98 per cent. If operation is performed many cases recover. Of the 78 cases collected by Dambriu and Papin in 1904, 34 died, a mortality of 43 per cent. (Besley, paper before Chicago Surg. Soc., Feb., 1907). Galactionoff ("Rovssky Vratch," Nov. 12, 1910) reports 15 cases operated upon for intraperitoneal rupture; 5 recovered (3 of them were operated upon during the first twenty-four hours; 1, after thirty-six hours, and 1, after forty-eight hours). In extraperitoneal rupture without operation there are 11 per cent. cures and with operation 30 per cent. (See Daniel N. Eisendrath, "Jour. Amer. Med. Assoc.," Oct. 25, 1902; Samuel Alexander, "Annals of Surgery," Aug., 1901.)

Atony of the bladder is a condition in which the expulsive power of the bladder is diminished or lost because of impairment of muscular tone. The bladder is very thin, and the muscles are flaccid and often the seat of fatty degeneration. Sometimes the viscus is very large and sometimes it is very small. A slight degree of atony is physiological after middle age.

The **causes** are senility, distention from true paralysis, chronic over distention from obstruction, and acute overdistention. In most cases there is obstruction of the urethra. In that rare condition known as *idiopathic atony* there is no evidence of obstruction. Walker ("Annals of Surgery," Nov., 1910) reports 12 cases of idiopathic atony. He says the patients were between the ages of twenty-two and forty. He regards the condition as due to a lesion in the reflex centers.

Symptoms.—In atony of the bladder the patient passes water frequently (a symptom probably existing for some years), and especially at night; he may even do so while asleep. The stream, when voluntarily passed, has little projection, but seems to drop at once from the end of the penis. Residual urine exists for years and may at any time set up cystitis, and retention with incontinence is apt to occur. This condition is *not* vesical paralysis resulting from a lesion of the nervous system.

Treatment.—In treating atony of the bladder measure the residual urine: if it amounts to 4 oz., use a soft catheter night and morning; if it amounts to 6 oz., use the catheter every eight hours; if it amounts to 8 oz., use the catheter every six hours (J. W. White). The patient should be taught how to use the catheter and how to keep it sterile. (For Methods of Disinfecting Catheters see article on page 1457.) The bladder is from time to time washed out with 3 gr. to the ounce of boric acid solution at a temperature of 100° F. Strychnin, electricity, ergot, and urotropin may be ordered.

True Paralysis of the Bladder.—Vesical paralysis results from a lesion of the nervous system causing paralysis of the motor nerves or of the motor paths from which they are prolongations (fracture of the vertebræ, spinal meningitis, syphilis of the cord, myelitis, and hemorrhage about or into the spinal cord). A traumatic paralysis comes on suddenly. Hysteria may be responsible for temporary palsy. If the detrusor muscles alone are palsied there is complete retention of urine. If the sphincter is paralyzed the urine dribbles constantly. Even when there is dribbling a quantity of urine is retained below the level of the internal meatus. In such a case there is incontinence with partial retention (the *overflow* of Sir Henry Thompson). If the patient sits down or assumes the knee-chest position he may empty the bladder by contracting the abdominal muscles. In cases of real retention the detrusors may be temporarily paralyzed. In such a case the sphincter may finally relax from fluid pressure, and atmospherical pressure or contraction of abdominal muscles may cause urine to dribble, the bladder remaining full (the *overflow of retention* of the elder Gross). In some cases of vesical paralysis there is retention; in some cases, incontinence of urine. If the sensory as well as the motor path be involved in a lesion, the patient has no sensation to notify him of dribbling or of retention.

Treatment.—Treat the cause. Employ regular aseptic catheterization by a soft instrument. In some cases the bladder may be subjected to faradism (one electrode in the bladder and one in the perineum or on the abdomen above the pubes). Kilvington ("Brit. Med. Jour.," 1907, vol. i) pointed out that the nerve-supply of the bladder and rectum is from the second and third and sometimes also from the first sacral nerves. He suggested treating some otherwise incurable cases of vesical paralysis by anastomosing a nerve-root above the lesion to certain sacral nerves below the lesion. Bird did the first operation, but it failed. Mills and Frazier (see page 972) performed intradural anastomosis of the last lumbar nerve to the third and fourth sacral nerves. The patient was much benefited ("Jour. Amer. Med. Assoc.," Dec. 21, 1912).

Foreign Bodies in the Bladder.—The term "foreign body" is, at best, a poor one, since a stone is a foreign body. The term, however, is generally used to designate material held within the viscus and of purely extraneous origin. There has been a great variety of foreign bodies removed from both the male and female urinary bladder. We have seen a lead-pencil, hair-pins, a willow twig, a glass rod, and a piece of chewing gum removed, as well as portions of catheters and filiform bougies. For reports of foreign bodies found in the bladder the reader is referred to text-books upon genito-urinary diseases.

Most of the foreign bodies are found in the bladders of masturbators. In them the glans penis or the clitoris has become so inured to friction that they must seek deeper for sensation, consequently men resort to titillation of the verumontanum and posturethra, and women, to irritation of the vesical neck. The object used to stir sensation may slip from the grasp and pass backward into the bladder. The careless use of the filiform bougie is a great danger. Always test the filiform for defects and for tensile strength before using it. If you use the Gouley catheter, see that the tip through which the filiform must lace is not sharp or square, else it may shear off a portion of the bougie All foreign bodies sooner or later induce cystitis. Every foreign body, if allowed

to remain, will become encrusted with urinary salts and constitute a nucleus for stone formation.

Diagnosis, Symptoms, and Treatment.—*Diagnosis* is made by the history, if given correctly, of the case. The stone-searcher, the *x*-ray, and the cystoscope are most useful in diagnosis. The *symptoms* are similar to those of stone in the bladder. The *treatment* is removal, with subsequent care of the resultant cystitis.

Vesical Calculus, or Stone in the Bladder.—The salts normally in solution in the urine may become deposited as calculi and may be imprisoned in any portion of the urinary tract. The commonest primary calculi are those composed of uric acid, urates, calcium oxalate, and fusible phosphates. In 80 per cent. of cases primary calculi are composed of uric acid and urates. A primary calculus may become coated with another material (secondary calculus). The formation of uric acid and urate calculi is explained under Renal Calculus (see page 1427). Vesical calculi are usually renal calculi that have passed through

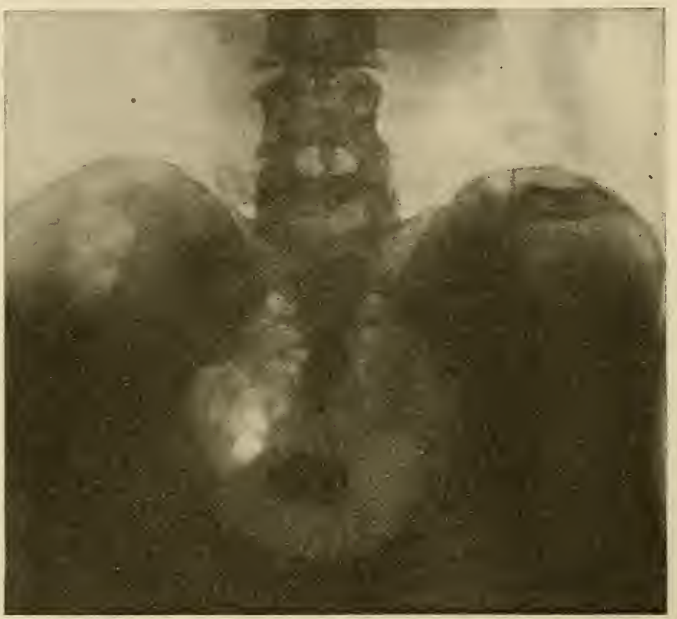

Fig. 966.—Stone in bladder shown by *x*-rays.

the ureter and become enlarged by new accretions. New accretions from an alkaline urine will cause the formation of a secondary phosphatic stone. Phosphatic calculi may be formed in the bladder when chronic cystitis causes and maintains an alkaline urine. Uric-acid calculi are smooth, round or oval, and hard, but easily broken. On section they present the color of brick-dust and are marked by concentric rings. Their nuclei are dark by comparison. They are soluble in dilute potassium hydrate and in nitric acid. They are combustible and leave scarcely any ash. Urate of sodium and urate of ammonium often occur together in stones, and these calculi are not in rings, are not so hard as the uric-acid stones, and are fawn colored on section. Oxalate of lime stones are round, with many projecting nodes like the mulberry, hence the term "mulberry calculus." They are very hard, and section shows the color to be brown or green and that they possess wavy, concentric rings. This form of calculus is soluble in hydrochloric acid. The so-called fusible calculus of the early writers, which is composed of a phosphate of magnesium, ammonium, and calcium

(*triple phosphate*), constitutes the commonest form of phosphatic stone and of large stone. It is light, soft, smooth and white, and shows no laminæ on section. Some rare forms of primary stone are composed of xanthin, cystin, indigo, urostealith, calcium phosphate or calcium carbonate, or blood concretions.

A stone having layers of different substances may be formed; for instance, there is often found a uric-acid nucleus surrounded by phosphates, the latter surrounded by some uric acid or urates, and these again by phosphates. In some cases oxalate of lime alternates with uric acid, urates, or phosphates (Bowlby). Bowlby states that the alternating uric-acid and phosphatic layers are due to the altering reactions of the urine; that when the urine is acid uric acid is deposited on the stone, but when cystitis makes the urine alkaline the stone receives a phosphatic coat.

Anything that favors the formation of an excessive urinary deposit may cause vesical calculus, and among such causes are defective digestion, failure in processes of oxidation, excess of solids and nitrogenous elements in the diet, deficient exercise, etc. If to the urinary condition established by the above factors catarrh of the genito-urinary tract is added, pus or mucopus in the concentrated urine may induce stone. Children are predisposed to uric-acid stones, and old people to phosphatic stones. In an old man with enlarged prostate and chronic cystitis a stone forms rapidly above any accidental nucleus. The nucleus may be phosphate crystals glued together by mucus, a blood-clot, uric-acid gravel, or a foreign body. Stone is rare in females because of the shortness, the large diameter, and the ready dilatability of the urethra. Stone is very rare in the negro. Gout, rheumatism, lithemia, enlarged prostate, vesical atony, urethral stricture, and catarrhal inflammation of the kidney, the ureter, and the bladder are predisposing causes.

Symptoms.—In not a few cases the vesical symptoms are antedated by an attack of nephritic colic. Hence the necessity for cystoscopy after renal colic if no stone has passed from the meatus, and the removal of any retained stone by the evacuator or the cystoscope. The severity of the symptoms of stone in the bladder depends more on the roughness of the stone than on its size. A small, rough calculus will produce intolerable anguish, whereas several large, smooth stones will cause but moderate pain. A patient with stone in the bladder complains of frequency of micturition, particularly in the daytime, the desire being sudden, uncontrollable, and invoked or aggravated by exercise. This symptom is more positive in youth than in old age. Pain of a sharp, burning character is experienced at the end of micturition, due to the contraction of the empty bladder upon the stone or stones. It disappears gradually as urine enters and distends the bladder. The usual seat of this pain is the under surface of the head of the penis, a little behind the meatus, and the pain may continue for some time. By pulling on the penis to relieve this pain the prepuce of a child may become pendulous. The pain varies in severity, being much worse during an attack of cystitis and after exercise; it may be absent in encysted stone; it may be present early in a case, but almost disappears as a case progresses, and it is always worse in the young than in the old. Stone in chronic cases of atony and in cases of vesical paralysis causes neither marked pain nor frequency of micturition.[1] In a case of enlarged prostate pain *precedes* the act of micturition, in urethral stricture it *accompanies* it, and in stone, as already stated, it *follows* it (P. J. Freyer, in "The Practitioner," Feb., 1898). The symptoms may be somewhat confused by the co-existence of vesical calculus and prostatic hypertrophy. Attacks of cystitis in a man with calculus are spoken of as *attacks of stone*. When a stone is small, it may during micturition roll into the urethral orifice, and so cause a sudden interruption of the flow of urine, the stream again starting when the patient changes his position. This symptom is seldom met with and is particularly rare in the old, the stone in them

[1] "American Text-Book of Surgery."

dropping into the sac back of the prostate and *below* the urethral orifice. Even if this symptom occurs, it is not conclusive, as a stalked tumor, a blood-clot, or a mass of pus or mucus may block the urethral orifice and cut off the stream. Hematuria may or may not be noted; it is most usual after exercise, and occurs at the end of the urinary act, the first urine passed being clear, the later urine being blood-tinged, and at the end of the act some drops of pure blood emerge. It is not one of the earliest symptoms. When it occurs it puts the patient in a great fright. It does not appear suddenly and profusely, but as gradual and trivial bleeding and with micturition. Blood appearing between acts of micturition comes from either the urethra or prostate (P. J. Freyer). The bleeding from a bladder tumor is profuse and the urine is mixed with blood and blood-clots and tumor fragments. Bleeding from a tuberculous ulcer of the bladder often resembles the bleeding caused by stone. Pus or mucopus will be observed if cystitis occurs with calculus disease. Priapism occurs in some cases. Pain of a reflex nature may be felt in the rectum, in the perineum, or in some distant part.

The above symptoms, even if all be present, do not prove that an individual has a stone in the bladder. To prove the presence of a stone the object must be pictured by the *x*-rays, seen through a cystoscope, or be touched by a

Fig. 967.—Thompson's calculus sound.

sound. Simple touching by a sound is not sufficient, the contact must be felt and heard. To sound a patient, have the bladder well filled with boric acid solution or salt solution, and place him recumbent, with the knees drawn up. Never sound a person while he is standing, because of the danger of syncope. In an ordinary case in a male use a sound with a very slight curve (Fig. 967); in a man with hypertrophied prostate use a sound with a short and decided curve. The caliber of a stone-sound is No. 13 of the French scale. The instrument is carefully boiled and anointed with yellow liquid cosmolin. Examine the entire bladder systematically, and don't be sure a stone is present until contact with the sound is both heard and felt. The stone may be difficult to find, or it may elude the instrument entirely when it is encysted, when it rests in a diverticulum, when it is fixed to the roof or anterior wall of the viscus, or when it is crusted with lymph or blood-clot. In doubtful cases always insist on a second examination, giving ether if the first has been very painful. Occasionally, as Freyer pointed out in 1884, a small stone will be found by using a Bigelow evacuator, the current causing the calculus to knock against the tube. In many cases stone in the bladder may be detected by means of the *x*-rays (see Fig. 966). Use the cystoscope in all cases of suspected stone. If a stone is fixed in a diverticulum or projects from the ureter, or is in a sac back of the prostate, it may be missed by sound and evacuator tube, but be shown by the *x*-rays and the cystoscope. A stone, when it is detected, should always be measured by Thompson's instrument, an arrangement looking something like a small edition of a lithotrite, but having very delicate blades. The composition of the stone is assumed from an examination of fragments which pass through the urethra or which adhere to the measure. Remember that the outer layer of a calculus may be soft phosphate and the inner portion may be the harder uric acid, urate, or oxalate.

Stone in Females.—Calculus in the female is a rare complaint. In over 900 patients operated upon by Freyer for stone there were only 20 females. Pain and increased frequency of micturition, which are symptoms of stone in men and women, are in women commonly caused by other conditions, notably by uterine disease and displacement. A straight sound is used to examine a female

for stone. If the surgeon is still uncertain after sounding, he uses a cystoscope or dilates the urethra and explores the bladder with his little finger.

Stone in children can occur at any age, and congenital cases have been placed on record. The uric-acid stone is most common. The symptoms are like those of the adult. The pain causes the male child to pull at the penis and the prepuce becomes pendulous. If in a child with stone the stream of urine is blocked from time to time, the child strains to empty the bladder, and after a time a hernia may form or prolaspe of the rectum take place.

Treatment.—In people predisposed to stone (for instance, by lithemia) the physician should foresee the danger and antagonize it. Insist on the urine being kept dilute by the freest use of water and of milk, and reduce to a minimum the amount of alcohol, meat, sugar, and fat which is taken. Let the patient live chiefly on green vegetables, salads, bread, fruit, eggs, fish, poultry, weak tea or coffee, water, milk, and, if desired, a little red wine. Continued purging does harm by concentrating the urine, though a laxative may be employed when indicated. Moderate open-air exercise is of immense importance, sunshine and fresh air being Nature's correctives for a condition of imperfect oxidation power. If the urine be very acid, use piperazin, 15 to 20 gr. daily, liquor potassii citratis, phosphate of sodium, or borocitrate of magnesium. If the urine be phosphatic and alkaline, order mineral acids and strychnin, or, what seems to be very efficient, urotropin. Urotropin is given in 5-gr. capsules four times daily. If the urine be filled with oxalate, use the mineral acids with an occasional course of phosphate of sodium. Travel and rest at the seaside or at some spa are often of service in all forms. Always endeavor to prevent cystitis, and treat it promptly when it does occur. When a stone is once formed it is an idle dream to think of dissolving it. An operation must be done. Some very small stones may be crushed in view through the cystoscope by one of the several intravesical forceps, but in an immense majority of cases a very much more formidable operation is required. The operation selected depends upon the age, the state of the bladder and the prostate, the dilatability of the urethra, the kidney condition, the size and composition of the stone, and the number of calculi present (see Operations on the Bladder).

Bacteriuria (see page 1431 *et seq.*).—Most urines contain bacteria which soon die. If the bacteria live and multiply the condition is called bacteriuria. When there is bacteremia, bacilli frequently enter the urine. Bacteremia is a common cause of bacteriuria. If bacilli are present in numbers, the condition is called *bacilluria*. The variety and number vary greatly in different individuals. In typhoid fever typhoid bacilli are found. In many cases of nephritis bacteria are present. In pulmonary tuberculosis, vesical tuberculosis, and renal tuberculosis, bacilli may be found in the urine. In some cases numerous colon bacilli are found. They may seem to do no harm; they may cause nephritis; they may cause cystitis.

If a urine contains bacteria, inflammation of the genito-urinary tract may or may not exist, but even if it does not exist it is apt to occur at any time. In some persons the urine is found swarming with colon bacilli. Colon bacilli are capable of causing a very severe type of cystitis and nephritis. Bacterial urine explains many cases of urinary fever (see page 1515).

Cystitis.—Inflammation of the bladder is, as a rule, a complication of some other disease of the genito-urinary tract, but it may arise after exposure to cold and wet. Traumatism from a catheter, the presence of a stone, the spread of a urethral inflammation, pus infection, vesical tuberculosis or cancer, and the use of such drugs as cantharides, turpentine, alcohol, urotropin, and sandalwood oil in large doses may produce it. It appears not unusually during an exanthematous fever or in conditions of vesical paralysis; it often follows retention; frequently accompanies enlarged prostate and urethral stricture, and sometimes arises from concentration of urine or accompanies bladder

growths. Acute cystitis causes discoloration and swelling of the bladder walls, and there is present a catarrhal discharge which is mixed with urinary elements, serum, mucus, often pus and epithelial débris. Ulceration, sloughing, or false-membrane formation may occur. Chronic cystitis is an inflammatory condition always due to bacteria. We frequently speak of a chronic cystitis as due to stone in the bladder, hypertrophy of the prostate gland, or tumor of the bladder. These conditions do not cause chronic cystitis, but act by rendering the bladder vulnerable to micro-organisms. Among the causative organisms we may mention the Bacillus coli communis, the gonococcus, the Bacillus tuberculosis, the Bacillus typhosus, the Urobacillus liquefaciens septicus, and the various pyogenic bacteria (Leonard Freeman). The bacillus aërogenes lactis has been found (Luetscher, in "Jour. Clinical Research," 1914, vii, i). These bacteria may gain entrance on instruments or by way of the ureter, urethra, the lymph-vessels, or the blood.

In chronic cystitis there is an enormous production of thick, sticky mucus and the urine becomes alkaline. The excessive secretion of mucus and the great number of bacteria convert the urea into carbonate of ammonium, and this product, being irritant to the bladder walls, makes the inflammation worse. In chronic cystitis the bladder is contracted and has very thick walls, and the mucous membrane is thick, edematous, congested, and filled with large veins. The bladder may be ulcerated or encrusted with urinary salts. The urine contains bacteria, triple phosphate, pus, blood, and mucus, the blood emerging with the last drops of urine. Pyelitis may arise as a result of chronic cystitis.

What was formerly called inflammation of the neck of the bladder is an inflammation of the vesical trigone and of the posterior urethra. It is now usually called *urethrocystitis* or *trigonitis*.

Symptoms of Acute Cystitis.—Great frequency of micturition, with the passage, at each act, of a very small quantity of urine; the desire to urinate is almost constant, and there is intensely painful straining (*tenesmus*). The pain is acute and scalding, and may be felt in the head of the penis, above the pubes or in the perineum; it often runs into the loins and the thighs and radiates over the sacrum. Pain above the pubes indicates involvement of the fundus, and pain in the perineum and in the head of the penis points to inflammation of the bladder trigone. The urine, at first clear, loses its transparency, becomes full of thick mucus, and often contains a little blood or pus. The patient not unusually has some fever. A rectal examination causes violent pain. If retention arises, there will probably be a chill and high fever, and anuria may occur.

Treatment.—In treating acute cystitis endeavor to remove the cause. By allaying an irritation or removing an obstruction the bladder will often become able to empty itself of retained urine, which causes congestion of the bladder and thus renders infection probable or may be itself filled with bacteria. If cystitis arises after the administration of cantharides, put the patient in bed and give him liquor potassii citratis. If it arises after the use of a clean sound, order rest in bed, suppositories of opium and belladonna, diluent drinks, and ammonii benzoas or lupulin. If the inflammation is septic (as from the use of a dirty sound) or is very acute put the patient in bed, keep him warm, and use a hot sand-bag to the perineum and hot fomentations or poultices to the hypogastrium. Urotropin is a valuable prophylactic if the urethra or bladder is to be subjected to instrumentation. Hot hip-baths may be used. The hips should be elevated, and the bowels should be emptied by the administration of salines and by glycerin enemata. An exclusive milk-diet is desirable. The patient should drink copiously of sweetened water containing a few drops of aromatic sulphuric acid or of milk of almonds. We can sterilize the urine, if it be alkaline, by the administration of urotropin, giving a capsule con-

taining 7½ gr. of the drug three times a day. Others remedies which may be of service in sterilizing the urine are quinin, boric acid, salol, borocitrate of magnesium and salicylate of sodium. A valuable remedy consists of 15 gr. of salicylate of sodium and 15 gr. of benzoic acid, given three times a day in a little chloroform water. If the pain and straining still continue, order—

℞. Ext. hyoscyami ..... gr. viij;
Ext. cannabis indicæ ..... gr. viij;
Sacchar. alba ..... gr. xlviij.—M.
Div. in pulv. No. xxiv.
Sig.—One powder every four hours.

Or,

℞. Camphoræ ..... gr. viij;
Ext. cannabis indicæ ..... gr. viij;
Sacchar. alba ..... gr. xlvij.—M.
Div. in pulv. No. xx.
Sig.—One powder every three hours (Von Zeissl.)

The two most active agents in acidifying alkaline urine are the acid phosphate of sodium and the benzoate of ammonium. Boric acid not only acidifies urine but it is also antiseptic. Suppositories of extract of belladonna are of great value. Suppositories each of which contains 1 gr. of ichthyol are of service, and one may be used every four hours. Opium, unfortunately, constipates; when it is given, secure evacuations by the use of glycerin suppositories, by the administration of saline cathartics, or by the employment of enemata. If opium is necessary, it is given in a suppository containing 1 gr. of powdered opium and ⅙ gr. of the extract of belladonna every three or four hours. Hypodermatic injections of morphin may be required. Wash the bladder out daily with warm normal salt solution or warm boric acid solution. This can be done through a soft catheter or, better, by hydrostatic pressure. If retention occurs, use a soft catheter. If much blood is passed, give internally the tinctura ferri chloridi and blister the perineum. In acute *urethrocystitis* (*trigonitis*) the instillation of solutions of nitrate of silver (5 to 10 gr. to the ounce) may do good. A very acute cystitis is rarely arrested within a week or ten days.

Symptoms of Chronic Cystitis.—This condition may be a legacy from acute cystitis or it may appear without any acute precursory phenomena. There will be found frequency of micturition, but not so great as in the acute form. There will be slight tenesmus and moderate pain from time to time, usually radiating toward the head of the penis. Constitutional symptoms may arise when kidney damage has become pronounced or sepsis has occurred from absorption. The urine is ammoniacal, fetid, and turbid; it is filled with viscid, tenacious mucus or with mucopus; it contains a great excess of phosphates, and occasionally clots of blood. The condition of chronic cystitis with the production of immense quantities of thick mucus is often called *chronic catarrh of the bladder*. Chronic cystitis may eventuate in the formation of stone or in the production of serious disease of the bladder, the ureters, and the kidneys. It is very apt to cause retention of urine.

Chronic Tuberculous Cystitis.—Chronic cystitis may be due to tuberculosis. Primary vesical tuberculosis is very uncommon. When it does occur it will often be found that it has been preceded by gonorrheal infection of the bladder. Most cases of vesical tuberculosis are secondary to renal tuberculosis or to tuberculosis of the prostate, seminal vesicles, or epididymis. Some cases come on rapidly, many tubercle bacilli being found in the urine. Other cases come on more gradually, and in them the urine may contain few tubercle bacilli. In many such cases no tubercle bacilli are found. The tuberculous products caseate and ulcers form or fibrous organization takes place. A cystitis for which no cause can be found, and which is accompanied by pyuria and severe and lasting pain, is possibly tuberculous. Pyuria is usually present,

but in some cases the urine is perfectly clear. In some cases the patient has painful paroxysms of varying duration and feels well between the attacks. Finding tuberculosis of the kidney, prostate, seminal vesicle, or epididymis, increases the probability that tuberculous cystitis exists. The diagnosis is made by the cystoscope. Tuberculous ulceration is most common in the trigone and about the inner orifice of the urethra. A tuberculous ulcer is small. The adjacent mucous membrane is not inflamed, but contains grayish-white nodules (Louis E. Schmidt, "Jour. Amer. Med. Assoc.," July 19, 1902).

Treatment of Chronic Cystitis.—In treating chronic cystitis remove the cause, if possible (get rid of a stone, evacuate frequently residual urine, dilate a stricture, and remove a tumor). For chronic cystitis certain remedies are taken by the mouth. Water is drunk in large amounts, also iron spring-water (Marienbad, etc.). Diuretics which make the urine alkaline must not be given in association with urotropin. Free diuresis by such waters is often valuable but we must choose between diuresis so obtained and urotropin (J. W. T. Walker, Abstract in "Surgery, Gynecology, and Obstetrics," from "Clin. Jour.," 1915, xliv). Salol and boric acid, 5 gr. of each four times a day, are very valuable. Salol in fluidextract of triticum repens does good; so does chlorate of potassium, 10 gr. daily. Either borocitrate of magnesium, quinin, or salicylate of sodium with benzoic acid may often be used with benefit. A valuable combination to correct alkalinity and to exercise an antiseptic action consists of benzoate of ammonium and boric acid, 15 grains of each, given several times a day. Alum, tannic acid, uva ursi, copaiba, cubebs, buchu, and turpentine have all been recommended, and possibly may be of some benefit. Urotropin is useful in many cases, if the urine be alkaline. This drug prevents the development of bacteria in the urine (Nicolaier) and antagonizes the tendency to sepsis and urinary poisoning. It is given in 5-gr. capsules, from four to six being given daily. Alkaline diuretics must not be given if urotropin is administered. Colon bacillus cystitis is treated by giving sodium benzoate and urotropin internally. In obstinate cases a vaccine should be made and given. In cases of chronic cystitis (even the tuberculous form) Stellwagen has had excellent results from the following capsule: 3 min. of creosote, 6 min. of oil of sandalwood, 1 min. of oil of cinnamon, 1 gr. of pepsin. One capsule after each meal. Whatever remedy is used, see that the bowels move once a day and that the skin is active. Champagne and beer must be avoided. If residual urine gathers, a soft catheter must be regularly employed. If it is possible to introduce a catheter of considerable size, catheterization may be all that is needed in the case. In some cases of chronic cystitis the retention of a catheter from three to five weeks is of the greatest service. If the case is very severe, the bladder must be washed out daily with peroxid of hydrogen (25 to 40 per cent. solution), nitrate of silver (1:8000), boric acid (5 to 10 per cent.), carbolic acid (1:500), corrosive sublimate (from 1:20,000 to 1:5000), or permanganate of potassium (1:4000). If nitrate of silver or permanganate of potassium be used, first rinse out the bladder with distilled water. If any other agent be used, first wash out the bladder with either boiled water or normal salt solution. The daily injection of a 2 per cent. solution of ichthyol may prove useful. Collin uses a 1 per cent. solution of guaiacol carbonate in sterile olive oil. Some surgeons occasionally employ, at intervals of a number of days, strong silver solutions (30 or 40 gr. to the ounce). If a strong solution be used, after the drug flows away wash out the bladder with a solution of common salt. The bladder is usually washed out by attaching to the free end of a soft catheter, the other end of which is in the bladder, a tube which is connected with a graduated bottle, the force being obtained by elevating the reservoir (*fountain irrigation*). The bladder can be irrigated without using a catheter, the resistance of the compressor muscle of the urethra being overcome by the pressure of a column of water. The reservoir is raised to the height of 6 feet. The patient sits in a chair. The tube of the reservoir has upon it a

clamp to control the flow, and in its end a large bulbous tip which will fill the meatus (Valentine's instrument). The tip is inserted into the urethra, the clamp on the tube is loosened, and the patient is directed to take a deep inspiration. In a short time the bladder fills with water, the tube is removed, and the patient empties the viscus naturally. In some cases it is necessary to wait quite a while for the column of water to tire out the muscle. If the fluid will not enter, direct the patient to make efforts as in micturating, the pressure of the fluid on the anterior surface of the cut-off muscles being kept up. If this fails, direct him to urinate, and then the surgeon makes another attempt to get the fluid to enter. After a little practice a patient learns how to admit the fluid.

Chronic trigonitis is treated by anesthetizing the bladder locally twice a week (by means of novocain or alypin) and by instilling from 30 to 60 minims of a 2 per cent. solution of nitrate of silver. Direct applications of a 5 per cent. solution can be made through a Kelly cystoscope. If a cyst forms it should be punctured. If the papillæ hypertrophy they should be curetted. In the male these procedures are carried out through an operative cystoscope, in the female through a Kelly tube (H. W. E. Walker, in "Med. Record," 1916, lxxxix).

If the cystoscope discloses tuberculosis of the bladder and there is known to be tuberculosis of one kidney, cure of the bladder is impossible without preliminary nephrectomy. In tuberculous cystitis collargol may be injected once a day. A 1 per cent. solution is used and it is allowed to remain for a long time. The method is painless. Collin advises the instillation of 30 min. of the following mixture into the bladder and posterior urethra: 5 gm. of guaiacol, 1 gm. of iodoform, 100 gm. of sterile olive oil. About 30 min. of this are injected once a day. Rovsing, of Copenhagen (Meeting of French Urological Assoc. of 1910), uses, in tuberculosis of the bladder, a fresh solution of carbolic acid (3 to 6 per cent.). He injects from 25 to 50 c.c. through a catheter, allows it to remain in the viscus for two or three minutes, lets it run out, and repeats this procedure until the fluid emerges clear. This treatment is carried out at first every other day. When, on the intervening day, the urine remains clear the interval between treatments is lengthened. Rovsing claims to have cured 28 cases in from four to six weeks. During treatment he makes a cystoscopic examination every other week to determine the progress of the case. The injections are usually very painful and would be intolerable without a preliminary injection of a local anesthetic (25 c.c. of a 1 per cent. solution of eucain). Sometimes, in tuberculous ulceration of the bladder, curetting through a cystoscope is useful. In other cases the bladder must be opened, the ulcer curetted, and the viscus drained.

In cystitis, and in *incrusted cystitis* particularly, injections of lactic bacillus cultures are very useful. We owe this knowledge to David Neuman of Glasgow ("Lancet," August 14, 1915). In this condition bacteria destroy the mucous membrane, phosphates are deposited, and the urine is very bloody and ammoniacal. The injections are made after the establishment of suprapubic drainage. Neuman prepares the agent as follows ("Lancet," Ibid.): Dissolve 1 part of sugar of milk in 40 parts of sterile water, boil it for ten minutes, allow it to cool, add one tube of Oppenheimer's lactogen to 20 ounces of the solution, keep it under sterile conditions at a temperature of 70° F. for ninety-six hours, shaking occasionally. Before using the solution of bacilli wash out the bladder with a solution of permanganate of potash, beginning with a strength of .025 per cent. and gradually increasing to .1 per cent. If there is a great quantity of mucus present first wash the bladder with a solution of potassium hydrate (i ℥ to a pint) then with sterile water until the fluid is neutral, then with the solution of bacilli.

The lactic bacilli destroy pyogenic organisms.

If the ordinary methods of treatment fail to cure chronic cystitis; if the bladder resents catheterization and irrigation; if in spite of irrigation the

urine does not become clear; and if there are evidences of infection of the patient and breaking down of his general health, drain by perineal or suprapubic cystotomy and through the incision wash the bladder frequently and thoroughly. If a persistent cystitis is due to stricture which dilatation fails to cure, perform external perineal urethrotomy and employ perineal drainage.

Ulcer of the bladder may be due to injury, cystitis, tuberculosis, malignant tumor, or gonorrhea. A form of ulceration particularly common in anemic women is a solitary, punched-out ulcer (Louis E. Schmidt, "Jour. Amer. Med. Assoc.," July 19, 1902). Ulcers may be single or multiple. Some are non-indurated and superficial. Some are indurated and deep. Chronic ulcers are nearly always within the area of the trigone. Perforation may occur.

A perforation may occur into the peritoneal cavity or into the perivesical cellular tissue. In the former case, after the onset of marked hematuria, there are shock, abdominal pain, and peritonitis. In the latter case there is extravasation of urine or abscess formation.

Tuberculous ulcer is discussed on page 1474 and cystoscopic ulcer on page 1447.

Schmidt (Ibid.) points out that gonorrheal ulceration is apt to be multiple, and causes severe pain and bloody, turbid urine. As a rule, when the bladder is ulcerated, the urine contains blood, blood-clots, or tissue débris, but the urine may be clear when there is a tuberculous ulcer or solitary ulcer.

Diagnosis is usually made by the cystoscope. In some cases it is made by exploratory suprapubic incision.

Treatment.—If there is one ulcer, or if there are a few ulcers, curet or excise with cutting forceps, through an operative cystoscope (Buerger), use irrigations, and keep the urine aseptic. In widespread ulceration perform suprapubic cystotomy, curet the diseased mucous membrane, and insert a drainage-tube. In some cases of malignant growth the cautery is used as a palliative measure. Perforation is treated as is rupture of the bladder (see page 1465).

Tumors of the Bladder.—These growths are usually said to be very rare, but in Guyon's statistics they are found to constitute 3.9 per cent. of all cases of genito-urinary disease. They are almost 5 times as common in males as in females. They are most frequently met with between the ages of fifty and sixty, although myxoma is met with in childhood only and sarcoma is most common in the young (Lincoln Davis in "Annals of Surgery," April, 1906). Persistent vesical irritation may, perhaps, be an element in causing tumor. Tumors of the bladder may be either innocent or malignant, the latter being the commonest. Innocent tumors which may arise from the bladder are papillomata or villous tumors, adenomata, mucous polypi (myxomata), fibrous polypi, myomata, and angiomata. A myoma may attain a great size (even that of a child's head). The common form is intravesical. There is an interstitial form and a peripheral form. Papilloma is far and away the most common form of innocent tumor. Cysts may also arise. Malignant tumors are sarcoma (comparatively rare) and carcinoma (encephaloid, rare; epithelioma, common). Munwes ("Zeit. f. Urology," Nov., 1910) collected 107 cases of sarcoma. Sarcoma begins in the submucosa. The majority of bladder carcinomata are secondary to growths of the rectum, prostate, or uterus. Adenocarcinoma and scirrhous carcinoma are practically always secondary to rectal, prostatic, or uterine tumors. Papillary cancer and epithelioma are not unusually primary (Mandlebaum, in "Surg.,.Gynecol., and Obstet.," 1907). Primary carcinoma, like primary sarcoma, most commonly arises in or near the trigone. Any tumor of the bladder, innocent or malignant, will eventually cause death if allowed to remain. Papilloma is very apt to become cancerous.

Symptoms.—The innocent tumors rarely cause cystitis or irritation, though by obstructing the ureters or the urethra they may induce disease of the kidneys. Hematuria is almost invariably present at some time during the

existence of a bladder tumor. It is apt to be profuse, and the urine contains blood, blood-clots, and perhaps fragments of tumor. The bleeding is intermittent, may occur even when the patient is at rest, and, except in malignant disease, is seldom preceded or accompanied by pain. Bleeding usually occurs at the termination of micturition, the first urine being clear and the last red or clotted. Often hemorrhage is the only phenomenon produced by a papilloma or a mucous polypus. Hemorrhage may occur from a myoma. Malignant tumors cause cystitis, and the urine contains mucus, blood, and pus. The growth may become crusted with salts from the urine. Cancer is decidedly and often horribly painful. In malignant disease the rectum usually becomes involved. Hydronephrosis may be caused. Metastases to the lungs are common. Ulceration may occur into the peritoneal cavity or rectum. A malignant tumor progresses much more rapidly than an innocent growth, although in vesical cancer metastases are not formed so early as in some other regions. Innocent tumors are felt with difficulty with the sound, but malignant tumors are easily felt. In some cases a tumor can be detected by a bimanual examination (a finger in the rectum and the fingers of the other hand on the abdomen). Make a careful study to determine whether or not a growth has infiltrated the prostate, the seminal vesicles, the rectum, or the perivesical tissues. Bleeding follows the use of a sound. There may be difficulty in starting the stream in micturition, there may be interruption or irregular halts in the stream. The latter condition is called *stammering of the bladder*. The urine should be examined microscopically to see if it contains villi, portions of fibroma, colonies of cancer-cells, or fragments of epithelioma. A cystoscope should be employed in order to reach a diagnosis. If the urethra is too narrow for the cystoscope, this channel must be dilated. If there be profuse bleeding an irrigating cystoscope must be employed. In doubtful cases exploratory suprapubic cystotomy is advisable.

Treatment.—Some innocent tumors may be cured by high-frequency electro-coagulation. This method is very valuable. Some use the Oudin, some the d'Arsonval current. Various names are given to the method besides the one employed above, viz.: dessication, fulguration, thermo-coagulation, high-frequency cauterization. The application is made through a cystoscope. In extensive malignant growths, beyond surgical removal, electro-coagulation may be used to arrest bleeding and lessen pain (for a Collective Review of this method see Henry G. Bugbee, in "Internat. Abstract of Surgery," December, 1915). Papillomata are particularly amenable to this treatment. Recurrence is rare. Some innocent tumors (for instance, peripheral myomata) are treated by suprapubic incision and removal of the growth and a portion of the bladder wall. A papilloma which recurs after electrocoagulation should be treated by excision with a portion of the mucous membrane and submucous tissue of the bladder wall. The perineal operation only enables the surgeon to reach and remove growths of small size, pedunculated growths, and growths near the neck of the bladder. (See Operations on the Bladder.)

Among the operations practised for malignant disease are *partial cystectomy* with resection of one or both ureters, partial resection of the bladder wall, removal of the growth without resection of the wall (a useless procedure), curetting (which is futile). Complete extirpation of the bladder (*total cystectomy*) for cancer has been performed by Bardenheuer, Héresco and others. Goldenberg reported 26 cases, with a mortality of over 60 per cent. It is usually done in two stages, in the first operation the ureters of a man being transplanted into the rectum, the ureters of a woman into the rectum or vagina. Héresco prefers skin implantation in the hypogastric region, because the ureters can then be catheterized and the pelvis of each kidney can be disinfected. About three weeks later the bladder is removed. The adjacent lymph-nodes along the internal iliac vessels and in front of the sacrum must be removed in all

cases. The space left by removing the bladder is drained through the perineum. The surgeon should bear in mind that vesical scirrhus and adenocarcinoma are practically always secondary growths, and if he cannot remove the primary growth he should not extirpate the bladder. The complete procedure has been carried out successfully at one operation (Tuffier and Dujarier, "Rev. de Chir.," April, 1898). Some surgeons prefer preliminary double lumbar nephrostomy; others transplant the ureters in the skin surface. The operation of complete extirpation is of questionable value. In most cases it has proved a fatal failure. Munwes ("Zeit. f. Urology," Nov., 1910) reported 69 radical operations for sarcoma. Only 3 patients lived for more than a brief time.

In Rafin's collection of 30 cases of cancer there were 17 deaths. One case was alive five years after operation, 1 fifteen months, and 1 seven months after. Watson's table of 25 cases of cancer shows 14 deaths and only 2 of the survivors were alive and free from recurrence after three years.

Complete extirpation should be employed only when cancer involves the bladder extensively. I agree with Berg ("Annals of Surgery," Sept., 1908), that if less than one-third of the bladder is involved the operation should be partial cystectomy with implantation of the ureters into the portion of bladder remaining. The surgeon removes the anatomically related lymphatic area and always bears in mind that vesical adenocarcinoma and scirrhus are secondary growths. Partial cystectomy saves the performance of the fatal operation of transplanting the ureters as is ordinarily done, or the questionable operation of lumbar nephrostomy with all of its unpleasant consequences. In Rafin's collection of 96 cases there were 21 deaths (a mortality one-half that of complete cystectomy); 50 cases were traced—5 were well over three years and 16 over six months (Berg, Ibid.). Henry Morris lays down the following rule: "When an infiltrating growth is felt, *per rectum* or *per vaginam*, or with the sound, to be involving a large surface of the bladder wall, to be infiltrating its coats, especially in the neighborhood of the ureters and neck of the bladder, no operation whatever should be proposed unless the hemorrhage is copious or the symptoms of cystitis severe, and then an incision for palliative purposes only should be made" (Treves's "System of Surgery").

Many surgeons content themselves in vesical cancer with suprapubic cystotomy, removing the growth and a portion of the bladder wall. If removal be not possible, they curet, cauterize, and drain. Radium and the *x*-rays may be of service to prevent recurrence after an operation for cancer, and in inoperable growths. After cystotomy for irremovable cancer of the bladder, radium is sometimes left in the bladder for several hours.

Operations on the Bladder.—Lateral Lithotomy.—*Lithotomy* is the removal of a stone from the bladder. *Lateral lithotomy* is an operation which was once a glory of surgery, which is every year becoming less popular, but which is still at times employed by surgeons, especially for stone in children. This operation should not be performed if the stone is over 2 inches in its short diameter; it is rarely justifiable if the stone weighs 3 oz. or more (Cage); and it must not be performed for encysted stone, or on a person with a deep perineum, a narrow pelvic outlet, or an enlarged prostate. For one week before the operation keep the patient in bed, wash out the bladder daily with hot boric acid solution, and administer salol and boric acid by the mouth, 5 gr. of each four times a day. The night before the operation give a saline, order a hot bath, and have the perineum, the scrotum, the buttocks, and the inner sides of the thighs shaved, cleansed and dressed antiseptically. In the morning an enema is to be given. At the time of operation the bladder should contain several ounces of boric acid solution. The instruments required are a lithotomy knife, a straight probe-pointed bistoury, a grooved staff, a stone-sound, stone-forceps and scoops, a tenaculum, an aneurysm needle, a fountain-syringe, curved needles and a needle-holder, hemostatic forceps, a tube with chemise (see Fig. 260), a Paquelin cautery, a Clover crutch, and a lithotrite.

Place the patient upon his back, anesthetize him, and find the stone by sounding. If the stone is not discovered by the sound at that time, *do not operate*. Place the buttocks so that they project beyond the edge of the table, introduce the staff into the bladder, flex the legs and thighs, and fasten the patient in the lithotomy position with a crutch. During the first incision the handle of the staff is held toward the belly; after the first cut the staff is set perpendicularly and is hooked up under the pubes. An incision is made, starting just to the left of the raphé of the perineum and 1¼ inches in front of the edge of the anus, and passing downward and outward to between the anus and the ischial tuberosity, but one-third nearer the former than the latter. In the adult this incision is 3 inches in length. The first incision is superficial and does not reach the staff, but it is this incision which may cut the rectum. After making the first cut the nail of the left index-finger feels for the groove of the staff, the staff is hooked up, the knife is entered into the groove and is pushed into the bladder, and as it is withdrawn the wound is enlarged. As the knife enters the bladder there is a gush of fluid. The finger follows the knife and stretches the wound, the staff is withdrawn, and the stone is felt for and extracted with forceps. Liston showed years ago the value of keeping the finger in the wound. This maneuver retains some water in the bladder, and as a consequence causes the stone to rest at the lowest part of the viscus, and when the forceps are introduced they at once come upon the stone. In withdrawing the stone make traction in the axis of the pelvis, and do not rotate the calculus until it is entirely out of the prostatic urethra. Wash or scrape away débris or incrustation from the wall of the bladder, see that no other stone is present, syringe out the viscus with warm salt solution, insert a tube, apply antiseptic dressings around the tube, and put on a T-bandage. The end of the tube which is external to the dressings is fastened to the tails of the T-bandage. A rubber cloth is put on the bed, under the body and legs, and the patient's buttocks rest upon a mass of old linen, the scrotum being raised on a pad. The knees are bent over pillows. Change the linen as soon as it becomes wet. Remove the tube in forty-eight hours. The urine begins to come by the urethra from the eighth to the twelfth day. In children the incision is not so long, it is dilated by forceps instead of by the finger, and no tube is required. In lateral lithotomy the prostatic and membranous portions of the urethra are opened, the prostate gland is partly divided by the knife, and the wound is dilated by the finger. One objection to the operation is that it is possible to cut the rectum, and another is that inflammation may occlude the ejaculatory ducts and cause sterility.

Suprapubic Lithotomy.—This operation is the removal of a stone through an opening above the pubes. It is in many instances the preferable operation. The mortality of this operation is higher in children than that of lateral lithotomy; in adults and in individuals beyond middle life the mortality is decidedly less than is that following the lateral operation. It is used for the removal of multiple calculi, for very hard stones, for stones above 2 inches in their short diameter, for calculi in men with enlargement of the prostate, for foreign bodies incrusted with sediment, when the perineum is deep, when the pelvic outlet is narrow, for encysted stones, for calculi associated with a vesical tumor, and when the urethra will not permit the use of a lithotrite. Before doing the operation determine the carrying capacity of the bladder when the patient is not anesthetized. This gives the safe limit of distention. Under an anesthetic the bladder will receive 3 or 4 more ounces than the safe amount. The patient is prepared as for lateral lithotomy, except that the pubes are shaved, and the lower part of the abdomen and the upper part of the thighs are disinfected. During the operation the penis is kept wrapped in a piece of antiseptic gauze.

In performing the operation place the patient in the Trendelenburg position. It is necessary to distend the bladder and raise it in order to have the

prevesical space uncovered by peritoneum. In most cases this is accomplished by distention of the bladder and the Trendelenburg position. In a few cases in which the bladder holds very little fluid a rectal bag is used to lift the bladder. If a rectal bag is to be used an assistant oils it and pushes it (empty) above the sphincters. It is filled after the bladder has been injected. Draw off the urine with a soft catheter, wash out the bladder with a solution of silver nitrate (1 : 8000 to 1 : 5000), and inject the bladder with the same solution. In a child under the age of five inject 3 to 4 oz.; in an adult it is usual to inject 10 to 12 oz. Withdraw the catheter and tie a tube around the penis to prevent the escape of fluid. After injecting the bladder with fluid, if the viscus is not well lifted, inject the rectal bag with water and clamp its tube with forceps. In a child inject from 2 to 4 oz. of warm water into the rectal bag; in an adult inject 10 oz. Bristow suggested the injection of air into the bladder. Some surgeons simply inject air by means of a catheter and a brass syringe or a Davidson syringe. Air injection is not recommended if fluid can be used. In operating on an air-distended bladder there is greater danger of trauma, shock, and postoperative bleeding. If air be injected, a rectal bag is never used, and the patient is placed on his back rather than in the position of Trendelenburg. The best method of injecting air is that of F. Tilden Brown,[1] by means of a bicycle pump. A catheter is introduced, the bladder is washed out, the catheter is fastened to a bandage, the bicycle pump is attached, the operation is proceeded with, and when the transversalis fascia is exposed the bladder is filled with air, the soft catheter is clamped, and the bladder is opened. Make a 3-inch longitudinal incision in the median line of the hypogastric region, terminating over the symphysis. When the prevesical connective tissue is reached push it up with a gauze-covered finger slowly and gently and with a sweeping motion. In close association with this tissue are the prevesical fat and peritoneum. Any roughness may be responsible for disaster. If the peritoneum should appear, push it up. Hold the wound edges apart by retractors. The large veins are seen, giving the bladder a blue color. Avoid these veins if possible, but even if they should be cut bleeding will usually cease when the bladder has been opened and the rectal bag has been emptied and removed. Clamp bleeding vessels. Pass a stay suture of strong silk on each side of the contemplated incision in the bladder. Catch each suture by a hemostat and let it hang. Open the viscus in the middle line above, and cut toward the pubes. Explore the bladder, remove the stone or stones, scrape away incrustations, ligate bleeding vessels outside the bladder, and irrigate the viscus with hot saline solution. Introduce a double tube into the bladder, and attach to its external end a long tube to siphon off the urine. The bladder can be drained very satisfactorily by a siphonage apparatus (Fig. 968). Suture

Fig. 968.—Cathcart drainage. The Y-tube is of glass and is darkened in order to be shown against a white background.

[1] "Annals of Surgery," Feb., 1897.

the muscles and fascia at the upper part of the wound. Dress with dry antiseptic gauze and a rubber-dam, the dressings and binder being split to go around the tube. Catch the urine which siphons over in a bottle containing some antiseptic fluid. Change the dressings as often as they become wet. Take out the tube in four or five days, and allow the wound to heal by granulation. The patient may get up in two weeks. Many Continental surgeons advocate immediate suture of the bladder after incision. Albert, Vincent, Bassini, DeVlaccos, and others advocate immediate suture. The suture material should be catgut. After suturing a catheter is kept in the bladder to drain the viscus. Immediate suture may be employed in patients of any age, but should not be used if the urine is very septic or if pyelonephritis exists. In some cases the attempted closure will fail; in others it will only partially succeed; in others it will prove successful; but even if it only partially succeeds it will tend to prevent dissemination of urine in the prevesical cellular tissue. The chief causes of death after suprapubic lithotomy are septicemia, secondary hemorrhage, cellulitis, peritonitis, and suppression of urine. J. W. White estimates the relative mortality of suprapubic and lateral lithotomy as follows: In children the suprapubic operation gives a mortality of 12 per cent.; the perineal, of 3 per cent. In adults the suprapubic gives a mortality of 12 per cent.; the perineal, from 8 to 12 per cent. In old men the suprapubic gives a mortality of 25 to 30 per cent.; the perineal, 30 to 40 per cent.

Crushing of the Vesical Calculi.—This is now done in one sitting, the old operation of Civiale, which required repeated crushings, being obsolete. In every case of suspected stone (as before stated) the cystoscope should be used.

Contra-indications to Litholapaxy.—Papilloma, malignant tumor, projecting prostatic lobes, encysted stone, and diverticuli.

Litholapaxy (*Bigelow's operation*, or *rapid lithotrity*) is the operation for removing a stone from the bladder in one sitting by thoroughly crushing the stone and completely washing away the fragments. This operation is wonderfully successful if done by an expert. Few of us do it sufficiently often to learn how to perform it with great rapidity, certainty, and safety. It is the best operation in most cases if performed by a very skilful man. It is the operation in the majority of cases for even the general surgeon to select, but the general surgeon will have better results in certain difficult cases after suprapubic lithotomy than after litholapaxy. Sir H. Thompson says this method is suited to 29 cases out of 30. Litholapaxy should be employed if the bladder will hold at least 4 oz. of fluid and is in a fairly healthy condition; if the urethra is tolerant and permits freely the passage of instruments; if the stone is not too hard, does not weigh over 2¼ oz., and is not over 2 inches in diameter. It is not suitable for multiple calculi, for large and hard calculi, for encysted stones, or for a patient with marked enlargement of the prostate gland, with vesical atony, or with cystitis. An easily dilatable stricture need not prevent the surgeon doing litholapaxy. The stricture can first be dilated, and later Bigelow's operation can be performed, but firm, gristly strictures demand a cutting operation. If the urethra is intolerant to instrumentation, the patient being prone to febrile attacks when it is attempted, cut instead of crushing. An individual laboring under kidney disease will do better after this operation than after cutting (Cage). In diabetes, locomotor ataxia, and conditions of exhaustion patients are best treated by Bigelow's operation, unless cystitis exists.

The Indian surgeons have had the most admirable results from litholapaxy. It has often been claimed that such results were due to racial peculiarities of the patients and various factors regarding their habits, diet, etc. The fact, however, that some of these very surgeons have returned to England and repeated their triumphs in London shows how large a part masterly dexterity played in obtaining success.

J. A. Cunningham ("Brit. Med. Jour.," Aug., 1887) reports upon 10,073 Indian cases of litholapaxy. The mortality was 3.96 per cent.

Cabot, of Boston, in 116 cases had but 4 deaths, and 2 of these were due to pneumonia.

The preparation of the bladder is the same as for lithotomy. Be sure to measure the stone, and to ascertain also whether a lithotrite can readily be introduced and manipulated. The instruments required are a stone-sound (see Fig. 967), lithotrites (several sizes, Figs. 969–971), an evacuating bulb and tubes (straight and curved, Figs. 972, 973), soft catheters, a glass irrigator to inject the bladder, and instruments in case the surgeon is forced to cut. The patient is anesthetized and is placed upon his back, a pillow is inserted under the pelvis, and he is well wrapped up. The urine is drawn and a measured amount of warm boric acid is allowed to flow into the bladder. This plan is better than having the patient retain his urine, as in the latter case there is

Fig. 969.—Bigelow's lithotrite.

Fig. 970.—Thompson's lithotrite.

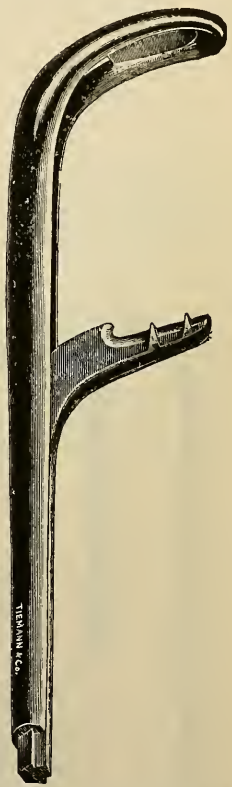

Fig. 971.—Forbes's lithotrite.

no certainty as to the amount of fluid in the viscus. It is well to introduce at least 5 or 6 oz. of fluid, if possible. If the bladder will not hold 4 oz. the operation is unsafe (Thompson). The lithotrite, preferably the instrument of Forbes (Fig. 971), is now introduced the handle being gradually raised to a vertical position as the penis is drawn up on the shaft, but not being depressed until the instrument has passed by its own weight into the prostatic urethra. Thompson's plan for catching the stone is as follows: After introducing the lithotrite, let its

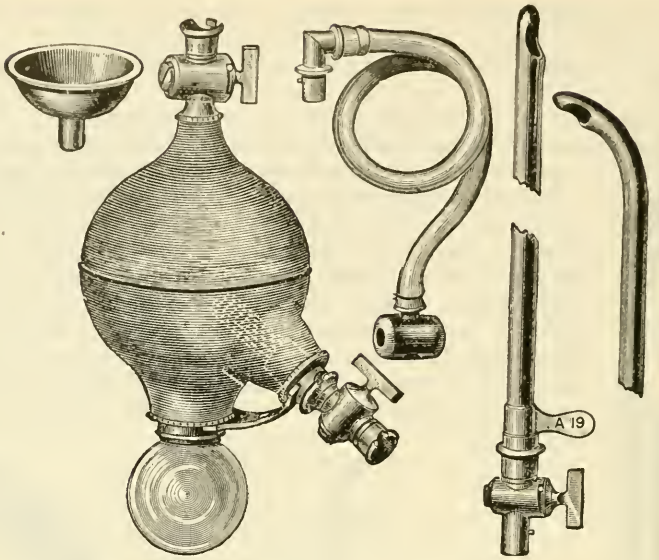

FIG. 972.—Bigelow's latest evacuator.

lower end rest for a few seconds on the bottom of the bladder, so that currents will subside; then draw back the male blade, wait a moment, close the blades, and in almost every instance the stone will be caught. If the stone is caught, press firmly to see that the calculus is well held, lock the instrument, and break the foreign body by screwing. When resistance suddenly ceases the stone has either slipped or has been crushed; if crushed, the blades should have been felt forcing through the stone and the calculus should have been heard to break. When resistance ceases catch and crush again as above directed. Rapid movements with the lithotrite are improper, as they establish currents which are apt to push away the stone. If the above maneuver does not catch the stone, see if the calculus is near the neck of the bladder. Pull the instrument close to the vesical neck, and open it, not by pulling the male blade, but by pushing the female blade. If the operator still fails to catch the stone, or if, after crushing, a large fragment knocks against the evacuator, and this fragment cannot pass, conduct a careful search: turn the blades to the right side, open, and close; then to the left side, open, and close; next turn the point around behind the prostate, open, and close. After catching a stone with the lithotrite, turn the instrument very slowly, so as to detect the catching of the bladder wall if it has occurred, and crush the stone in the middle of the bladder with the blades up. After crushing several times, proceed to evacuate. Fill the aspirator with warm saline fluid. Insert an evacuating catheter, its point being in the center of the

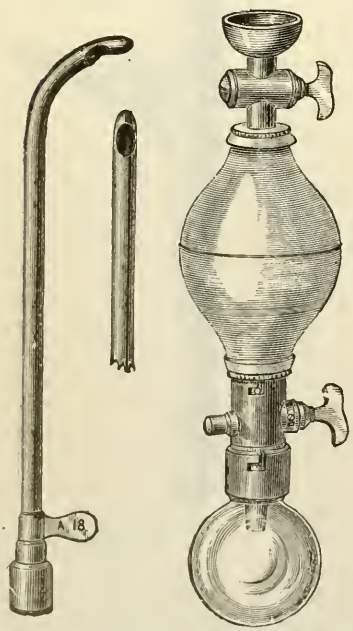

FIG. 973.—Thompson's evacuator.

bladder, let the fluid and fragments run out, and attach the aspirator to the catheter; turn the valve, and compress and relax the bulb so that an ounce or more of fluid is forced in at each squeeze, the compression coinciding with expiration. The débris falls into a bulb, and the pumping is continued until the fragments cease to pass, whereupon the point of the catheter is pushed against the floor of the bladder and another trial is made. If fragments which cannot gain exit are felt knocking against the tube, withdraw the evacuator, crush again, and again use the aspirator. When no more débris comes away and no more fragments are felt, withdraw the tube and carefully sound the bladder. Keyes advises the operator to seek for a final fragment by listening with a stethoscope while pumping at the bulb and searching the bladder with the tube. The amount of blood usually obscures a cystoscopic view. This operation will rarely occupy over forty minutes, though Bigelow has protracted it for three hours, the patient recovering. A serious complication is severe bleeding, due to damage done with the instrument or to the presence of a tumor which easily bleeds. The injection of moderately hot water or of adrenalin solution (1 : 10,000) usually checks hemorrhage, but if bleeding is dangerous in amount the operation of litholapaxy should be abandoned and suprapubic lithotomy should be performed.

If clogging of the lithotrite with fragments occurs, forcible pushing of the blades together repeatedly will probably amend it; but it will never happen if the surgeon uses a proper form of instrument. A lithotrite with a fenestrated blade will not lock. Forbes's lithotrite is a very powerful instrument, the blades of which will not lock. If the blades of a lithotrite should become forcibly and hopelessly locked, make a perineal section, clear out the blades, close them, and then withdraw the instrument.

After-treatment.—Put the patient to bed, apply a bag of hot water to the hypogastrium, and give him a hypodermatic injection of morphin as he recovers from ether. Give a hot hip-bath every night, and administer liquor potassii citratis in moderate doses every day. If urethral fever occurs, use quinin and morphin, wash out the bladder several times daily with warm boric acid solution, and tie in a rubber catheter. If retention occurs, use the catheter. If cystitis appears, treat as in an ordinary case. The urine ceases to be bloody in two or three days, and the patient may get up in a week. Before the case is discharged cystoscopy should be practised to be certain that no fragments of stone remain.

Litholapaxy in Male Children.—It was once taught that a child, because of the small size of the bladder, the small diameter of the urethra, and the readiness with which the mucous membrane is lacerated by even slight violence, is a poor subject for crushing. Lateral lithotomy is known to be eminently successful when performed upon children. The elder Gross did this operation upon 72 children, with only 2 deaths. Keegan, however, has persuaded the profession that rapid lithotrity is perfectly applicable to children. He shows that the bladder of a child of even less than two years of age is quite large enough to allow the surgeon to manipulate an instrument; that the mucous membrane is in no danger if the operator is careful, and that the urethra is by no means so small as was supposed. The urinary meatus must often be incised, and after doing this, Keegan states, there can be passed in a boy of from three to six years a No. 7 or 8 lithotrite (English), and in a boy of from eight to ten years a No. 10 or even No. 14. It is, however, just to state that the operation is more delicate than a like procedure on older persons, and that no one is justified in doing it who has not had considerable experience in adult cases. Furthermore, it should be noted that Keegan's mortality by this operation has been 4.3 per cent., while Gross's mortality from lateral lithotomy on children has been under 3 per cent.

Special points relating to litholapaxy on male children are as follows: use well-

fenestrated lithotrites; have a stylet to punch out the fragments blocking the evacuator; and crush the stone to a fine mass. There can usually be employed a No. 8 lithotrite and a No. 8 evacuating tube (English scale).

Perineal Lithotrity (*Keith's Operation*).—This operation is employed by some surgeons in dealing with very hard or very large calculi in male adults, or in cases in which it is impossible to introduce a lithotrite into the bladder. Keith's operation consists in opening the urethra from the perineum, passing a lithotrite through the wound, into the urethra and along the urethra into the bladder, and crushing the stone, introducing an evacuator and removing the fragments. In Keith's operation the incision is median and opens the membranous urethra. In very large stones Milton thinks the surgeon should open the bladder as in ordinary lateral lithotomy, introduce a lithotrite through the incision, and crush the stone before extracting it, thus avoiding the infliction of injury upon important structures.

Operation for Stone in Women.—If the stone be small, give the patient ether, place her in the lithotomy position, dilate the urethra by the uterine dilator until it admits the index-finger, and remove the stone by the finger, the scoop, or the forceps. If the stone is found to be too large to pass, crush it by a lithotrite and get rid of the débris by the evacuator. Large stones (2 oz.) may require suprapubic lithotomy. Vaginal lithotomy is never required. If done, it is very likely to leave as a legacy a vesicovaginal fistula. In female children dilate the urethra, crush the stone, and evacuate.

Cystotomy or Cystostomy.—These terms mean the opening of the bladder. If the opening be made for diagnosis or treatment and be then closed or allowed to close, the operation is a cystotomy. If the wound be deliberately kept open it is a cystostomy. The bladder may be opened for drainage, for diagnosis, for the removal of stones or tumors, or for the treatment of ulcers. This opening may be done by (1) a suprapubic cut (as in suprapubic lithotomy),(2) a lateral perineal cut (as in lateral lithotomy), or (3) a median perineal cut (as in median lithotomy).

The operation may be completed in one sitting, or the bladder may be only exposed, the opening of it being delayed for several days until it becomes adherent to the margins of the wound (Senn's operation). Senn's operation prevents infiltration of urine into the prevesical space, and it is advisable to select it if the urine be very foul.

A sinus may persist after suprapubic cystotomy, but usually the wound heals unless it be kept open by some expedient.

The effects of suprapubic drainage are very beneficial in cases of chronic cystitis associated with hypertrophy of the prostate gland, the urine being foul. Drainage causes the urine to become clear and the mucous membrane of the bladder to become normal. If the opening be made as a permanent drain, there will usually be incontinence, as the new channel has no sphincter action (Dandridge). Figures 977 and 978 show tubes for prolonged drainage.

Suprapubic Cystotomy (or Cystostomy).—The operation is employed to allow the surgeon to explore the bladder, to treat an ulcer, to provide drainage, or to remove a tumor. If the operation be for calculi, it is known as suprapubic lithotomy (see page 1478). After the bladder is opened its interior can be illuminated by the rays of an electric lamp, which is fastened with a mirror to the forehead of the operator. If an ulcer be found, it is scraped with a curet or a spoon. Most cases of tumor require suprapubic cystotomy. It is true that a small single growth at the vesical neck is accessible by median cystotomy, but the area for manipulation is very narrow and the growth cannot be seen. Every large growth, all cases of multiple tumors, and all cases of tumor in individuals with great depth of perineum or with enlarged prostate require suprapubic cystotomy, an operation which allows one to feel and to see the growth, which gives room for manipulation, and which permits thorough

exploration of the entire bladder. The patient is put in the Trendelenburg position if water distention be used, but is placed horizontally if air distention be employed. After opening the bladder as for stone (see page 1479), hold the edges of the incision apart by means of a speculum (speculum of Keen or Watson) or by retractors, and reflect the electric light into the wound. Growths when seen can be twisted off, a pair of forceps holding the base and another pair being used to twist, but after removal by twisting they will always recur unless the base and the mucous membrane about the base be removed. Broad malignant growths may require partial cystectomy. Some growths (as inoperable cancer) are removed piece by piece with Thompson's forceps (Figs. 974–976), the base of the tumor being scraped. Such a procedure is merely palliative. Soft growths are scraped away by a curet, a spoon, or the finger-nail. If bleeding be severe, check it by pressure, by hot water, by a 1:10,000 solution of adrenalin chlorid, or even by the actual cautery. In some cases the

wound is allowed to heal rapidly. In others the bladder is drained for a considerable time. In some it is kept open permanently. Permanent drainage is desirable in some cases of enlarged prostate, and in such cases Senn's tube (Figs. 977 and 979) or Stevenson's tube (Figs. 978 and 980) may be employed.

Median Cystotomy (or Cystostomy).—The same incision is made in the perineal raphé for median cystotomy as for median lithotomy. A grooved staff is introduced and is hooked up under the pubes; an incision is made into the membranous urethra, and is extended backward for ¾ inch, and a finger is carried into the bladder. If searching for a growth, find it by the finger. The usual rule has been to catch it in Thompson's forceps and twist it off. Such an operation is totally inefficient. Soft growths may be scraped away. Stop bleeding by digital pressure or by injections of hot water or adrenalin chlorid (1:10,000). Median cystotomy does not allow anything like the free-

dom of access given by suprapubic cystotomy, and the latter operation is the best for tumor cases. The median operation may be used for drainage.

Fig. 977.—Senn's silver tube.

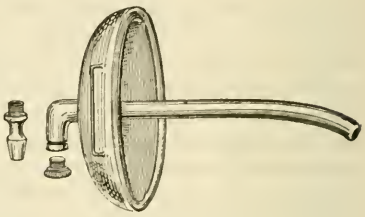

Fig. 978.—Stevenson's suprapubic drainage-tube.

Growths in the Female Bladder.—It was long the custom to dilate the urethra as in a case of stone, and scrape, twist, or pull the growth away or ligate it. This plan is inefficient, as by it the base of the tumor is not removed. It is

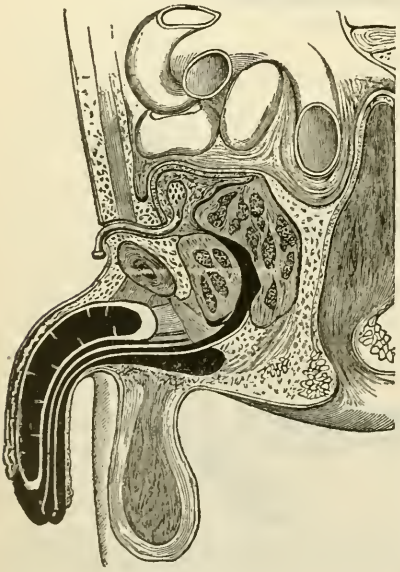

Fig. 979.—Senn's tube applied. The instrument does not press upon the sensitive neck of the bladder.

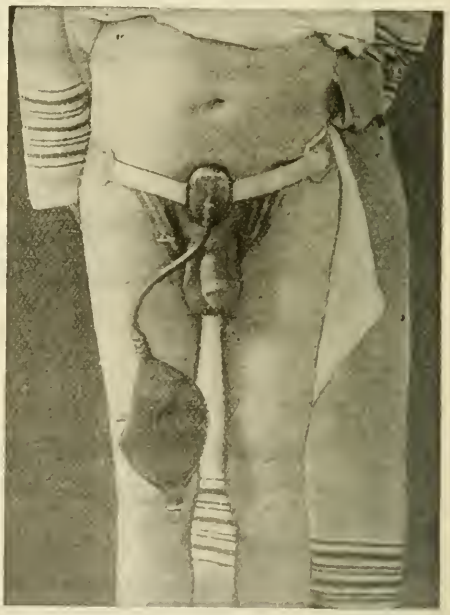

Fig. 980.—Stevenson's suprapubic drainage-tube in place and attached to a receptacle for urine.

usually best, if high frequency electro-coagulation fails or will evidently be useless, to perform a suprapubic operation. If the growth is large or if there are multiple growths, always perform suprapubic cystotomy.

Diseases and Injuries of the Urethra, Penis, Testicle, Prostate, Seminal Vesicle, Spermatic Cord, and Tunica Vaginalis

Injuries of the penis and urethra may arise from traumatism to the perineum or the penis, from cuts and twists of the penis, from the popular "breaking" of a chordee, from tying string around the organ, from forcing rings over it, from the passage of instruments, or from the impaction of calculi. Vio-

lence inflicted upon an erect penis may fracture the corpora cavernosa. The writer saw one man with a glass rod broken off in the canal, he having been in the habit of introducing it at the dictate of morbid sexual excitement. A patient in the Insane Department of the Philadelphia Hospital pushed over his penis a ring which ulcerated into the urethra. These injuries are treated on general principles.

Perineal Bruises.—If the perineum be bruised without rupture of the urethra, the perineum and scrotum swell and become discolored; water is passed with difficulty because the extravasated mass of blood in the periurethral tissues compresses the canal more or less; the water is not bloody; and there is severe pain and much shock. Some authors include under rupture those cases in which laceration of the spongy tissue occurs, without involvement of the mucous membrane or of the fibrous coat, but they are properly contusions.

Treatment of Bruises and Wounds.—Place the patient in bed and establish reaction, and when reaction is complete employ opiates for the relief of pain. Apply an ice-bag to the perineum. If, notwithstanding these measures, swelling continues, introduce a silver catheter (No. 12 English), tie it in, and make pressure upon the perineum by a firmly applied T-bandage or by a crutch braced against the foot-board of the bed. Even when swelling is slight, retention of urine may occur from projection of a submucous blood-clot into the canal of the urethra. In some cases it may become necessary to incise the perineum and evacuate the blood-clot. After twenty-four hours have passed, if hemorrhage has ceased, substitute a hot-water bag for the ice-bag, and empty the bladder every 6 hours by a soft catheter. Occasionally, though rarely, an abscess forms. *Punctured wounds of the urethra* require ordinary dressings. *Incised wounds of the urethra*, when longitudinal, are closed by suture. Healing is rapid and ill consequences are not to be feared. Stricture does not follow. When the wound is transverse, introduce a catheter, suture the wound over the instrument, and remove the catheter at the end of the third day. If a catheter cannot be introduced, employ sutures, but at the first evidence of extravasation open the wound, and if drainage is not free perform external perineal urethrotomy.

Rupture of the Urethra.—By this term is meant a lacerated or a contused wound of the urethra, destroying partially or entirely the integrity of the canal. A lacerated wound may be induced by fracture of the cavernous bodies during erection, the symptoms being severe hemorrhage, intense pain, retention of urine, and inability to pass an instrument; infiltration of urine occurs, and gangrene is a common result. The writer has seen 1 case of rupture of the penile urethra due to a man's slipping while shaving, the penis being caught in a partially open drawer, the drawer being shut by his body coming against it. Rupture, however, is almost invariably located in the perineum, and it arises when the urethra is suddenly and forcibly pressed against the arch of the pubes by a blow, by a kick, or by falling astride a beam or a fence-rail or on a wagon wheel. Retention of urine due to stricture may lead to extravasation of urine. The lesion of urethral rupture consists, in some cases, of laceration of the spongy tissue and the mucous membrane, a cavity being formed which communicates with the canal, and which fills with urine during micturition. In other cases, not only the spongy tissue and the urethral mucous membrane are rent asunder, but the fibrous coat is also torn, the canal opening directly into the perineal tissues, in which forms a huge cavity that fills with blood and later with urine and pus. The urethra may be torn entirely across, but in most cases a small portion at least, of its circumference is uninjured. Rupture never occurs primarily and alone in the prostatic urethra. Some think it is extremely rare in the membranous urethra unless due to pelvic fracture. I believe that it occurs not unusually in the membranous urethra. When we recall that this is the fixed portion of the tube we should expect rupture here rather than elsewhere. It is very unusual in the penile

urethra. The seat of rupture in the great majority of cases is in the region of the bulb. Very rarely is the skin broken.

The **symptoms** of rupture of the fixed urethra are considerable pain, aggravated by motion, pressure, and attempts to pass water; decided shock; in some cases micturition is still possible, blood preceding and also discoloring the stream, for some blood usually runs into the bladder; retention of urine quickly arises; in a vast majority of the cases retention is absolute from the very first, and it is due to the interruption in the integrity of the canal and to the occlusion of the channel by blood-clots. Bleeding, which is usually free, lasts for several hours, some little blood generally appearing externally and much being retained in the perineum, inducing progressive swelling. The presence of a large swelling is regarded as evidence of urethral rupture. The blood which is effused in the perineum may extend under the fascia to the penis and scrotum. The swelling soon becomes reddish, purple, or even black, pressure upon it is apt to cause blood to run from the meatus, and it is enlarged when attempts are made to urinate. After a time, if the surgeon does not act, the urine fills the perineal cavity and widely infiltrates, and there ensue gangrene, sloughing, and sepsis, life being endangered or fistulæ being left as legacies. The course of the extravasated urine will often enable one to locate the seat of injury. In rupture of the membranous urethra, if uncomplicated, the urine remains between the two layers of the triangular ligament until a channel is opened for it by sloughing or by the knife. When extravasation occurs behind the posterior layer of the ligament the urine finds its way to the perineum in the neighborhood of the anus. When the rupture is in front of the anterior layer of the ligament the urine, directed by the deep layer of the superficial fascia, finds it way into the scrotum and up on the belly, but does not pass into the thighs (Fig. 981). A contusion is distinguished from a rupture by the facts that in the former the perineal swelling is not very extensive and does not enlarge on attempting micturition, while in the latter it is extensive and does enlarge on attempting to pass water. Furthermore, contusion does not cause urethral hemorrhage, while rupture does. A contusion sometimes, but not often, prevents the passage of a catheter; a rupture almost always, but not invariably, does so. The mortality from severe rupture with extravasation is about 14 per cent. (Kaufman).

Fig. 981.—Rupture of the urethra and extravasation of urine.

Treatment.—In some very rare cases it is possible to suture the urethra, and this procedure should be carried out when possible. In order to suture, perform suprapubic cystotomy and also make a perineal section. Find the posterior end of the ruptured urethra in the perineum by passing a catheter from the bladder into the urethra. Suture by way of the perineum and with silk. The sutures pass through all of the coats of the urethra. The roof of the canal is sutured first, then a steel sound is introduced from the meatus, and the urethra is sutured around the instrument. The sound is withdrawn and the

bladder is drained by Cathcart's siphon as illustrated in Fig. 968 or by a double tube. In recent cases of ruptured urethra the usual treatment is as follows: Immediately perform median perineal section and turn out the clot; trim off lacerated edges; find the proximal end of the urethra, pass a catheter from the meatus into the bladder, and leave it *in situ* until healing has begun around it. If the catheter cannot be passed from the meatus, open the bladder above the pubes and find the proximal end of the torn urethra by retrograde catheterization. In retrograde catheterization we push an instrument from the bladder into the wound and use it to guide a catheter from the meatus into the bladder. When rupture occurs back of a stricture it is a good plan to excise the cicatricial tissue. In cases with extravasation make a median incision and numerous transverse cuts to secure drainage for areas of retained urine or pus. Then at once perform suprapubic cystotomy. Drain suprapubically and from the perineum for about two weeks, by which time sloughing tissue will have separated. Then find the posterior urethra by retrograde catheterization and do a perineal operation to repair the damaged urethra. (See Eugene Fuller, in "New York Med. Jour.," Nov. 23, 1901.) The wound is packed with iodoform gauze, and the bowels are tied up with opium for a few days. Some surgeons strongly disapprove of the custom of retaining the catheter, believing that the instrument does no real good, as urine is certain to get between the catheter and the walls of the urethra. They think it is quite enough to stuff the wound with gauze, the patient urinating through the wound for the first few days, after which time a catheter is used at regular intervals. Whatever method is employed, healing will require from six to eight weeks, and the patient must during the rest of his life, from time to time, introduce large-sized bougies.

Foreign Bodies in the Urethra.—These bodies may be calculi, bodies introduced by injury, as shot, bone, etc., bodies entering from a fistulous opening into the rectum, or bodies introduced from the meatus, as broken bits of catheters, straws, pins, etc.

The **symptoms** and **treatment** vary with the size and the nature of the body. Sometimes there are almost no symptoms; at other times there are found great pain, retention of urine, and hemorrhage. Examination is made by the urethroscope, by feeling carefully with a finger in the rectum, and by searching very gently with a sound, taking care not to push the body back. In some cases the body can be removed by aid of the urethroscope. Employ this plan if possible. If it is not possible, try the following plan: If the bladder is well filled with water when the body becomes impacted, inject a little oil into the meatus, close the lips with the fingers, and direct the patient to attempt forcibly urination, the surgeon opening the meatus when the urethra is widely distended, the foreign body being often forced out. If this maneuver fails, and the foreign body be impacted in the pendulous urethra, prevent its backward passage by at once tying a rubber tube around the penis. Try to squeeze the body out, and, if unsuccessful, endeavor to catch it with a wire loop, with a scoop, or with the long urethral forceps. If these methods fail, cut down upon the body and remove it, dividing any existing stricture. If it be lodged just back of the meatus, incision of the meatus will permit extraction. If a hairpin is in the canal, the ends of the pin are almost always pointing to the meatus; to prevent them catching on attempted withdrawal, the penis must be squeezed to approximate the ends of the pin, and when they are adjacent a part of a silver catheter is slipped over to retain them in this position, when the pin can be extracted. If this fails, drag the penis against the belly, by rectal touch force the sharp ends of the pin out through the integument, cut one end off, and then withdraw the other. An ordinary large-headed pin is forced out in the same way, and when the head is turned externally it is extracted by way of the meatus. If a hard or sharp foreign body be lodged in the prostatic urethra, do not catch it with an instrument or try to drag it forward. To do so will

be apt to tear the membranous urethra. It is better to push it into the bladder and remove it later by cutting or, if it be a stone, by crushing (H. Hartmann, in "La Presse Méd.," July 24, 1901). If a lithotrite loaded with fragments be caught in the urethra, the surgeon must perform a perineal section, to enable him to clean and close the blades. After the blades have been closed the instrument may be easily withdrawn.

Urethrorrhea is not urethral inflammation, but is a condition of sensitiveness of the urethra and oversecretion of the glandular elements. It may be due to masturbation, sexual excess, and also, as Sturgis points out, to withdrawal during sexual intercourse, and to ungratified sexual passion. A drop or two of transparent mucus is found at the meatus in the morning, and a considerable amount may flow away while straining at stool or upon the diminution of an erection. This flow at stool is often called defecation spermatorrhea. This discharge stains, but does not stiffen linen (Sturgis). The discharge contains mucus, mucous corpuscles, epithelial cells, but no gonococci or pus organisms. The patient may be well in all other respects, but in many cases there are neurasthenic symptoms, sexual weakness, or even impotence. It is well to explain to the patient that the overaction of the muciparous glands is Nature's effort to facilitate the passage of the fluid of the orgasm and to alkalinize an acid urethra which would inhibit the activity of spermatozoids. Quacks fatten on these unfortunates. This condition may be readily distinguished from prostatorrhea by the absence of Böttcher's crystals (see page 1524) and from that very rare condition, spermatorrhea, by the absence of spermatozoids.

Treatment.—In an uncomplicated case improvement or cure will follow the abandonment of evil habits and the systematic passage of steel sounds. If complications arise, they must be treated.

Urethritis, or Inflammation of the Urethra.—Urethral inflammations can be divided into two classes: (1) *simple* or *non-specific*, in which infection is due alone to pyogenic cocci (particularly the Bacillus coli communis and the Staphylococcus pyogenes), and (2) *specific*, in which the gonococcus is present.

Non-venereal, non-specific, pyogenic, or **simple urethritis** may be due to several causes, such as traumatism; great acidity of the urine; chancre in the urethra; contact with menstrual fluid, leukorrheal discharge, the discharge from malignant disease of the uterus, ordinary pus, or acrid vaginal discharge; the passage of instruments; the administration of irritant diuretics; strong injections; worms in the rectum; a febrile malady; venereal excess and masturbation; the passage or impaction of foreign bodies, and papillomata of the urethra. A temporary and mild urethritis sometimes accompanies early syphilitic eruptions. Simple urethritis is less severe and prolonged than gonorrheal urethritis, though clinically in the early stage the physician cannot invariably distinguish between the two forms. The diplococci of gonorrhea are never found in the discharge of simple urethritis, although there may be numerous other diplococci. In medicolegal cases testimony is not admitted as to the presence or absence of diplococci, as judges do not admit that their presence proves or their absence disproves gonorrhea. In the non-specific inflammation pus is not always present, many cases stopping short of pus formation after a varying period of catarrh, but any catarrh may become purulent. A simple urethritis may be caused or may be prolonged for an indefinite period by the presence of large amounts of oxalate in the urine or the existence of the uric-acid diathesis (see Gouty Urethritis).

Treatment.—Seek for the cause and remove it. Correct any abnormal condition of the urine by means of suitable diet, drugs, and mode of life. Mild astringent injections are useful. It may be necessary to flush the urethra repeatedly with a solution of silver nitrate (1: 8000).

Traumatic Urethritis.—The onset of pain in traumatic urethritis is coincident with the introduction of the foreign body. The discharge, which may be bloody, mucous, mucopurulent, or purulent, comes on within twenty-four hours.

Treatment.—If the inflammation be slight, prescribe diluent drinks, paregoric, a saline, or the following:

℞. Tinct. belladonnæ..... f℥ss;
Sodii bromid..... ℥iv;
Tinct. opii camphorat..... f℥j;
Syrupus zingib..... f℥ss;
Aquæ destil.....q. s. ad. f℥vj.—M.
Sig.—A tablespoonful every six hours.

If the inflammation be severe, put the patient to bed, apply hot fomentations to the perineum, give diluent drinks, employ suppositories of opium and belladonna, and watch for fever and other complications.

Gouty Urethritis.—This condition first manifests itself in the posterior urethra, not in the anterior, as does clap. Its symptoms are great vesical irritability; pain on urination; discharge, usually scanty, associated with uric acid in the urine and perhaps joint symptoms of gout. The *treatment* comprises dieting and the usual remedies for gout. Purgatives are given freely, and full doses of colchicum, piperazin, urotropin, or the alkalis; hot baths, low diet, diluent drinks, and diaphoretics are indicated. A chronic discharge from the prostatic region is apt to linger; for this there is nothing better than the usual gouty remedies and saline waters with copaiba, cubebs, or sandalwood oil. In many cases it is necessary to flush the urethra once a day with a solution of silver nitrate (1:8000).

Eczematous Urethritis.—Berkley Hill states that this disease is very obstinate, is probably associated with gout, and is met with in adults of full habit or who are beer-drinkers and who have eczema of the surface of the body. He states also that the glans penis near the meatus is red and tender, and that the interior of the urethra is in the same condition. Pain is constant, and it is aggravated by micturition. The discharge is scanty. The *treatment* comprises injections of cold water or irrigation with iced water, and internally the administration of arsenic with the alkalis.

Tuberculous urethritis is due to a tuberculous ulcer, which is most apt to be seated near the vesical neck. There is a little pain on micturition, but there is intense pain at one spot on passing a bougie. The discharge is slight and at times bloody. The bladder is very irritable, and severe cystitis arises and persists. The *treatment* includes warmth, nutritious diet, and cod-liver oil, curettement, and local applications of iodoform through a urethroscope, and living as much as possible out of doors. The climate of southern California is peculiarly well suited to these cases. The bladder is washed out once a day with boric acid solution. Iodoform emulsion is injected daily. Tuberculin may prove of value. After a time the surgeon will probably be forced to drain by perineal or suprapubic cystotomy (see Tuberculous Cystitis, pages 1472 and 1473).

Pyogenic Chancroidal Urethritis.—This condition is sometimes seen in association with chancroid of the urinary meatus.

Pyogenic Urethritis of Urethral Chancre.—A urethritis may occur in this condition.

Pyogenic Syphilitic Urethritis.—A temporary and mild urethritis sometimes accompanies early syphilitic eruptions.

Examination of a Patient in Whom a Urethral Discharge Exists.—Learn accurately the history. Obtain some of the discharge and examine an unstained slide and a slide stained for gonococci. In some cases take cultures. Learn the amount of the twenty-four-hour urine and study a sample chemically

and microscopically, being sure to determine the amount of urea. Learn if the discharge discolors or stiffens linen; if it is only found in the morning; if it simply glues the lips of the meatus together; if it is seen during the day; if it is noted particularly or only after sexual excitement or straining at stool. Inquire as to pain, frequency of micturition, passage of blood, nocturnal emissions, manner of urinating, etc. In many cases insert a finger in the rectum, feel the prostate and vesicles, massage them, and see if discharge appears at the meatus after stripping the penis. If discharge does appear, collect a specimen and examine it. In some cases it is necessary to pass a sound. Carefully cleanse the meatus, glans, prepuce, and urethra before passing a sound. Cleanse the meatus, glans, and prepuce with a 1: 6000 solution of corrosive sublimate. Irrigate the urethra with boric acid solution and fill and clean the urethra with emulsion of iodoform and glycerin (5 per cent.), and after using the instrument irrigate again with boric acid solution (Valentine's method). Examine the urine by the three-glass test.

The Three-glass Test (*Valentine's Plan*).—Take as many 3-oz. tubes as are required to receive all the urine from the bladder. The first tube contains the washings from the anterior urethra; the second and other tubes, additional material from the bladder; the last tube contains material expressed from the posterior urethra, prostate, and seminal vesicles. Examine the urine and the sediment in the first two glasses and in the last glass. Note particularly if *shreds* are present. The shreds of gonorrhea are white in color and of variable length, and float in the urine. They are composed of pus-corpuscles and of epithelial cells which have undergone fatty degeneration. Some of these shreds form in the ducts of Cowper's glands, some in the glands of Littré, some in the prostatic sinuses, some in the utricle, some in the folds around the verumontanum, and some are from inflammatory patches along the entire length of the urethra. A 1 per cent. solution of methylene-blue injected into the anterior urethra will stain the urethral shreds, while those from the bladder will not be stained by it.

Gonorrhea (Clap; Specific Urethritis; Tripper; Venereal Catarrh).—Gonorrhea is an acute inflammation of the genital mucous membrane, nearly always of venereal origin, due to the deposition and multiplication of gonococci in the cells of the membrane and a mixed infection with the cocci of suppuration. The disease is inaugurated by gonococci. After a few days or more secondary pyogenic infection develops and complications may result from the gonococci or from the bacteria causing the mixed infection. The disease attacks with the greatest ease surfaces covered with squamous epithelium. The gonococci enter into and multiply in the superficial epithelial cells and pass between the deeper cells, where they lodge and multiply as the superficial cells are cast off. The pus from the urethra contains epithelial cells with gonococci on or inside of them, and also pus-cells with gonococci within them as a result of phagocytosis. Cultures are made with difficulty. Gonococci do not stain by Gram's method, but stain best with a weak, watery solution of an anilin dye. These bacteria are said not to be pathogenic to animals, although some observers deny this assertion. Gonorrhea is one of the most common and widely disseminated diseases. Probably one-half of all sterile women and many sterile men have been rendered so by this disease. It is responsible for not a few cases of abortion, for an enormous majority of female pelvic diseases, and it causes many cases of blindness by infection of children's eyes during delivery.

Gonorrhea in the Male.—In the male, clap begins within the meatus and fossa navicularis and extends backward throughout the length of the urethra. The mucous membrane swells and becomes hyperemic, and there is a discharge, first of mucus and serum, and then of pus. In severe cases the discharge is bloody (*black gonorrhea*) or green. For a week or more the inflammation increases, then becomes stationary for a time, and then declines, the discharge

growing less profuse and thinner, a watery discharge lasting for a considerable time. An ordinary case of genuine gonorrhea lasts from six to ten weeks, and even a case limited purely to the anterior urethra will rarely be cured within four or five weeks. During the acute stage the entire penis swells and the corpus spongiosum becomes infiltrated with inflammatory exudate. An interesting fact is that gonorrhea may induce mild septicemia without demonstrable complications, the condition causing, according to Thayer ("Amer. Jour. Med. Sci.," Nov., 1905), a continued fever which, perhaps, lasts a number of weeks. In true gonorrheal septicemia the blood must contain gonococci (*gonococcemia*). In the case recorded by Thayer and in the one recorded by Blumer and Hayes, and in the one recorded by Stellwagen ("Therapeutic Gazette," April 16, 1910), cultures were obtained from the blood. Gonorrhea may produce grave septicemia with systemic complications. It tends particularly to attack serous membranes or other endothelial structures (joints, pericardium, endocardium, pleura, tendon-sheaths, intima of vessels, etc.). Among the complications are gonorrheal arthritis, myelitis, poliomyelitis, and multiple neuritis. There are 3 cases of gonorrheal myositis on record (Martin W. Ware, "Amer. Jour. Med. Sci.," July, 1901). Phlebitis may arise. Mild endocarditis may arise or severe endocarditis may occur, identical symptomatically with ulcerative endocarditis due to other bacteria. In 6 reported cases of endocarditis gonococci were obtained by cultures from the blood *intra vitam* (Thayer, Loc. cit.). Cerebral embolism may result. Cerebrospinal meningitis can occur (fluid obtained by lumbar puncture contains gonococci).

Gonorrheal rheumatism is discussed on page 723. Gonorrheal peritonitis is rare. Infection of the peritoneum through the blood is very rare. The majority of cases of gonorrheal peritonitis occur in women and are due to direct extension from the Fallopian tubes. Gonococci have not been found in the exudates of cases of pleuritis and pericarditis supposed to be of gonorrheal origin. A child may contract gonorrheal ophthalmia during delivery, and any person may develop it by getting gonococci into the eyes.

Symptoms of Acute Inflammatory Gonorrhea.—The period of incubation of gonorrhea is from a few hours to two weeks. The usual period is from three to five days, when symptoms of the *prodromal stage* or *stage of onset* begin. The patient notices on arising a drop of thin fluid which glues the lips of the meatus together, and he feels some heat and itching or tickling about the meatus or in the navicular fossa. There may be uneasiness or actual pain unconnected with urination, and there is sure to be scalding pain on urination. The meatus is red and swollen, has a glazed appearance, may be covered with a little mucopus, and the lips are glued together by the discharge. It may be possible to squeeze out a drop or two. Even so early the fluid contains gonococci. The urine appears clear, but on shaking some flakes are noted. They are epithelial cells. Within forty-eight hours the *first stage*, the *florid stage*, the *acute stage*, or the stage of increase, becomes established. The meatus is now red, swollen, and everted (*fish-mouth meatus*); the entire glans may be red and swollen; if the prepuce is long, it becomes swollen, reddened, and constricted, and in many cases very edematous; the lymphatics at the frenum and on the dorsum of the penis may be red, swollen, tender, and cord-like; micturition causes severe pain (*ardor urinæ*), which is due to distention of the inflamed urethra and to stinging by the acid urine. Bumstead thus described the act of micturition in acute gonorrhea: "During the act the patient involuntarily relaxes the abdominal walls, holds his breath, and keeps the diaphragm elevated in order to diminish the pressure on the bladder and lessen the size and force of the stream" ("Venereal Diseases," by Robt. W. Taylor). Because of the narrowing of the canal the stream of urine becomes narrow, weak, twisted, forked, or is delivered in little bursts or drops. Retention may result from spasm of the muscles. When the acute or florid stage is fully developed, the entire urethra is inflamed

from the meatus to the triangular ligament; there is constant uneasiness or actual pain in the penis and perineum, increased by walking and by sitting down suddenly or carelessly. Insomnia is common; *chordee* occurs, especially when the patient is warm in bed. By "chordee" we mean a condition of painful erection in which the penis is markedly bent. The rigid infiltration of the corpus spongiosum prevents it distending to accommodate itself to the enlarged corpora cavernosa, and in consequence the organ curves. There is frequent micturition, with tenesmus and a profuse creamy discharge, which is yellow, greenish, or even bloody. The discharge soils and stains the victim's linen and may crust upon the linen, the meatus, or the glans. The commonest complications of this stage are *balanitis* (inflammation of the mucous membrane of the glans penis), *balanoposthitis* (inflammation of the surface of the glans and the mucous membrane of the prepuce), *phimosis* (thickening and contraction of the foreskin, so that the glans cannot be uncovered), and *paraphimosis* (catching and fixation of the retracted prepuce behind the corona glandis, with such swelling of the glans and prepuce that it is impossible to bring the prepuce forward over the glans). This is a dangerous condition and it should be reduced at once. In the *second* or *stationary stage*, which lasts from the end of the first to the end of the second week, the acute symptoms of the first stage continue. The most common complications of this stage are *peri-urethral abscess* or *phlegmon* (infection of a urethral gland or of submucous structures), *folliculitis* (inflammation of the follicles of Littré), hemorrhage, retention of urine (which is rare), gonorrheal arthritis, lymphangitis, and diminutive bubo on the dorsum of the penis (*bubonulus*), solitary and painful bubo of the groin, which may suppurate, *Cowperitis* (inflammation of Cowper's glands), inflammation of the prostate or of the bladder, gonorrheal ophthalmia, and *chordee* (painful erection with downward bending of the penis). In the *third* or *subsiding stage* the symptoms gradually abate, the discharge becoming scantier and thinner, and finally drying up. This stage is of uncertain duration, and in it there may occur *epididymitis*, or inflammation of the epididymis. Among possible complications we may mention peri-urethral abscess or phlegmon, Cowperitis, cystitis, prostatitis, bubonulus, folliculitis, gonorrheal arthritis (see page 723), infective endocarditis, tenosynovitis, pyelitis, purulent ophthalmia, perichondritis, and peritonitis.

Examination for Gonococci.—Every urethral discharge should be examined for gonococci in order to make a positive diagnosis. This examination is made several times during the progress of the case, so as to determine when the organisms disappear. Many non-gonorrheal conditions are due to cocci strongly resembling gonococci. Free pus and numerous cocci usually mean gonorrhea. So do complications. The examination of the smear is not absolutely conclusive. Cultures are conclusive. If there be a free discharge, fluid for examination can be easily obtained. If the discharge be scanty or occasional, have the patient partially empty the bladder. Then the surgeon massages the prostate and urethra and smears fluid on the slide. Then the patient empties his bladder into two glasses. Each specimen is to be centrifuged and examined for pus (Keyes, "Amer. Jour. Med. Sci.," Jan., 1912). The taking of a smear and its examination are easy. Place a drop of discharge upon a cover-glass, lay another cover-glass over this, and slide the glasses apart. Dry and fix the slides in the flame of an alcohol lamp. Bring the cover-glasses in contact with a saturated solution of methylene-blue in 5 per cent. carbolic acid water. The staining material is allowed to remain in contact with the slides for five or ten minutes, the glasses are washed with water, are then placed in a solution of 5 drops of acetic acid to 20 c.c. of water, and kept there "long enough to count one, two, three slowly," and are again washed with water. Examination with the microscope shows the gonococci stained blue.[1] In doubtful

[1] Schutz's method, as set forth by R. W. Taylor in his work upon "Venereal Diseases."

cases, especially when the microscope fails to show genococci, make cultures. Cultures must be made in suspected gonorrhea in a child, from the fluid of an inflamed joint, from the discharge in gleet or purulent ophthalmia, and from the blood in obscure infections.

Subacute or **catarrhal gonorrhea** develops in men who have previously had gonorrhea, as a result of prolonged or repeated coition or of contact with menstrual fluid or leukorrheal discharge. There is profuse mucopurulent discharge, but very little pain on micturition, and seldom chordee or marked irritability of the bladder.

Irritative or Abortive Gonorrhea.—In this disease the symptoms, which are identical with those of beginning clap, do not increase, but disappear within ten days.

Chronic Urethral Discharges.—**Chronic urethral catarrh,** which may follow gonorrhea, is characterized by the occasional presence of a drop of clear, tenacious liquid. This discharge becomes more profuse as a result of sexual excitement or the abuse of alcohol.

The persistence of a small amount of milky discharge, because of localization of inflammation in one spot or the production of a granular patch or a superficial ulcer, characterizes *chronic gonorrhea.* There is some scalding on urination; erections produce aching pain; there are pain in the back and redness and swelling of the meatus. All the symptoms are intensified by sexual excitement, by coitus, by violent exercise, or by alcoholic excess.

Gleet.—If a chronic gonorrheal urethritis lasts over ten weeks, it is called gleet. In gleet the lips of the meatus are stuck together in the morning, and squeezing them discloses a drop of opalescent mucopurulent fluid (the *morning drop*). During the day the discharge is rarely found. The discharge is yellow or has a yellowish hue; it stains the linen distinctly, and contains pus shreds, epithelium, and at times gonococci. The urine is clear and contains pus, gonorrheal shreds, and comma-shaped hooks. The discharge is not obviously purulent, and contains amyloid corpuscles. There are frequency of micturition, pains in the back, and dribbling of urine, and a bougie may find a stricture of large caliber, or at least will discover that the urethra is rigid from inflammatory infiltration. A discharge may be maintained by *chronic prostatitis.* In this condition there are frequency of micturition; a sense of weight or dull pain in the perineum; diminished projectile force of the stream of urine; there is often a tendency to sexual excitement and premature emission. In *prostatorrhea* a milky discharge gathers in the urethra during sleep and flows during muscular effort or while the patient is at stool. The linen is stained but slightly and the lips of the meatus are not glued together on waking. There is a history of masturbation or sexual excess. The condition is not aggravated particularly by alcohol or sexual intercourse. In chronic anterior urethritis there is a discharge from the meatus or sticking together of the lips in the morning. In chronic posterior urethritis there is no discharge of pus from the meatus. If the three-glass test be made, it will be found that in a case of chronic anterior urethritis only the first portion will be cloudy and show shreds; if there be posterior urethritis of not very long standing, both portions will be a little clouded, the first containing clap shreds, the last hook-shaped shreds. In a very chronic case neither sample will be cloudy, but the first portion will contain shreds. In gleet the rigidity of the urethra causes the retention of small quantities of urine back of the thickened areas after each urination. This retained urine decomposes and adds to inflammation. Indulgence in alcohol, sexual excitement, or sexual intercourse aggravates the condition.

Treatment of Acute Gonorrhea.—*General Care.*—Wash the hands after touching the parts and dry them on an *individual towel,* which is not used upon the face. Wear a suspensory bandage. Avoid violent exercise, especially bicycle riding, and also exposure to dampness. Moderate exercise is allowable. The patient

must not only refrain from sexual intercourse, but must not permit himself to indulge in sexual excitement, and must not drink a drop of liquor, malt, vinous, or spiritous, unless he be a heavy or a regular drinker, in which case we should permit the moderate use of a well diluted rye or Scotch whisky. Some men become actually ill without their regular daily stimulants and such men should have them in moderation. Some surgeons permit the moderate use of claret to all patients. At least twice a day wash the penis for five minutes in a cup of warm water containing 1 dram of salt. Passing the urine while the penis is immersed in warm fluid lessens ardor urinæ. Cut a small opening in a square piece of old linen, slip the linen over the glans, catch it back of the corona, and bring the ends forward with the prepuce. Never permit the cotton or linen to stick fast and plug up the lips of the meatus. If the lips tend to become sealed up, grease them with sterile vaselin. If the glans be completely naked, pin the foot of an old stocking upon the undershirt, put absorbent cotton in the toe, and place the penis within this bag. Never tie or fasten any material about the penis. The patient should drink freely of plain water or of water containing a little bicarbonate of sodium. He should obtain one bowel movement every day.

Diet and Instruction List (Dr. T. C. Stellwagen, Jr.).—*Meats.*—May have white meat of chicken, boiled fish, lamb.

Must not take beef, beef steak, veal, pork, liver, kidney, etc.; nor salt fish, meats, smoked, canned, or potted foods.

Vegetables.—May have rice, hominy, string beans, fresh peas, spinach, beans, baked potatoes (sweet and white), lentils, etc.

Must not take rhubarb, tomatoes, asparagus (Guitéras's rule. See Begg, in "Phila. Med. Jour.," June 7, 1902), lemons, oranges, limes, or peserved fruits.

Drinks.—Nothing but plain water and milk.

Must not take alcoholic beverages or carbonated drinks.

Must not take salt, spices, condiments, cheese or pickles.

Desserts.—Only of the simplest kind, made from milk and eggs, and take them sparingly.

General Rules.—Put on a suspensory bandage and wear it in conjunction with a piece of linen or a bag to catch discharges.

Wash the hands after handling the parts, and keep the fingers away from the eyes.

Keep the linen from contaminating the family wash.

Wash the organ frequently in warm salt water (1 teaspoonful of table salt to 1 glass of water).

When urination causes burning, immerse the organ in a basin of warm water and allow the urine to flow.

Keep the body warm and free from chilling.

Should not go about on rainy or snowy days without ample protection.

Should go to bed early.

Must not take cold baths. May take warm ones.

Should not eat between meals—it is unwise to overload the stomach.

Should drink freely of plain water or milk.

Should urinate when the desire comes.

Should keep away from females socially and sexually—and any other exciting influences, such as erotic sights, thoughts, and literature.

Must keep bowels loose.

A smoker should decrease the consumption of tobacco.

Never put pieces of cotton over the end of organ, as cotton so used prevents the free drainage of discharge. Should the lips of the opening seal together, wash clean in warm salt water and grease with vaselin.

A tea or coffee drinker may have a small amount once daily, but it will be better not to partake of either.

Should the patient be using an injection and find that the desire for urination becomes frequent at night, he must stop the injection and consult his physician.

The injection is never to be forced into the organ; it is to be introduced gently, and the bladder is to be empty when an injection is given.

Abortive treatment may be tried if the case is seen early. The use of strong solutions of powerful germicides has been abandoned because of the great pain they produce and the inevitable subsequent crippling of the urethra.

Abortive treatment is applicable to specially selected cases only and even then usually fails. It should never be used after the gonococci have invaded the submucosa, but only during the prodromal stage, when it is hoped that the germs are upon and not in the mucous membrane. This stage usually lasts but a few hours, usually not over forty-eight. The patient generally presents himself after this period has passed. When the symptoms as described in the prodromal period prevail, the abortive treatment may be tried, after explaining to the patient that it will cause some pain and discomfort and in the end may fail or even aggravate the inflammation.

Germicides may be used and with some chance of killing the infection, for as yet the organisms are growing upon the superficial strata of epithelium much as a sod of grass upon soil. When the deeper structures have been invaded it is folly to attempt to abort the disease.

The abortive method advocated by White and Martin and which has proved successful in Prof. Hiram Loux's clinic in a limited number of selected cases is as follows: After urination 4 drops of a 4 per cent. solution of eucain are injected into the urethra, after which 2 drams of ¼ per cent. solution of protargol are instilled and retained for three minutes. The injections are repeated every two hours while awake.

Each time the bottle is half emptied it is replenished with sterile water to its full capacity, until the end of the third day. If successful, recovery is accomplished in about seven days. Should a mucoid discharge persist an antiseptic astringent injection is employed to complete the cure. During the treatment the patient must be kept at rest. The diet should be bland and light and the usual balsamic remedies are administered. If the symptoms become hyperacute, stop the treatment at once and give a sedative.

Another abortive method is the use of hot retro-injections of corrosive sublimate solution (1 : 20,000), 2 pints being run through the urethra once a day. If in seventy-two hours the symptoms are not greatly improved, abortive treatment should be abandoned. Recent studies render it almost certain that there is no real abortive treatment. Abortive treatment, to be efficient, would have to be carried out before the gonococci penetrated the epithelial cells; in other words, would need to be instituted before the distinct symptoms of the disease appear. Janet says that we must alter our conception as to what constitutes abortive treatment, and he doubts if a case of true gonorrhea has ever been really aborted.[1] The method of irrigation with solutions of permanganate of potassium is really a prophylactic treatment. Janet applies his treatment as evidences of trouble present themselves, and before acute symptoms appear, and claims that in most persons the disease can be arrested in from eight to twelve days. The same plan of treatment is useful in a well-developed case.

Irrigation in Gonorrhea.—Irrigation can be used in an incipient or in a well-developed case. Janet's method is as follows: An irrigator is filled with a warm solution of permanganate of potassium (1 : 4000). The patient after emptying his bladder is seated upon a chair and his sacrum rests upon the extreme front edge of the chair (Valentine's position). The reservoir is joined to a glass nozzle by a rubber tube. The nozzle is introduced into the meatus, and the fluid is permitted to run gradually at first, with full force later. In anterior trouble the fluid is allowed to run out of the meatus by the side of the nozzle.

[1] "Ann. d. mal. d. org. gén.-urin.," 1896, p. 1031.

The anterior urethra is always irrigated first, the reservoir being 2 feet above the chair.

In posterior urethritis, after the anterior urethra has been irrigated, the reservoir is raised from 6 to 7 feet above the penis, the meatus is held tight about the nozzle, and the fluid overcomes the force of the compressor muscles of the urethra and the bladder sphincter and enters the bladder. If the muscles do not quickly relax, continue the hydrostatic pressure for several minutes, when relaxation will usually occur; but if it does not do so, tell the patient to breathe slowly and deeply, and to make efforts at urination (Valentine's plan). When the bladder is full the tube is withdrawn and the patient micturates. This procedure is practised once or twice a day for five or six days, or even longer, and the strength of the solution is gradually increased up to 1:1000. It has been claimed that after one or two weeks of this treatment gonococci permanently disappear in the majority of cases. Figure 982 shows the ingenious and very useful irrigator devised by Ferd. C. Valentine, of New York. Valentine[1] has constructed the table shown below, which is of use to a practitioner who wishes to employ irrigations with permanganate of potassium in the treatment of acute gonorrhea. I followed the method set forth in this table in a great number of cases, and regarded it an extremely useful systematic plan.

First day, first visit.		Anterior irrigation	1:3000
First day,	7 P. M.	Anterior irrigation	1:4000
Second day,	9 A. M.	Anterior irrigation	1:3000
Second day,	7 P. M.	Anterior irrigation	1:4000
Third day,	9 A. M.	Intravesical irrigation	1:6000
Third day,	7 P. M.	Anterior irrigation	1:5000
Fourth day,	9 A. M.	Intravesical irrigation	1:5000
Fourth day,	7 P. M.	Intravesical irrigation	1:5000
		Anterior irrigation	1:2000
Fifth day,	Noon.	Intravesical irrigation	1:5000
Sixth day,	Noon.	Intravesical irrigation	1:5000
Seventh day,	Noon.	Intravesical irrigation	1:5000
Eighth day,	9 A. M.	Intravesical irrigation	1:5000
		Anterior irrigation	1:3000
Eighth day,	7 P. M.	Intravesical irrigation	1:5000
		Anterior irrigation	1:2000
Ninth day,	9 A. M.	Intravesical irrigation	1:4000
		Anterior irrigation	1:1000
Ninth day,	7 P. M.	Intravesical irrigation	1:4000
		Anterior irrigation	1:1000
Tenth day,	9 A. M.	Intravesical irrigation	1:4000
		Anterior irrigation	1:1000
Tenth day,	7 P. M.	Intravesical irrigation	1:5000
		Anterior irrigation	1:500

For full directions regarding this method see Valentine's book, "The Irrigation Treatment of Gonorrhea." If a stricture exists, it is not advisable to employ this treatment. Excellent results can be obtained by irrigations with fluid containing silver nitrate (1 : 12,000 to 1 : 8000).

When a patient is treated by irrigation, after the entire subsidence of acute symptoms, a thin, colorless discharge may persist. This can be cured by the use of astringents. Two or three times a day an astringent is injected by means of a ½-ounce syringe. Dalton's formula is very useful: Zinc oxid and lead acetate, of each, ½ to 3 gr.; tincture of catechu, from 10 to 30 min.; glycerin, from ½ to 1 dram; and water to make 1 oz.; Ultzmann's formula is: Zinc sulphate, 16 gr.; pulverized alum, 8 to 12 gr.; carbolic acid, 3 gr.; and water to make 4 oz.

Many writers oppose the irrigation treatment, claiming that it increases the liability to complications, especially prostatic inflammation, and enhances the danger of recurrence. I believe in the method. I do not think it shortens

[1] "The Irrigation Treatment of Gonorrhea."

materially the duration of the disease, but do believe that it mitigates its intensity, makes the patient much more comfortable, and quickly causes the discharge to become mucopurulent. That it increases complications and the danger of reinfection is very doubtful. Much of the trouble which has followed its use has been due to raising the reservoir to too great a height.

Irritative gonorrhea will subside in a few days. The above directions should be followed, and the anterior urethra should be washed out several times daily with diluted peroxid of hydrogen, or irrigated once a day with a hot solution of permanganate of potassium (1 : 4000).

In *catarrhal gonorrhea* at once order injections (1 gr. to the ounce of sulphate of zinc; or zinci sulphas, 8 gr., plumbi acetas, 15 gr., water 8 oz.; or 5 gr. of sulphocarbolate of zinc to 1 oz. of water; or White's prescription of 1 dram each of acetate of zinc and tannic acid, 8 drams of boric acid, 6 oz. of liq. hydrogen peroxid). For injecting use a blunt-pointed hard-rubber syringe of a capacity of 3 or 4 drams. Let the patient urinate and then sit on a chair, his buttocks hanging over the edge; throw a syringeful of the solution into the urethra and let it run out at once, and throw in another syringeful and hold it in from three to five minutes.

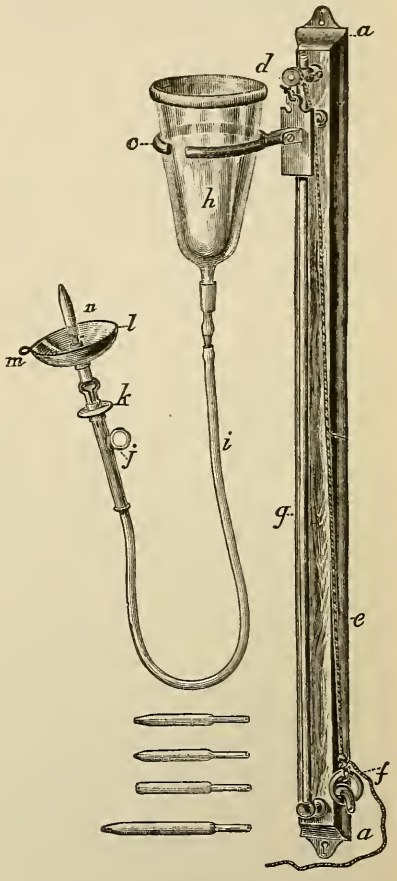

FIG. 982.—Valentine's urethral and intravesical irrigator: *a*, Board with attachments to be screwed to wall; *c*, open collar; *d*, pulley; *e*, cord; *f*, ring to suspend percolator; *g*, brass rod; *h*, percolator; *i*, rubber tube; *j*, ring for fourth finger; *k*, flange to graduate pressure; *l*, shield; *m*, ring to suspend shield; *n*, nozzle attached.

In *ordinary acute gonorrhea* we follow an old rule when we order balsams. The common custom is to give two capsules three times a day, each capsule containing 5 gr. of salol, 5 gr. oleoresin of cubebs, 10 gr. balsam of copaiba, and 1 gr. of pepsin. Clinical observation indicates that the balsams are of distinct value in gonorrhea. When used early, the discharge tends to become mucopurulent and the acute symptoms usually soon begin to subside (S. Behrmann in "Dermatologisches Centralblatt," Berlin, Nov. and Dec., 1901). Many practitioners will not use balsams until the third week. Bacteriological studies indicate that copaiba, when eliminated in the urine, has a certain amount of power in inhibiting the growth of gonococci, but that cubebs and oil of sandal have not such power. Yet oil of sandal is more useful than copaiba as a remedy. Salol is distinctly germicidal, hence it is given with the balsams. In a case treated by balsams an astringent injection is usually employed. The injection is used two or three times a day, immediately after micturition. As the inflammation subsides the strength of the injection should be gradually increased. A good plan is to order an 8-oz. bottle and 8 1-gr. powders of sulphate of zinc. Direct the patient to fill the bottle with water, in which one powder is dissolved; when this is used dissolve 2 powders in a bottleful of water, and so progressively

increase the strength. When the discharge ceases stop the injections gradually. Whenever a syringeful is taken from the bottle a syringeful of water is put into the bottle, and thus pure water is soon obtained, at which point injection is discontinued. If a simple astringent injection causes much pain, use a sedative injection—2 drams of boric acid, 8 gr. of aqueous extract of opium, and 8 oz. of liquor plumbi subacetatis dilutis. I have had about as much success with the above simple method as with the most complicated of plans. Complication and complexity are not criterions of usefulness.

Argonin, which is a combination of albumin, silver, and an alkali, is highly recommended by some authors as a local remedy for gonorrhea (Schäffer, Guthiel). A solution of this material is non-irritant, the silver is not precipitated by chlorids, and the agent destroys gonococci. It is used by injection or irrigation. If used by irrigation, employ a 1 : 500 solution twice a day. If used as an injection, employ a 1 : 200 solution six or eight times a day. When the discharge is found free from gonococci and remains free for three days, stop the argonin and use an astringent injection.

Protargol, metallic silver combined with a protein, is a yellow powder soluble in water, the solution not being acted on by light. It is a non-irritant germicide. Neisser, after demonstrating the presence of the gonococcus, administers protargol by injection, the first injections being of a strength of 0.25 per cent., the strength gradually increased to 0.5 per cent., and finally to 1 per cent. In the beginning he orders three injections a day, each injection being retained from fifteen to thirty minutes; after several days, when the symptoms improve, he gives only one or two injections a day, and these are continued for ten days after gonococci disappear from the discharge. After protargol is abandoned an astringent injection should be used for a time. Some surgeons use a 1 : 1000 solution of protargol, and irrigate the anterior urethra and flush the bladder twice a day. A silver salt used by many is argyrol, or silver vitellin. The injection used at first may be of a strength of 2 per cent. The drug should be retained in the urethra four or five minutes, and three or four injections should be given each day. The strength of the injection can be gradually increased to 5 per cent. or even more. I have not been impressed with the value of this preparation except in the earliest stages of gonorrhea. Picric acid has been highly commended as an injection. The strength of solution is 1 : 200, and it is to be retained in the urethra three or four minutes (de Brun's method).

Methylene-blue internally is occasionally of service in gonorrhea. A capsule containing 1 or 2 gr. of the drug is given three times a day. It makes the urine greenish blue and occasionally induces strangury. Urotropin renders the urine sterile. Salicylate of sodium may be of value late in the case.

In his clinic in Jefferson Hospital my colleague, the late Prof. Horwitz, introduced the following plan of treatment: A capsule containing balsam of copaiba, oil of sandal, and methylene-blue is given half an hour after each meal:

℞. Methylene-blue ..... gr. xxx;
Balsami copaibæ }
Olei santali } ..... āā f℥iss.—M.
Pone in capsulas No. xxx.
Sig.—One after each meal.

The patient begins at once to take, by hand injection, a 10 per cent. solution of argyrol. He takes it three times a day.

At each daytime injection the fluid is retained in the canal for five minutes. At the bedtime injection the fluid is retained for fifteen minutes. At first only about 1 dram is injected at a time, but as the urethra becomes accustomed to fluid distention the amount is gradually increased, until finally 4 drams may be given.

When the stage of decline begins (toward the end of the second week) a combined astringent and antiseptic treatment is used.

The capsules of methylene-blue, copaiba, and sandal, and the injections of argyrol are discontinued. A capsule containing oleoresin of cubebs, oil of sandal, and balsam of copaiba is given before each meal, and a capsule of urotropin is given after each meal. An injection of protargol (¼ of 1 per cent.) is given three times a day. This remedy is germicidal and also astringent. The strength is gradually increased until a 1 per cent. solution is used. By the end of the fourth week the patient has reached the terminal stage. Now capsules of sandal and salol are substituted for the cubebs, sandal and copaiba and an astringent injection is ordered. The following injection, recommended by J. Wm. White, is very satisfactory:

℞. Hydrarg. chlor. corros. ..... gr. ⅛;
Zinci sulphocarbolas ..... ʒss;
Acidi boraci ..... ʒij;
Acidi carbolici ..... ♏xv
Boroglycerid (25 per cent.) ..... fʒij;
Aquæ destil ..... q. s. ad. fʒvj.—M.
Sig.—Inject. Dilute if it causes much pain.

When the mucoid condition predominates in the discharge the following is useful:

℞. Zinci sulph ..... gr. xv;
Plumbi acetati ..... gr. xxx;
Glycerol tannin, Hydrastin (Lloyd's) ..... āā fʒiv;
Mucil. acaciæ ..... fʒiv;
Aquæ destil ..... q. s. ad. fʒvj.—M.
Sig.—As injection.

The formula of the "injection Brue" is as follows:

℞. Plumbi acetat ..... gr. xxx;
Zinci sulphat ..... gr. xvj;
Ext. krameriæ fl ..... fʒiv;
Tinct. opii ..... fʒiij;
Aquæ destil ..... q. s. ad. fʒvj.—M.
Sig.—As injection.

When all symptoms of clap have disappeared, any injection in use is gradually diluted. Whenever a syringeful of the fluid is taken from the bottle, a syringeful of water is put in. When the fluid becomes pure water the injection is discontinued. Balsams are stopped by gradual diminution in the number of daily doses. For three weeks after the entire disappearance of all symptoms alcohol is forbidden and sexual indulgence is prohibited. Should a relapse occur the patient is at once placed upon treatment as for the acute stage, and when the stage of decline again ensues he is placed again on antiseptics and astringents. Relapses are caused by a localized lesion or lesions in the anterior or posterior urethra, hence as soon as all acute symptoms subside an endoscopic examination is to be made and proper treatment is to be applied to any localized lesion. If during the treatment of gonorrhea a compliaption develops, local treatment of the urethra is at once discontinued and constitutional treatment suited to the new condition is prescribed.

If the onset of gonorrhea is marked by violent inflammatory symptoms (chordee, hemorrhage, severe pain, swelling, profuse purulent discharge), local treatment of the urethra is contra-indicated.

If the invasion is hyperacute, no local treatment of the urethra is permissible until the disease assumes the character of ordinary gonorrhea.

Not unusually gonorrhea passes into a low grade of anteroposterior urethritis that proves most rebellious to treatment. This condition is especially common when too stimulating a treatment has been used. A mild astringent

injection should be used three times a day. Every second or third day an injection of nitrate of silver (1:4000) should be given. If the silver salt sets up an acute inflammation the treatment used in the acute stage of gonorrhea is given until the symptoms abate.

A valuable plan in rebellious anteroposterior urethritis is daily irrigation of the anterior urethra with a warm solution of permanganate of potassium (1:6000), followed by the passage of a soft catheter and the filling of the bladder with a like solution. The patient empties his bladder after the catheter is withdrawn and thus flushes the entire urethra with the permanganate. The strength of the solution is gradually increased up to 1:2000.

Weiss used corrosive sublimate (1:20,000) in the manner just described. It is particularly valuable in cases of bacterial contamination, the gonococci having disappeared.

Treatment of Complications.—*Ardor urinæ* is relieved by urinating while the penis is immersed in hot water and by administering alkaline diuretics. *Chordee* requires a bowel movement in the evening, and sleeping in a cool room, under light covers, and on a hard mattress; bromid of potassium is given several times daily, and a considerable dose is given at night; it may be necessary to use suppositories of opium and camphor or to give hyoscin. *Balanitis* requires frequent washing of the head of the penis and prepuce in warm water, drying with cotton, and dusting with borated talc, stearate of zinc, or boric acid and subnitrate of bismuth (1:6). *Balanoposthitis* requires soaking in hot water, and injections of black wash under the prepuce until edema of the foreskin subsides, and then cleanliness and the application of a drying powder. *Phimosis* requires soaking the penis in hot water, and injections of hot water beneath the foreskin, followed by black wash. If this fails, circumcision must be performed. If *paraphimosis* occurs, grasp the head of the penis with the left hand, squeeze the blood out, and try to push the head back, while with the right hand the penis is pulled upon as if the surgeon intended to lift the individual by the organ. If this fails, cut the collar on the dorsum with scissors; or, what is better, for it gives free exposure, incise each side of the prepuce between the middle of the dorsum and the frenum. *Bubo* requires the application of iodin, ichthyol, or blue ointment, the use of a spica bandage, and rest. If a bubo suppurates, it must be opened or aspirated. *Acute posterior urethritis* is treated by rest, and if the symptoms are severe, by rest in bed. If the balsams do not irritate, they are given; if they do, they are withdrawn. Urotropin or salol is given and the patient is placed upon a milk-diet with orders to drink largely of flaxseed tea. Alkaline fluids do harm by favoring ammoniacal decomposition of the urine. Injections and irrigations are abandoned. Pain and vesical spasm are controlled by suppositories of opium and belladonna. If retention of urine occurs, have the patient urinate while in a hot bath; if this fails, use a soft catheter. *Acute vesiculitis* is treated as is acute prostatitis. Chronic vesiculitis is considered on page 1522. *Pyelitis* is treated by rest in bed, hot baths, wet cupping of the loin, milk-diet, diuretics, the taking of a large quantity of bland liquid, and the administration of salol or urotropin, and in some cases lavage of the kidney pelvis through a ureteral catheter with one of the silver preparations (1:15,000 of nitrate of silver). *Folliculitis* is treated by rest and the application of a hot-water bag to the perineum (if that be the part involved). If pus forms evacuate by incision. Later the follice may be dissected out or destroyed by cauterization. If the follicle opens into the urethra it may be cauterized through an endoscope *Peri-urethritis* is treated by rest and hot applications. If pus forms, an incision must be made. If the abscess is permitted to break into the urethra, rest and hot fomentations may be used, but at the first sign of urinary extravasation make an external incision. *Cowperitis* is treated in the same way as peri-urethritis. Gonorrheal rheumatism is considered

on page 723. *Acute prostatitis* and *cystitis* require confinement to bed, a milk-diet, the use of diuretics, hot applications to the perineum and hypogastrium (bags of hot sand), hot sitz-baths, suppositories of opium and belladonna or of ichthyol, leeching the perineum, the discontinuance of balsams and injections, and the administration of urotropin or salol. Heat can be applied by means of a stream of warm water which circulates through a metal instrument introduced into the rectum. *Abscess of the prostate* requires instant incision. In *retention of urine* the patient should try to pass the urine while in a hot bath; if this fails, a soft catheter is used. After relieving the bladder put the patient to bed and apply hot sand-bags as for acute prostatitis. *Chronic prostatitis* requires cold hip-baths, cold-water enemata, deep urethral injections, massage of the prostate, plain diet, avoidance of alcohol and overexertion, counterirritation of the perineum, and the relief of stricture or phimosis. Great benefit is occasionally derived from passing a soft bougie covered with blue ointment or with a 1 per cent. ointment of silver nitrate. If *epididymitis* arises, put the patient to bed, abandon injections, shave the hair from the groin, leech over the cord, elevate the testicles, and early in the case apply an ice-bag. Give a cathartic, a fever mixture, and suitable doses of bromid of potassium and morphin. The local application twice a day of 20 drops of guaiacol in 1 dram of cosmolin or olive oil gives relief. When swelling lingers, *after tenderness subsides* strap the testicle with adhesive plaster. A lingering case is benefitted by the internal use of iodid of potassium and the local application of ichthyol. In *gonorrheal ophthalmia* secure a watch-crystal over the unaffected eye, put the patient in a darkened room, rub the infected conjunctival sac with cotton soaked in a 2 per cent. solution of silver nitrate, wash out the affected eye repeatedly with hot boric acid solution, keep the pupil dilated with atropin, leech the temple, and give purgatives. Always send for an ophthalmologist.

When is Gonorrhea Cured?—It is said that Ricord declared: "We know when clap begins, but God alone knows when it ends." When actual discharge ceases a patient considers himself cured, and yet he may have residues of infection which are liable at any time to awaken into activity and produce anew an acute condition. Gonococci are frequently retained in the urethral glands and follicles or in areas surrounded by indurated mucous membrane. Gonococci may linger in these haunts for many months, some say for years. Keyes, however, maintains that they never persist in the male urethra over three years and that in 90 per cent. of cases, with or without treatment, they disappear within one year (Edward L. Keyes, Jr., in "Amer. Med. Sci.," Jan., 1912). It is customary to consider a man well when, after he has been without treatment for one week, shreds and pus disappear from the urine, when an examination of expressed mucus on three successive days fails to find gonococci, and when there has been no discharge for ten days. Furthermore, we must be sure that the prostate, Cowper's glands, and the seminal vesicles are free from disease. Never declare a man well under three months from the start of the disease unless gonococci are positively absent from the urine and the expressed discharge.

If a patient has "no morning drop," has been apparently well for three or four months, has no pus in the morning urine or in the expressed secretion of the urethra, prostate, and seminal vesicles, we can, without making cultures, affirm that he is well (Keyes, Ibid.).

Keyes also maintains that a man with a "pearly morning drop" who passes a urine containing pus-shreds, but who has no free pus in expressed secretions, is probably free from gonorrhea.

Treatment of Chronic Gonorrhea and of Chronic Urethritis Following Gonorrhea.—The first thing to do is to determine the *cause* of the prolongation of the discharge. Valentine's list of causes should be borne in mind

("Med. Record," June 29, 1901). They are as follows: (1) Lack of treatment; (2) misdirected treatment; (3) insufficient treatment; (4) overtreatment; (5) infraction of dietetic or hygienic regulations; (6) constitutional disturbances; (7) congenital or acquired deformities and complications; (8) involvement of the urethral adnexa; (9) marital reinfection. In a case in which a discharge persists or recurs the symptoms and general condition must be closely studied,

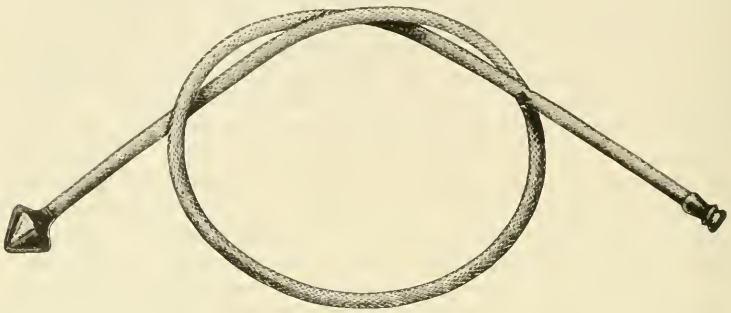

Fig. 983.—Bougie-à-boule.

the discharge must be examined microscopically, the condition of the urine must be determined, and the urethra must be explored.

Exploration of the urethra is inaugurated by inspection and external palpation. Palpation detects induration, peri-urethritis, follicular abscess or inflammation, Cowperitis, etc. The prostate and seminal vesicles are examined by a finger in the rectum. The interior of the urethra is explored

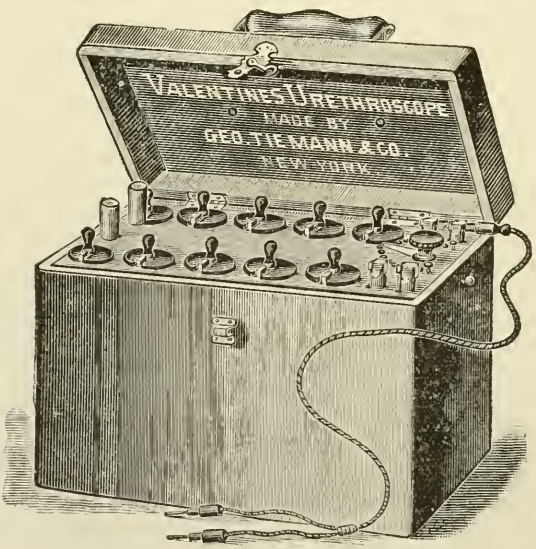

Fig. 984.—Valentine's urethroscope.

by a soft bougie-à-boule (Fig. 983). On withdrawing this instrument the shoulder catches in any contracture. It is to be borne in mind that a large steel sound can often be introduced with ease when the bougie-à-boule makes it evident that a contracture exists. The emergence of the instrument is arrested by a patch of thickening, a granular area, a zone of epithelial proliferation, a papilloma, or a stricture. In fact, anything which lessens the urethral caliber interferes with the withdrawal of the bougie-à-boule. It does not do to con-

clude that stricture exists simply because some lessening of caliber is appreciated. The bougie-à-boule finds its chief use in exploring the anterior urethra. If introduced into the deep urethra its emergence will be normally checked as its shoulder comes against the posterior layer of the triangular ligament.

In most cases the diagnosis is only certainly determined by the use of the urethroscope. This instrument has been perfected of recent years and is now an absolutely essential part of our armamentarium. I have long used Valentine's instruments (Figs. 984–987). Marks's air-dilating urethroscopes (Figs. 988, 989) are highly satisfactory. The anterior and posterior urethra can be thor-

Fig. 985.—Valentine's urethroscopic tube.

oughly examined and with the utmost ease. Before inserting a urethroscopic tube place the patient recumbent and cleanse the foreskin, glans, and anterior urethra as directed in the section on Cystoscopy. Insert a tube which readily passes the meatus, first cleansing the tube and obturator by burning alcohol upon them. Carry the tube to the anterior layer of the triangular ligament. Withdraw the obturator and insert the light. Turn on the light, mop the urethra with bits of cotton wrapped on a stick, and slowly withdraw the tube examining the urethra as its walls fall together back of the retracting tube.

Fig. 986.—Valentine's obturator.

After withdrawal of the tube irrigate the anterior urethra. To examine the deep urethra carry the instrument through the prostatic urethra. After the examination give an intravesical irrigation.

When the cause of a discharge is once determined, rational treatment can be instituted, and to determine the cause the electric urethroscope is indispensable. An erosion of the mucous membrane or a granular patch requires touching from time to time with a solution of silver nitrate (1 or 2 per cent. or even much stronger). These applications are made through the tube of the urethro-

Fig. 987.—Valentine's light carrier.

scope. A stricture or an infiltration is treated by gradual dilatation. This combines pressure and massage. If the caliber of the urethra be less than No. 21 of the French scale, conical steel sounds are used twice a week. If there be much hyperesthesia they are retained but a brief time; but as hyperesthesia diminishes the period of retention is lengthened, until an instrument can be kept in place without causing severe suffering for ten or fifteen minutes. It is not desirable to use cocain. Its use is not free from danger and, further, it obtunds the sensibility so that undue violence may be used, and it increases postoperative inflammation. Before and after using an instrument the ure-

thra must be cleansed by irrigation with salt solution or permanganate of potassium.

When the urethra becomes tolerant to instrumentation, a special dilator is employed to act particularly on the area of disease. If in the beginning of

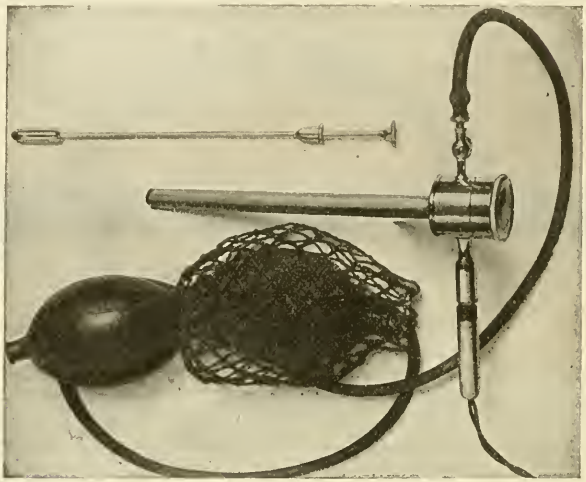

Fig. 988.—Marks's air-dilating urethroscope for examination of the anterior urethra.

treatment the caliber of the urethra is equal to or greater than No. 21 of the French scale, it is rarely necessary to precede the dilator by the use of conical sounds. Figs. 990–993 show various dilators. A dilator unless of a very modern type should be inserted in a sterile rubber cover before being used, otherwise it will cut, tear, or pinch the urethra when closed and withdrawn.

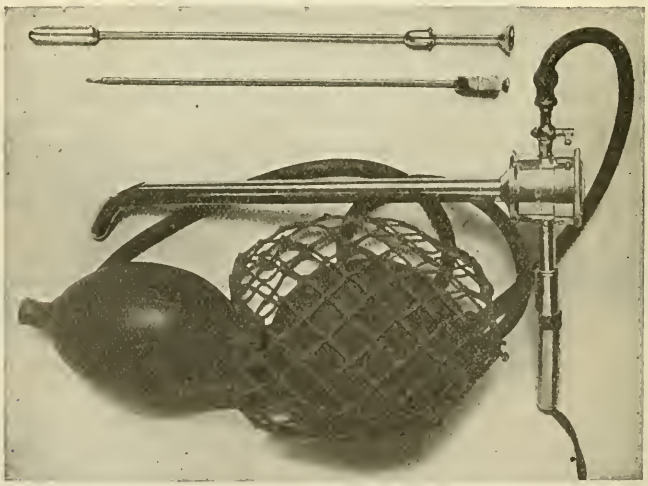

Fig. 989.—Marks's air-dilating urethroscope for examination of the posterior urethra.

Kollmann's dilator (new style) will not injure the mucous membrane and can be used without a cover (Fig. 990). A dilator should be lubricated with lubrichondrin, synol soap, or liquid cosmolin. If a two-bladed dilator be used at first, a four-bladed dilator must be subsequently employed.

A dilator is cleansed by scrubbing its blades with soap and water, placing them in alcohol, withdrawing, and burning the alcohol retained on the instrument.

The following rules for dilatation are of the first importance (Ferd. C. Valentine, in "Med. Record," June 29, 1901):

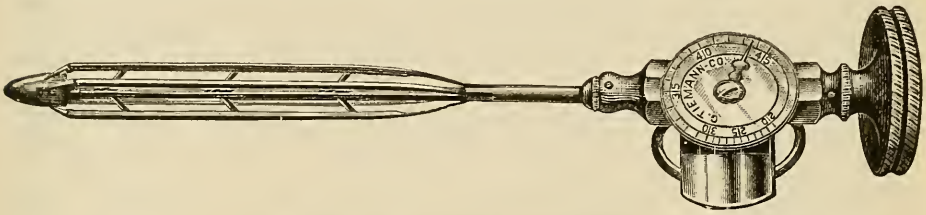

Fig. 990.—Kollmann's anterior dilator.

Fig. 991.—Oberlander's anterior dilator.

Fig. 992.—Kollmann's anteroposterior dilator.

Fig. 993.—Oberlander's anteroposterior dilator.

1. The first dilatation must stop at that point at which the first resistance to further dilatation is felt by the operator's fingers turning the screw that separates the blades.

2. Dilatations, if done by a novice, must in the beginning of treatment be repeated no oftener than every three or four days.

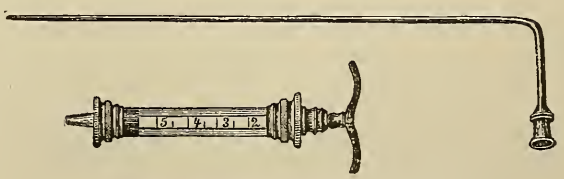

Fig. 994.—Kollmann's gland syringe.

3. Each dilatation, in point of time, must reach no greater duration than two minutes over that of the preceding session.

4. No dilatation must exceed one-half number (French Charrière scale) above the number attained at the next prior séance, regardless of any lack of resistance that may be present.

As a rule, glandular and follicular infiltrations are cured by the use of the dilator. If they are not, they must be treated through the tube of the urethro-

scope. The interior of a follicle may be cauterized by a heated electric wire, subjected to electrolysis, fulgurated by the Oudin current, or touched with a 3 per cent. solution of silver nitrate. A thickened crypt, gland follicle, or an area of induration may be slit by a knife. A polyp can be removed by a snare, the cautery, or special forceps. In a chronic inflammation of the urethra, in which the inflammation is superficial and in which the glands are not involved, irrigations, urethral and intravesical, constitute the best treatment. (See Valentine's treatise on "The Irrigation Treatment of Gonorrhea, its Local Complications and Sequels.")

In any lingering case of gonorrhea examine the urine, and direct suitable treatment for oxaluria, lithemia, or phosphaturia, if any one of these conditions exists. Such morbid states of the urine are occasionally responsible for great prolongation of the inflammation. In some cases a discharge is kept up by inflammation of the seminal vesicles (see page 1521).

Gonorrhea of the anus and rectum occasionally, though very rarely, occurs. It may result from pederasty, or in a woman from a flow of infectious material from the genitalia to the anus. It causes severe burning pain, aggravated by defecation. The parts are red, swollen, and tender. The discharge is profuse, being at first cream white, and then thicker and greenish. The diagnosis rests upon the history and the finding of gonococci in the discharge. The disease rarely extends above the anus. I have seen one undoubted case of rectal gonorrhea.

Treatment.—If the anus only be involved, spray it several times daily with peroxid of hydrogen, wash with salt solution, irrigate with permanganate of potash (1:4000), dust with talc powder, and interpose a piece of iodoform gauze between the inflamed surfaces. An ulcer, a fissure, or an excoriation is touched with lunar caustic. If the rectum becomes involved, secure a daily bowel movement and irrigate the rectum twic a day with boric acid solution or permanganate of potassium (1:4000).

Gonorrhea of the Mouth.—This is a very uncommon malady. It occurs in infants more often than in older people. Infection in infants may take place during birth if the mother has gonorrhea. The symptoms are those of violent stomatitis. The diagnosis is suggested by the condition of the mother and is proved by finding gonococci in the discharges from the mouth.

Treatment.—Wash the mouth frequently with boric acid solution, and swab the diseased areas at intervals with a 10 per cent. solution of argyrol.

Gonorrhea of the Nose.—It is alleged that this condition can arise, but an absolutely authentic case does not seem to be on record.

Gonorrhea in the Female.—There is much dispute as to the parts infected. Some observers maintain that the vaginal epithelium never contains gonococci and that gonococci found in a vaginal discharge have come from the cervix or uterine canal. Beyond a doubt, however, when young women who have not borne children contract gonorrhea the vulva and vagina usually suffer. In older women and in women who have borne children the vaginal tissues are altered and the cells are not nearly so prone to infection; hence in such subjects the vagina usually or at least often escapes. The initial infection is in many cases in the cervical canal, in some in the vulva or urethra. No matter what part has been first attacked, other parts usually become quickly involved in the acute process. The urethra is involved in almost every case. Chronic gonorrhea is prone to linger in the urethra, in the glands of Bartholin, in the cervical canal, or within the uterus or in the Fallopian tubes. The great danger of gonorrhea in the female is the development of ascending infection of the lining membrane of the uterus, which may reach the tubes, ovaries, and peritoneum.

When infection occurs during pregnancy or when pregnancy occurs during infection of the cervical or uterine canal, abortion may take place. Again,

a pregnant woman may not abort, but may go on to term and the child may receive a conjunctival infection during delivery and rapidly develop purulent ophthalmia.

In some cases when pregnancy occurs during the existence of gonorrhea the disease seems to pass away, and yet the child gets conjunctival infection during delivery or the mother subsequently develops pus-tubes.

Treatment.—Place the patient in bed during the acute stage of the disease, give hot hip-baths, keep the bowels open by means of saline purgatives, insist on a fluid diet consisting chiefly of milk, and flush out the urethra by having the patient drink considerable quantities of water. The external genital organs should be sprayed with peroxid of hydrogen every two or three hours, and after spraying should be dried with absorbent cotton and dusted with equal parts of starch and powdered oxid of zinc, or with powdered stearate of zinc. Pads of cotton fixed in place by a bandage are used to catch the discharge. If urethritis exists in this stage, we may give alkalis, balsams, and astringent urethral injections.

When the acute symptoms have somewhat abated an attempt should be made to prevent ascending infection from the cervical canal. The mucous membrane of the canal may be curetted away or be destroyed by pure carbolic acid or nitrate of silver. A wiser plan is to paint the cervical canal daily with iodin or a 10 per cent. solution of argyrol, painting the vaginal portion of the cervix at the same time with the same drug. The vagina is irrigated twice a day with a warm solution of permanganate of potash (1:4000) and is lightly packed with iodoform gauze. When the vulva particularly is involved, treat that part by applying acetate of aluminum (2 per cent.) locally or paint the vulva with silver solution (40 gr. to 1 oz.). If the vulvovaginal gland suppurates, open it.

If vaginitis exists and continues in spite of the treatment suggested above, wash out the vagina every two hours, first with 1 pint of hot solution of bicarbonate of sodium, next with 1 pint of hot water, and finally with 1 pint of astringent solution (1 teaspoonful of lead acetate, 1 teaspoonful of zinc sulphate, 1 teaspoonful of alum, or 4 teaspoonfuls of tannin to 1 pint of hot water). As the attack subsides, use vaginal suppositories, each containing 5 gr. of tannic acid. In some cases apply solutions of silver nitrate (1:200) or of argyrol (10 per cent.), and insert tampons of ichthyol (8 per cent.) moistened with boroglycerid (Le Blonde).

In chronic cases of urethritis use strong solutions of silver nitrate and irrigate the urethra and bladder with silver nitrate (1:8000).

For *uterine gonorrhea* observe the same general management. Swab out the uterus with tincture of iodin or nitrate of silver and insert tampons of iodoform gauze.

Gonorrhea in Children.—Male Children.—This disease is not very common. When it affects children under twelve it is usually due to some abandoned and diseased female having brought the child's penis in contact with her sexual organs. It may result from introducing infected materials into the penis. The symptoms are similar to, but more acute than, those met with in an adult. The finding of the gonococci is clinical but not absolute legal proof of the existence of gonorrhea, and it is to be remembered that boys may suffer from catarrhal urethritis as a result of introducing irritants, from balanoposthitis, or from overacid urine. Legal proof is afforded by the growth of the suspected micro-organisms on artificial blood-serum.

The *treatment* consists in confinement to bed during the acute stage, bland drinks, light diet, etc. Circumcision is necessary if phimosis exists. When the acute symptoms subside, injections are used as in an adult.

Female Children.—Gonorrhea is more common in female children than in male children, and the vagina is involved as well as the vulva and urethra.

A female child may suffer from catarrhal inflammation of the vulva, as a result of the contact of foul urine, of feces, of the presence of seat-worms, or of neglect of bathing. In such a case the vagina and urethra escape. Involvement of the vagina and urethra strongly suggests gonorrhea. A recently born child or a young infant may acquire gonorrhea directly from a diseased mother, or indirectly, by pus upon linen, from the mother's fingers, etc. A diseased nurse may infect the baby. Older children who have ceased to nurse may get the disease from infected linen, bathtubs, etc., and may by these means infect child after child in an institution. Now and then the disease arises by a man or woman deliberately bringing the child's private parts in contact with his or her own diseased organ.

The disease is acute: the urethra, vulva, and vagina are usually involved; the discharge is profuse, purulent, and often bloody. During the first day or two the discharge exhibits leukocytes but no gonococci, and the normal flora of the urethra disappear; later gonococci appear (Harmsen, "Zeits. f. Hyg. u. Infektionskr.," 1906, vol. iii). Microscopical examination of the discharge is absolutely necessary. Dry cover-slip preparations are made so as to obtain clap shreds from the discharge. An attempt should be made to obtain cultures. The gonococcus is very difficult to maintain in culture; it must be frequently transferred, and it grows best in an incubator at a temperature of 36° C. No attempt is made to grow it upon ordinary culture-media. The finger may be sterilized and punctured, blood thus obtained being smeared upon ordinary agar. Upon this composite material growth can be obtained. Animal blood-serum is not a good medium, but human blood-serum is (Lehmann and Neumann). Human blood-serum is obtained by opening a vein or from a fresh placenta.

Lehmann and Neumann ("Atlas and Principles of Bacteriology") find the following a satisfactory medium: Agar, containing 1 per cent. peptone and 5 per cent. glycerin, which has been liquefied and cooled to 50° C., is mixed "with one-half its volume of ascitic fluid or the fluid from ovarian cysts." Plate cultures and streak cultures should be made. This excessive care in proving the presence of the gonococcus is imperatively necessary in female children because of the medicolegal questions which may arise in such a case and also because of the danger there is of the case infecting other persons.

Surgeons are apt to be doubtful about the diagnosis in many supposed cases of gonorrhea in female children. The clinical picture may simply be that of catarrhal vulvovaginitis; it may be that of gonorrhea. The finding of the gonococcus is regarded as conclusive from a clinical standpoint, but not from the legal point of view. Again, as Taylor points out, in some cases in which the clinical evidence and microscopical findings seem to prove the existence of gonorrhea no proof can be obtained that the condition is of venereal origin, and in some cases in which everything indicates that the disease began as a catarrhal vulvovaginitis, a condition seemingly identical with gonorrhea has arisen. Obtaining a culture of gonococci is conclusive. The treatment consists in taking every care to prevent diffusion of the infection to others and to the patient's own eyes. She is put to bed, given frequent baths, and fed upon milk, etc. Irrigations of bicarbonate of sodium are employed, followed by protargol (1:5000, according to White and Martin). Later, astringent injections are indicated.

Treatment of Gonorrheal Arthritis and Endocarditis.—In a communication in the "Jour. Amer. Med. Assoc.," Jan. 27, 1906, pages 261–263, Messrs. Rogers and Torrey described the method of preparation of an antigonococcic serum for the treatment of gonorrheal arthritis. This serum in its present form, as manufactured by a good chemical company, seems possibly to be of some value in the treatment of gonorrheal infections of joints, tendon-sheaths, and allied structures. Dr. Thomas C. Stellwagen, of the Genito-urinary Department of

Jefferson Hospital, has used the material in a series of 26 cases of acute and chronic gonorrheal arthritis with encouraging results ("Therapeutic Gazette," April 16, 1910).

Preparation of the Serum.—To quote from Messrs. Rogers and Torrey's reports (Loc. cit.): "Rabbits were first used exclusively in producing the serum. Although a very potent serum may be obtained from these animals, it was found that the serum itself is decidedly toxic for some individuals and may produce a rather alarming reaction. In order to obviate this serious objection we have experimented with goats and sheep. Similar objectionable properties, although less in degree, were found to be present in goat serum, but from sheep serum they seem to be entirely absent. Accordingly in later work only these animals have been used. They should be full grown, uncastrated males. In immunizing these animals it has been found advantageous to pursue the following plan: The first inoculation may consist of the twenty-four-hour surface growth from 18 square inches of solid culture-medium, emulsified in about 30 c.c. of physiologic saline solution, and heated for one-half hour at 65° C."

In Stellwagen's studies and use of the serum it was found that the best results were obtained by giving the injections as close to the area of infection as possible, and, further, by giving them every day. The only untoward results noticed were now and then an eruption of wheals or urticaria accompanied by slight headache and itching, with a trivial rise of temperature. The acute cases generally showed marked improvement after about the seventh injection. The serum seemed to be of use in other complications also, such as orchitis, prostatitis, and epididymitis. Stellwagen maintains that the serum is a valuable adjunct in treatment, especially where the older standard remedies are slow to produce a result. The great claim for serum, however, has been in arthritis and other synovial infections, in which it seems, perhaps, to have some value.

The serum must not be confused with the vaccine, which is decidedly uncertain. When the vaccines were used in the venereal clinic of the Jefferson Hospital they did not produce the happy results that other clinicians have claimed for them.

Stricture of the urethra, or narrowing of the urethral caliber, is divided into *inflammatory*, *spasmodic*, and *organic*. The so-called *inflammatory* or *congestive* stricture is not a stricture, but is an inflammatory swelling of the mucous membrane.

Spasmodic stricture does not exist alone, but complicates organic stricture, a hyperesthetic urethra, or an inflamed bladder.

Organic stricture is a fibrous narrowing of the urethra, due, as a rule, to chronic gonorrheal inflammation or to traumatism. True organic stricture is very rare in children, but can occur. Abbe reported a case of impassable stricture in the deep urethra of a male child two and one-half years of age, due to urethral gonorrhea. There were also two strictures of the anterior urethra. External urethrotomy was performed. Traumatic strictures occur in the bulbous or membranous urethra, and are due generally to force applied to the perineum, the urethra being squeezed between the subpubic ligament and the vulnerating body. Strictures resulting from gonorrheal inflammation occur in the penile, bulbous, or membranous urethra. Stricture never forms in the prostatic urethra except as a result of traumatism. Recent non-traumatic strictures are soft and are easily distended. Old strictures and traumatic strictures are very dense. A resilient stricture is one which contracts quickly after dilatation. The nearer a stricture is to the meatus, the more fibrous it is.

A *congenital* stricture is congenital narrowness of a portion of the urethra, usually the portion near the meatus. The more fibrous a stricture is, the more it narrows the urethra and the less dilatable it will prove. A stricture may be

annular (forming a ring around the urethra), tubular (surrounding the urethra for a considerable distance), or bridle (when a band crosses the urethra from wall to wall). A stricture of large caliber will admit an instrument larger than a No. 15 French sound. A stricture of small caliber will not admit a No. 15 French sound. An impermeable stricture will not admit the passage of any instrument. "Impermeable" is more or less a relative term. A stricture may be impermeable when an anesthetic is not used, and permeable when the patient is anesthetized, or may be impermeable to one surgeon, but permeable to another. Impermeability is often a temporary condition due to spasm or to inflammatory edema about an organic stricture.

Symptoms and Results of Stricture.—There is usually a history of repeated attacks of urethritis. There may exist a chronic discharge, the amount of which is variable. There is a feeling of weight in the perineum and soreness of the back, and frequency of micturition is complained of. Hypochondriacal tendencies are usual. In a deep stricture there is difficulty in starting the stream in micturition. In most cases the stream is small, twisted, and forked. There is often interruption or "stammering" of the stream, and it dribbles long after the conclusion of the act, so that the penis must be "milked" before it is returned within the clothing. The urethra back of a stricture dilates, a pouch forms, drops of urine collect and decompose, and in the mucous membrane or the parts adjacent there results a chronic inflammation which may go on to ulceration or to periurethral abscess. A urinary fistula follows the opening externally of a periurethral abscess. Retention of urine may occur, not from actual obliteration of the tube by the growth of the stricture, but from closure of the lumen of the urethra by muscular spasm and from edematous swelling in the neighborhood of the stricture. Edematous swelling may be due to cold, wet, venereal excitement, the use of alcohol, overexertion, etc. Spasm of the muscles results, and contact of the urine increases the spasm, and spasm with edema of the mucous membrane closes the urethra. Spasm may exist in the urethra itself and in the muscles of the neck of the bladder, but is only a temporary condition. In old strictures the bladder is hypertrophied and often fasciculated, and is very liable to cystitis. The diagnosis of stricture and of its location is made by the use of exploratory bougies. In this examination the author follows to a great extent Ramon Guiteras's[1] plan which is as follows: Have the patient pass urine into two glasses. Examine the urine for clap-shreds. Cloudiness in the first glass shows that urethral discharge exists. Cloudiness in the second glass points to cystitis. The patient is placed recumbent with his shoulders elevated, and the urethra is washed out with warm salt solution or boric acid. Bulbous sounds are inserted, beginning with No. 15 French. If this passes with ease, take a larger size and note where strictures are situated by the catch on withdrawal. If No. 15 does not pass, use a smaller size. Remember that the posterior layer of the triangular ligament catches a bulbous instrument on withdrawal. If the meatus be too small to permit of exploration, divide it by a curved bistoury, cutting from within outward. After cutting the meatus bleeding is arrested with styptic cotton, and a piece of absorbent cotton is tucked into the cut. After each act of micturition the patient inserts a fresh bit of cotton, and after three days the urethral examination may be proceeded with.

Treatment.—A stricture of large caliber in the deep urethra requires gradual dilatation. A steel bougie is introduced every fifth day, the size being gradually increased. Never anoint a bougie with vaselin, as it may become a nucleus for a stone in the bladder; use liquid cosmolin, glycerin, synol soap, or lubrichondrin. Before passing an instrument the patient urinates and his urethra is washed out with salt solution or boric acid solution. Glans, meatus, and urethra are cleansed as directed on page 1492. The sound is rendered sterile by boiling

[1] "Med. Record," Nov. 14, 1896.

before using. Gradual dilatation can be effected by the use of the dilator of Oberlaender, the tube being distended to the extent of 3 mm. every fifth day. If after dilatation there be urethral spasm, pain, or very frequent micturition, suspend the treatment for a number of days and order each night a hot hip-bath and a dose of paregoric. During gradual dilatation the patient should not use alcohol, should refrain from sexual excitement, should avoid cold and damp, and should take internally capsules containing boric acid and salol.

FIG. 995.—S. W. Gross's exploratory urethrotome.

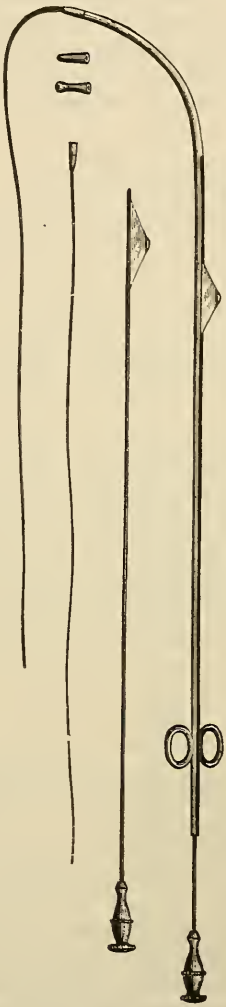

FIG. 996.—Maisonneuve's urethrotome.

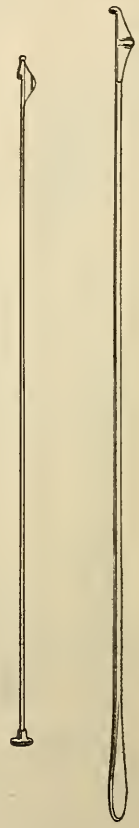

FIG. 997.—Horwitz's modification of Maisonneuve's urethrotome.

It is rarely necessary to dilate above No. 32 French. After the surgeon finishes treatment he teaches the patient to use an instrument and directs him to pass it once a month, because gradual dilatation rarely cures a stricture, and if dilatation be permanently abandoned contraction will probably occur. Strictures in the pendulous urethra, if soft, are treated by gradual dilatation; if fibrous and contractile, by internal urethrotomy. For fibrous stricture in or near the bulb external urethrotomy should be combined with internal division. External

urethrotomy secures drainage, and by performing it we greatly lower mortality. In performing internal urethrotomy prepare the patient carefully; for several days before the operation give salol and boric acid by the mouth, and wash out the bladder repeatedly with boric acid solution. Be thoroughly aseptic. Anesthetize the patient. Before cutting irrigate the urethra with warm normal salt solution, and after cutting irrigate again, pass a rubber catheter into the bladder and tie it in. These precautions will prevent urethral fever. In cutting, insert Gross's urethrotome (Fig. 995) back of the stricture, spring out the blade, cut the stricture on the roof of the urethra, close the blade, withdraw the instrument, and pass a full-sized bougie.

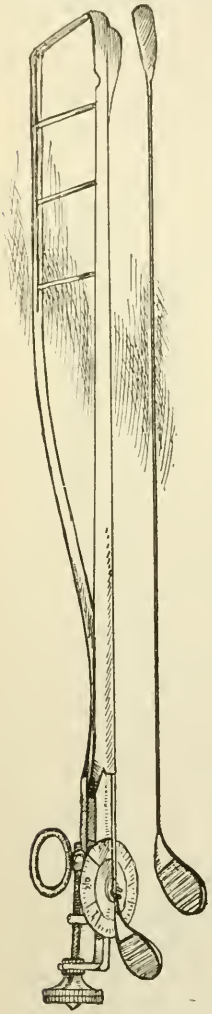

Fig. 998.—Otis's dilating urethrotome.

Stricture of the meatus requires incision by a knife and the use of a meatus bougie until healing is complete. Strictures of small caliber in front of the membranous urethra require gradual dilatation and, if this fails, internal urethrotomy or divulsion. Internal urethrotomy can be performed with the urethrotome of Maisonneuve (Fig. 996) or the Otis-Wyeth instrument (Fig. 998). The instrument of Maisonneuve is shaped like a sound, has a groove upon its surface, and into this groove a shaft carrying a triangular knife can be inserted. The staff is screwed to a guide, the guide is carried into the bladder and the staff follows it. The point of the staff is carried to the prostatic urethra and the guide curls up in the bladder. The penis is held upon the stretch, the blade is inserted and pushed down through the stricture. This instrument cuts the stricture, but not the healthy urethra. Stricture within 1 inch of the meatus is divided on the floor of the urethra. A deeper stricture is divided on the roof, except at or near the bulbo-membranous junction. In such a stricture the roof is divided by internal urethrotomy and the floor by external urethrotomy. In using a urethrotome do not overdilate or cut deeply. To do so will cause deformity of the penis. For *divulsion* the patient is prepared as for internal urethrotomy. The dilator of Gross (Fig. 999), or divulsor of Sir Henry Thompson or of Gouley (Figs. 1000, 1001) is introduced, the blades are separated, the instrument is withdrawn, a large bougie is passed, and a catheter is tied in the bladder. Strictures of small caliber in the deep urethra are seldom permanently benefited by gradual dilatation. The best method is combined internal and external urethrotomy. In strictures of the deep urethra, if only a filiform bougie can be introduced, the bougie may be left in place, and in a day or two another can be slipped in beside it, until in a few days the channel becomes permeable to a metal bougie. A tunneled catheter can be slipped over the filiform bougie, both be withdrawn, and a metal bougie passed. A tunneled and grooved staff

Fig. 999.—Gross's urethral dilator.

can be carried in over the bougie and external urethrotomy performed. Thompson's dilator can be carried in over the filiform and the stricture divulsed. What is known as *modified rapid dilatation* consists in first dilating, as described above, by the Thompson dilator and then introducing the powerful dilator of Gross (Fig. 999) to distend the urethra to the limit. This operation tears and lacerates rather than dilates and has been practically abandoned. In impassable stricture of the deep urethra perform external perineal urethrotomy without a guide (the operation of Wheelhouse).

If a perineal fistula exists, dilate, divulse, or cut the stricture and retain a catheter in the bladder for forty-eight hours. After this period dilate the urethra every fourth or fifth day by a metal instrument. Every morning and evening draw the urine by a soft catheter, introduce boric acid solution

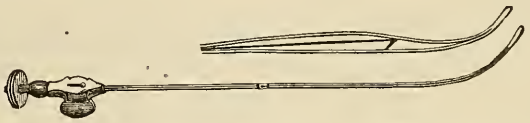

Fig. 1000.—A Thompson's divulsor may be carried in over a filiform and the stricture divulsed.

into the bladder, remove the catheter, and let the man empty his bladder naturally. A part will flow from the fistula and a part from the meatus. Day by day the quantity which comes from the fistula lessens, and finally the abnormal opening heals.

Urethral Fever.—Any operation upon the urethra may be followed by a chill owing to shock (urethral shock), and this may be followed by a nervous fever. Urethral fever proper is sapremia following a urethral operation. The condition is due to absorption of toxic elements which may be in the urine, may have been in the urethra, or may have been introduced from without. It usually follows the first urinary act after operation. It begins with a violent chill and presents the characteristics of a septic fever. It is accompanied by a marked tendency to urinary suppression, and may eventuate in septicemia

Fig. 1001.—Gouley's divulsor.

or pyemia. Urethral fever can be prevented by rigid antisepsis. If this fever should arise, a catheter must be tied in the bladder, the bladder and urethra must be repeatedly irrigated with aseptic or antiseptic fluids, and the patient must be given antiseptics and stimulants by the mouth.

Urinary Fever.—Sir Benjamin Brodie pointed out that the withdrawal of residual urine in a case of enlarged prostate may be followed by very serious symptoms. The condition is spoken of as urinary fever, and was said to be due to the sudden and complete emptying of a bladder which had become accustomed to retaining permanently a considerable quantity of urine. Modern studies prove that urinary fever is due to infection of the bladder and kidneys, and not simply to the sudden withdrawal of all of the urine from the bladder, although such a procedure leads to vesical congestion and probably favors infection. The bacteria most often found are pyogenic cocci, colon bacilli, and microorganisms which cause putrefaction and decomposition of urea.

The condition does not arise promptly, suddenly, and violently, as does urethral fever, but begins rather insidiously after several days. Mr. C. Mansell Moullin[1] thus describes the condition:

"So far as the broader features are concerned, the symptoms that present themselves in these cases are remarkably uniform. They do not begin at once. Nearly always some few days elapse before there is anything to excite suspicion. Then the urine becomes cloudy, though it may still retain its acid reaction. A small quantity of albumin, more than can be accounted for by

Fig. 1002.—Syme's grooved staff.

the amount of pus that is present, makes its appearance. Under the microscope there are a few hyaline casts, perhaps a blood-corpuscle or two, numerous pus-corpuslces, and myriads of bacteria. The specific gravity is lower than it ought to be, and is lower than it was before the catheter was used. The total amount passed in the twenty-four hours may either increase until it is as much as 7 or 8 pints, or diminish until it scarcely reaches 20 oz. There is seldom any definite rigor, but there may be numerous slight chills. The pulse grows

Fig. 1003.—Wheelhouse's staff.

more rapid and feeble. The tongue becomes red and dry. There is complete anorexia. Delirium sets in at night, and in a considerable proportion of cases the symptoms rapidly grow worse and worse until, at the end of a few days, the patient sinks into a semicomatose condition from which he seldom rallies. Postmortem there are all the signs of recent acute cystitis and pyelonephritis. The mucous membrane lining the pelvis and calices of the kidney, the ureters, and the bladder is swollen and stained by old and recent hemorrhages, and here and there a thin layer of pus is adherent to it. The pelvis and the ureters are

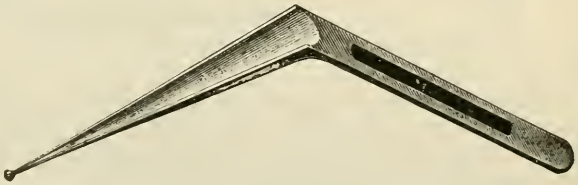

Fig. 1004.—Teale's probe gorget.

dilated, the apices of the pyramids are eaten away, the cortex is shrunken and hard, the capsule is adherent, and in places between the tubules are minute collections of pus differing in shape and outline according to the anatomical arrangement."

Treatment.—Aseptic catheterization is necessary if we would avoid urinary fever; and as the urethra contains some of the causative organisms, the prepuce, glans, and meatus should be washed with soap and water and irrigated with

[1] "Lancet," Sept. 10, 1898.

boric acid or permanganate of potassium solution, and the urethra should be irrigated with boric acid solution or permanganate of potassium before the sterile catheter is introduced to draw the urine.

If urinary fever arises, it may be possible to control it by frequently irrigating the bladder with warm normal salt solution, solution of nitrate of silver (1:8000) or boric acid solution, and by administering stimulants, diuretics, diaphoretics, saline cathartics, urotropin, salol or boric acid, quinin, and nutritious food. In severe cases perform suprapubic cystostomy for drainage.

Perineal section is external perineal urethrotomy. There are three methods—the operation of Syme, of Wheelhouse, and of Cock.

Syme's Operation.—This operation is employed if a stricture is very contractile, if dilatation fails to cure, or if urethral instrumentation invariably causes pronounced urethral fever. The patient is anesthetized, Syme's staff (Fig. 1002) is introduced, and the surgeon makes an incision in the midline of the perineum and exposes the staff just above the shoulder of the instrument. The knife is carried along the groove and divides the stricture. A catheter is passed into the bladder from the meatus and is retained for several days, and the wound is dressed antiseptically. After the catheter has been removed it must be used every six hours until the urine passes by way of the meatus only. During the rest of the patient's life a full-sized sound should be passed at monthly intervals.

Wheelhouse's Operation.—This operation is employed for the treatment of impermeable stricture. Wheelhouse's staff (Fig. 1003) is passed into the urethra until it blocks on the stricture. The perineum is incised down to the staff and in front of the stricture. The edges of the cut urethra are held apart by forceps, the surgeon seeks for the opening through the stricture, passes a fine probe through it, divides the stricture, carries into the bladder from the wound an instrument known as a probe gorget (Fig. 1004) to dilate the canal and furnish a solid floor to facilitate the introduction of a catheter. With the gorget in place a metal catheter is carried from the meatus into the bladder. The gorget is removed and the catheter is tied in place. After three or four days the catheter is removed and is then passed frequently. The perineal wound is, of course, dressed antiseptically.

Cock's Operation.—This operation opens the urethra back of the stricture without the aid of a guide and relieves retention of urine. The surgeon introduces into the rectum the index-finger of the left hand, and the tip of the finger is rested upon the apex of the prostate gland. The surgeon incises the median line of the perineum, the back of the knife being toward the anus. When the point of the knife is felt to be near the finger the handle is lowered slightly, the blade is placed a little obliquely, and the urethra is opened. A catheter is passed into the bladder from the wound and retained for a time, and the stricture is subsequently treated.

Gibson's Operation for Impermeable Stricture (C. L. Gibson, in "Med. Record," Aug. 6, 1910).—Open the posterior urethra by Cock's operation (see above). In most cases it is now possible to pass a small urethrotome from the urethral wound forward. If this can be done the deep stricture is at once divided. If it cannot be done a filiform is passed from the urethral wound out through the urinary meatus. This maneuver may require the aid of a special instrument (Gibson's retrograde filiform carrier). The straight staff of the Flührer urethrotome is threaded over the filiform bougie in front of the meatus. It is pushed back until it passes through the stricture, when the knife is inserted and "pushed home." This trivial cut permits the passage of a large urethrotome (for instance, Otis's). The stricture is now freely divided (up to No. 30 French). After division of the stricture a No. 30 French steel sound is carried from the meatus into the bladder. A tube to drain the bladder is introduced through the wound.

Epispadias is a congenital cleft in the corpora cavernosa, the roof of the urethra being completely or partly absent. In complete epispadias there are absence of the pubic arch and exstrophy of the bladder.

Partial epispadias may sometimes be remedied by a plastic operation.

Hypospadias is a congenital cleft in the floor of the urethra, the meatus opening on the floor at some point between the scrotum and the end of the glans penis, the channel in front of the meatus being a gutter and not a tube.

Hypospadias of the glans is the most common form. In this condition the urethra has no floor as it passes beneath the glans, the site of the urethra is indicated by a groove, and the foreskin is absent below. Partial hypospadias requires no treatment except possibly dilatation or incision of the meatus. People who suffer from it are very prone to develop chronic urethral inflammation. In hypospadias of the penis the ill-developed cord-like corpus

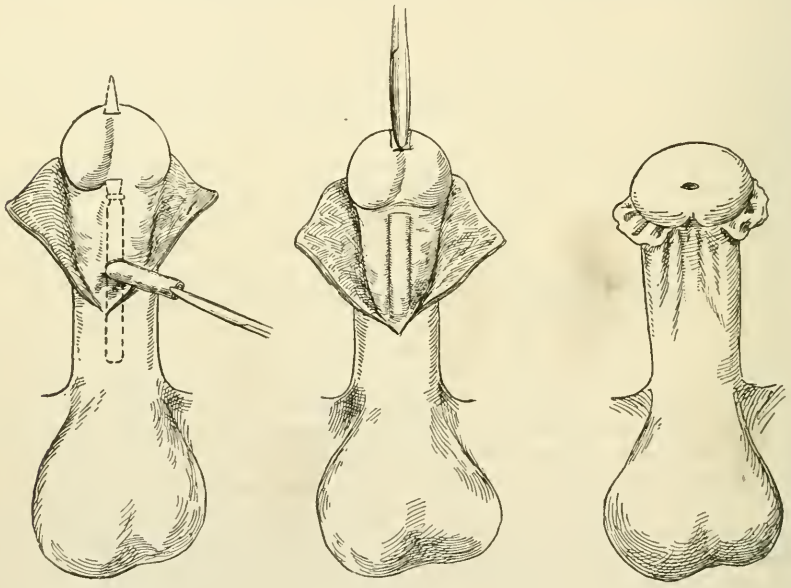

Fig. 1005. Fig. 1006. Fig. 1007.

Figs. 1005–1007.—Beck's operation for hypospadias.

spongiosum draws the penis to the scrotum. In this variety of the deformity the penis is very short.

In complete hypospadias the opening of the urethra is back of the scrotum in the perineum, the penis is dwarfed and bound down, and looks not unlike a clitoris, the scrotum is divided into two portions, a gap existing between them, and in many cases the testicles have not descended. Such individuals are occasionally mistaken for females. In the penile, complete forms of hypospadias a plastic operation should be performed between the eighth and tenth years of age. Such an operation, unfortunately, may fail. Hypospadias is rare in women, but it may occur. In such a case the urethra opens into the vagina. Figures 1005, 1007 show the ingenious operation successfully practised by Carl Beck for penile hypospadias.

Chancroid (*soft chancre; the local venereal sore*) is an ulcer, usually of venereal origin. The name "chancroid" was introduced by Clerc, who believed that a soft sore resulted from inoculating a person already syphilitic with the

products of a hard sore. He further held that when a soft sore arose the syphilitic poison lost its infective properties, and "could be transmitted as a soft sore to a healthy person, and not cause general infection."[1] The chancroidal ulcer is not connected with the syphilitic poison, but is developed by inoculation with the bacterium of Ducrey. Until recently it was believed that a chancroid was not produced by a special poison, but arose after inoculation with inflammatory products or irritating secretions. It seems to have been proved, however, by Krefting and Colombini that the organism discovered by Ducrey in 1889 is the real cause. This organism is grown on a medium of fresh blood and bouillon or in "unmixed human blood." (See Lincoln Davis, "Observations On the Distribution and Culture of the Chancroid Bacillus," "Report of Research Work," 1902–03; the Division of Surgery of the Medical School of Harvard University.) As a rule, chancroids are of venereal origin, and result from contact with other chancroids, pus, mucopus, or areas of ulceration. A chancroid appears soon after intercourse, usually within five days, always within ten days. It is first manifested by a pustule which ruptures and discloses an ulcer. This ulcer has sharply defined and undermined margins; it looks "punched out;" the base is gray and sloughy;

FIG. 1008.—Buttonhole perforation of the prepuce following phagedenic chancroid (Horwitz).

FIG. 1009.—Buttonhole perforation of the prepuce following phagedenic chancroid (Horwitz).

the discharge is profuse, purulent, foul and auto-inoculable, and causes fresh chancroids by flowing over the parts. The area around a chancroid is red and inflamed, and considerable pain is apt to be complained of. The original chancroid spreads and new sores appear. The edge of a chancroid is rarely indurated unless caustics have been used or there is mixed infection with syphilis. Inflammatory induration fades gradually into the tissues, but the induration of a hard chancre is sharply defined. Fournier says that a chancroid may have a hard base if the sore is located in the sulcus back of the glans, on a lip of the meatus, or on the lower border of the prepuce of a man with phimosis, or when the ulcer is inflamed. The surgeon should always ask if the sore has been cauterized and how it has been treated. When a chancroid after a time displays marked and sharply outlined induration it points to mixed infection with chancroidal and syphilitic organisms. Chancroids are not followed by constitutional symptoms, but are apt to be accompanied by painful inflammatory buboes which are prone to suppurate. In hospital practice about 30 per cent. of patients with chancroids develop buboes. The bubo may be either unilateral or bilateral. In the majority of cases the adenitis of chancroid is due to the

[1] "Syphilis," by Alfred Cooper.

absorption of toxins alone and the pus may be entirely free from bacteria. Cases have been reported in which non-indurated sores were followed by syphilis. It is probable that a mixed infection existed, and that induration was overlooked, because a papular initial lesion was beneath the chancroidal ulcer. When inflammation in chancroids is high, a rapidly destructive ulceration known as *phagedena* may arise (Figs. 1008 and 1009), but this process is more common in syphilitic sores.

Treatment.—Ordinary cases of chancroid are treated by spraying with peroxid of hydrogen, drying with cotton, touching each sore first with pure carbolic acid and then with pure nitric acid, and dressing with black wash or dusting with iodoform or with calomel. Every few hours the patient soaks the penis in hot salt water (a teaspoonful of salt to a pint of water), sprays the sores with peroxid of hydrogen, dries with cotton, and dresses with black wash or dusts with iodoform or with calomel. As soon as granulation begins the sores should be dressed with 1 part of ointment of nitrate of mercury to 7 parts of cosmolin. Mild cases do well without cauterizing, peroxid of hydrogen being frequently used and a drying powder being employed. In chancroids with phimosis slit up the foreskin, smear the raw edges of the wound with pure carbolic acid, and treat the ulcers by cauterization. A regular circumcision usually fails because of infection of the stitch-holes. Phagedena requires the internal use of iron, quinin, and milk-punch, and the local use of powerful caustics (bromin or nitric acid or even the actual cautery). In some cases continuous antiseptic irrigation is valuable. When a bubo first begins, order rest, apply iodin or an ointment of belladonna and ichthyol, and make pressure by a spica bandage of the groin. Some surgeons advise the injection of 20 to 40 min. of a solution of carbolic acid (10 gr. to the ounce), but I have never seen any benefit from it. Some inject a 1 per cent. solution of bichlorid of mercury, but the proceeding causes intense pain. Welander recommends the injection of a 1 per cent. solution of benzoate of mercury. I have had no experience with this method. If the bubo persists, though it does not suppurate, it should be completely excised. If pus forms, several methods of treatment are open to us: aspiration, injection with a solution of carbolic acid, squeezing out the acid and injecting 10 per cent. ointment of iodoform and glycerin, and sealing the opening with collodion (Scott Helms). Hayden makes a puncture, squeezes out the pus, washes out the cavity with peroxid of hydrogen, and then with corrosive sublimate solution, injects warm iodoform ointment, and dresses with cold, moist, corrosive sublimate gauze to set the ointment. Otis, Fontain, Perry, and others commend this plan. We have sometimes found it to succeed. If the above-mentioned plan fails, if it is not used, or if an ulcer or sinus exists, incise, curet, cauterize with pure carbolic acid, cut away hopelessly infiltrated skin, and pack the wound with iodoform gauze. In some cases it will be necessary to extirpate fragments of gland.

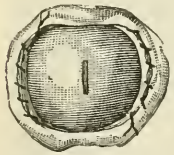

FIG. 1010.—Circumcision completed (Esmarch and Kowalzig).

Phimosis is a condition of the prepuce that renders retraction over the glans impossible. It is usually congenital, but it may arise from inflammation. Congenital phimosis causes retention of sebaceous matter, which decomposes and lights up inflammation and the prepuce is apt to grow fast to the glans. Congenital phimosis may induce irritability of the bladder, incontinence of urine, prolapse of the rectum, and various nervous symptoms.

The **treatment** is *circumcision*. Asepticize the parts. Grasp the foreskin and the mucous membrane by two pairs of forceps, draw the prepuce forward, catch the skin (at the point it is desired to cut) horizontally between the arms of the handle of a pair of scissors, and cut off the redundant prepuce. Retrench the excess of mucous membane by trimming with scissors ¼ inch

from the glans, stitch the skin to the mucous membrane with catgut, and dress with sterile gauze (Fig. 1010).

Fracture of the penis, which is a laceration of the cavernous bodies with extravasation of blood, occurs occasionally during coition.

The **treatment** consists of cold and bandaging to arrest bleeding, and in some cases incisions to let out clot.

Gangrene of the penis arises from phagedena, from tying constricting bands around the organ, from fracture with excessive hemorrhage, and from paraphimosis. If extensive, it requires amputation.

Cancer of the penis (Fig. 1011) is commonest in persons with phimosis. Penile cancer is practically never seen in Jews. It may develop from a syphilitic scar or ulcer or from venereal warts. I have seen one case of Paget's disease of the glans penis. Cancer developed. It has been claimed that contact cancer of the penis may develop as a result of intercourse with a woman suffering from cancer of the cervix uteri. The inguinal glands on both sides are involved early and the deep glands in the inguinal canals are usually involved (J. H. Cunningham, Jr., in "Trans. Am. Assoc., G. U. Surgeons," 1914). In a limited epithelioma of the foreskin circumcision is performed and the glands of the groin are removed; if a well-developed cancer affects the glans, amputation of the penis is imperative and removal of the inguinal glands is absolutely necessary. Certain recent superficial cases without glandular involvement may apparently be cured by fulguration.

Fig. 1011.—Cancer of penis (Horwitz).

Amputation of the Penis.—Ricord advised cutting off the organ by a single stroke of the knife, making four slits in the mucous membrane of the urethra, and stitching each of these flaps to the skin. Treves splits the skin of the scrotum along the raphé, separates the halves of the scrotum down to the corpus spongiosum, passes a metal catheter down to the triangular ligament, inserts a knife between the corpus spongiosum and the corpora cavernosa, withdraws the catheter, cuts the urethra across, detaches the urethra from the penis back of the triangular ligament, cuts around the root of the penis, divides the suspensory ligament, detaches each crus from the pubes, slits up the corpus spongiosum ½ inch, stitches its edges to the rear end of the scrotal incision, introduces a drainage-tube, ligates the vessels, and sutures the wound.

Seminal Vesiculitis.—Inflammation of the seminal vesicles is due to the extension of a gonorrheal inflammation, to a pyogenic process, or to tuberculosis. The symptoms vary greatly because in some cases the vesiculitis is associated with trigonitis, in others with prostatitis, in others with urethritis.

Acute vesiculitis is made evident by frequent and painful micturition, pains in the anus, rectum, and perineum, and possibly the hip-joint, back, and thighs. The cords and epididymes are painful and tender and epididymitis may occur. Defecation and micturition are excessively painful. There may be vesical tenderness and tenesmus and even retention of urine. Persistent and perhaps painful erections may take place, nocturnal pollutions are common, and in some cases bloody and purulent ejaculations occur. Rectal examination detects the enlarged and tender vesicles external to the lateral lobes of the pros-

tate and on a higher level. Massage of the vesicles causes pus or blood mixed with pus to enter the urethra from which it can be squeezed.

Treatment.—Abandon local urethral treatment, and treat the patient as for acute prostatitis.

Chronic vesiculitis may result from the acute form or may develop insidiously in an individual with gonorrhea. It is one of the possible causes of a chronic urethral discharge. The patient suffers from imperative and frequent demands to micturate, and he has a gleety discharge which becomes irregularly worse and better, but does not disappear. In many cases there are symptoms of chronic cystitis. Micturition is frequent and painful, the cords and epididymes are tender and painful, urinary retention may occur, repeated attacks of epididymitis are noted in some cases, defecation causes pain, and pains are complained of in the anus, perineum and other parts. The enlarged and tender vesicle can be felt through the rectum and massage of it causes mucopus, which may be bloody, to enter the urethra. Erections are at first frequent and painful. In most cases sexual hypochondria develops. This chronic inflammation is believed to persist because of narrowing of the duct and consequent incomplete drainage of the vesicle. In chronic seminal vesiculitis sooner or later there

Fig. 1012.—Dufaux's prostatic masseur.

is sexual weakness, nocturnal emissions occur, and the semen may contain blood and pus. Calculus may develop in a vesicle. Such a calculus is composed of phosphate of lime.

Treatment.—Treat the posterior urethritis by ordinary methods. Use hot rectal enemata. Milk the ducts by Fuller's method once every seven days. During massage the patient's bladder should be full. He leans over a chair-back, the knees being straight and the body at a right angle to the thighs. The surgeon covers his finger with a rubber stall, anoints it with oil or synol soap, introduces it into the rectum, and makes pressure over the pubes with the fist of the other hand. The finger comes in contact with the lower half of the vesicle; it makes firm pressure for a moment and is then drawn slowly toward the duct. This stroking is repeated several times. The other vesicle is treated in the same manner. These maneuvers empty the vesicles and hasten the resolution of inflammation. In many cases the finger reaches only the very lowest part of the vesicle. In such a case practice massage by means of Dufaux's rubber masseur (Fig. 1012). After the completion of the stripping the patient should micturate, and the bladder and urethra should be irrigated.

Tuberculosis of the Seminal Vesicles.—Primary tuberculosis is very unusual. As a rule, there is evidence of antecedent tuberculosis of the testicle or prostate gland. About 50 per cent. of the cases occur in individuals under forty years of age. The diseased vesicle is at first nodular and indurated, but later undergoes caseation and softening. Finally the disease passes through the capsule and invades adjacent structures. Dreyer collected 36 cases and found that in 34 of them the lungs were involved.

Tuberculous vesiculitis may be unilateral or bilateral. In unilateral tuberculous epididymitis the corresponding vesicle is apt to become diseased. In bilateral disease of the testicles both vesicles are liable to become victims. Peritoneal tuberculosis may follow tuberculous vesiculitis. In very unusual cases spontaneous cure is obtained by fibrous-tissue formation. On palpa-

tion, a tuberculous vesicle is found to contain here and there hard and but slightly tender nodules.

Treatment.—If tuberculous epididymitis is followed by tuberculous vesiculitis, it is justifiable to remove the vesicle after removing the epididymis or testicle, provided the prostate and other parts of the genito-urinary tract are free from disease and there is no distant lesion of tuberculosis. If both testicles or epididymes are removed, both vesicles can be extirpated. If a vesicle or both vesicles suffer from primary tuberculosis, operation is advised by some surgeons. Reported cases, however, do not seem to favor operation.

Kraske, Schede, and Rydygier have removed the vesicles after preliminary resection of the sacrum. Zuckerkandl, Diettl, and Schede have employed the perineal route. Villeneuve reached them by way of the inguinal region. The curved perineal incision of Zuckerkandl is the method usually preferred. H. H. Young makes a suprapubic incision, strips the peritoneum from the bladder, and reaches the vesicles from behind. He calls it the suprapubic-retrocystic-extraperitoneal method (H. H. Young, in "Annals of Surgery," Nov., 1901). For a Collective Review of the Surgery of the Seminal Vesicles see John R. Caulk, in "Internat. Abstract of Surgery," Nov., 1915.

Acute Prostatitis.—Acute inflammation of the prostate gland may be caused by inflammation in adjacent structures, the use of instruments or irritant applications in the deep urethra, injury by a passing or impacted calculus, various infectious diseases, a stricture of the urethra, but particularly by gonorrhea. The gland enlarges greatly, the prostatic fluid exudes mixed with blood and pus, and the gland-ducts become distended with pus. A distinct abscess may form. The orifices of the ejaculatory ducts become distended and filled with pus, and the seminal vesicles or epididymes may also suffer. An abscess is liable to form in the cellular tissue outside of the prostate.

Symptoms.—There is a feeling of weight, fulness, or soreness in the perineum; a persistent pain at the neck of the bladder; frequent micturition, pain being present and becoming most severe as the last drops are voided; perineal tenderness; painful defecation; and bulging of the anal mucous membrane. If a finger be introduced into the rectum, it causes severe pain and palpates the enlarged and tender gland, unless the outlines have been destroyed by periprostatitis, in which case there will be felt a large, boggy, tender mass. (See Henry Morris on "Injuries and Diseases of the Genital and Urinary Organs.") These symptoms are accompanied by distinct elevation of temperature. The inflammation may abate without suppuration, but, as a rule, pus forms, the temperature becomes characteristic, the pain becomes pulsatile, micturition causes agony, the inflammatory mass is felt per rectum to be softening, and sometimes the swollen perineum becomes dusky red. Retention of urine is almost certain to occur. The abscess may rupture into the urethra or the rectum, or may diffuse in the periprostatic cellular tissue and subsequently may open in the perineum. Spontaneous evacuation may be followed by recovery or by the development of annoying or dangerous complications.

Treatment.—Keep a hot-water bag on the perineum and three or four times a day use rectal injections of hot water. Order frequent sitz-baths. Place the patient on a milk-diet. Leech the perineum. Give suppositories of opium and belladonna and also suppositories of ichthyol, and administer urotropin by the mouth. Retention of urine is relieved by a soft catheter. When pus forms it may be possible in some cases to rupture the abscess into the urethra by the passage of a steel sound. If this can be accomplished it will be fortunate. Occasionally a specialist may succeed in opening the abscess through an operating cystoscope. Most cases require to be cut externally. What is known as the *boutonniere operation* is the method of choice. The patient is placed in the extreme lithotomy position. The index-finger of the left hand

is introduced into the rectum and carried to the apex of the prostate. A straight bistoury is entered to the side of the median raphé and carried into the abscess cavity, and the opening is dilated by forceps. The urethra is not to be opened.

Chronic prostatitis may arise from stricture, venereal excess, chronic cystitis, or stone in the bladder, but gonorrhea is the common cause. The prostate is usually, but not always, enlarged, is somewhat softened, and the ducts contain pus and blood.

Symptoms.—There is usually a mucopurulent discharge or fluid can be obtained by massage of the prostate. There is a feeling of weight and fulness in the perineum, there is increased frequency of micturition, and the prostate is very sensitive to digital pressure. The patients are neurotic, frequently suffer from nocturnal emissions, and have but feeble power of erection. The prostatic urethra is extremely hyperplastic. All the symptoms are aggravated by worry, sexual excitement, or violent exercise. An abscess may form and rupture into the urethra.

Treatment.—Tonics and nutritious food are essential. Intravesical irrigations with nitrate of silver solution (1 : 8000) do good. Massage of the prostate is useful. Some cases are benefited by touching the posterior urethra through a urethroscope tube with nitrate of silver (3 gr. to the ounce) or by injecting by means of Ultzman's syringe a few drops of silver nitrate solution (5 gr. to the ounce). Rectal suppositories of ichthyol may be ordered. Blistering the perineum at intervals may prove of service. At intervals of three or four days a full-sized cold steel sound should be gently introduced. If an abscess forms, open it through the perineum. Hot or cold rectal injections of normal saline solution are useful.

Prostatorrhea.—Just as overaction of the glands of the urethra constitutes urethrorrhea, so overaction of the glandular apparatus of the prostate constitutes prostatorrhea. Prostatorrhea is not inflammatory, although the prostate and posterior urethra are often congested, and the latter region is usually hyperesthetic. In some cases urethrorrhea exists with prostatorrhea. Prostatorrhea is produced by sexual excess, masturbation, ungratified sexual desire, riding a bicycle with an improper seat, and sometimes by riding horseback. The condition is usually accompanied by marked neurasthenia, and may be associated with spermatorrhea and impotence.

The patient notices a milky or gray discharge after straining at stool (*defecation spermatorrhea*), after violent exercise, sexual excitement, or a bicycle ride. The discharge also gathers in the urethra during sleep. Examination of the discharge shows it to be prostatic fluid, although spermatozoids are sometimes found. It is not purulent and contains Böttcher's spermatic crystals. These crystals are rhombic prisms and terminate in fine points or rhomboid margins (Casper's Genito-Urinary Diseases by Bonney). The composition of these crystals is uncertain but Fürbringer proved that they are found in prostatic fluid only. The meatus is not glued up in the morning and the linen is very slightly stained. The urine is clear and contains small comma-shaped hooks. Sexual excitement and alcohol do not appreciably aggravate the condition. The bladder is irritable, and there is frequency of micturition and often some pain in the head of the penis at the termination of the act. Nocturnal emissions may occur.

Treatment.—The patient should correct bad habits. If there be urethral hyperesthesia or prostatic congestion, irrigate the bladder and urethra once a day with a solution of silver nitrate (1 : 4000), and every fourth or fifth day introduce a cold sound. In some cases the occasional instillation into the prostatic urethra of a few drops of a 1 per cent. solution of nitrate of silver does good.

For the irritable bladder give hot hip-baths at night. The following prescription is of service: 15 gr. of bromid of potassium, ½ dram of tincture of hyoscyamus in ½ oz. of cinnamon-water, three times a day. Hot enemata are of service.

After the hyperesthesia of the urethra has abated and nocturnal emissions have ceased, the neurasthenia is treated by cold sponging of the body night and morning, the continued use, at intervals of several days, of a large-sized cold sound, irrigation every second or third day with silver nitrate (1 : 4000), and the administration of strychnin and other tonics.

Prostatic Calculi.—Corpora amylacea are present in the prostate with such frequency that they may be regarded as normal. The nucleus of one of these bodies is composed of inspissated mucous and epithelial cells in a state of degeneration. About the nucleus layers of albuminoid material form which, under the microscope, resemble the cells of starch. In youth corpora amylacea are microscopic. In older persons they are visible to the unaided eye. When small they cause no trouble. When they enlarge notably, inflammation arises, and lime salts are deposited in the body. These true prostatic calculi are multiple, brown or black in color and are commonly faceted. If such a calculus ulcerates into the urethra urinary salts will be deposited; they will enlarge greatly, and an abscess will form.

A prostatic calculus may arise in the bladder or urethra or in a prostatic pouch. After prostatectomy the pouch may become filled with a mass of lime salts and urinary salts.

If prostatic calculi cause symptoms, the symptoms are those of chronic prostatitis or chronic posterior urethritis. Perhaps they can be felt by a finger in the rectum or by a metal sound in the urethra. Some are visible through a urethroscope. The *x*-rays show them.

Treatment.—Removal through a urethroscope or by means of a perineal incision.

Hypertrophy of the Prostate Gland.—It was pointed out by Morgagni that in old men difficulty of micturition is due to obstruction by an enlarged prostate gland. Enlargement of the prostate gland may be brought about by different forms of growth. It is, as a general thing, a senile change, occurring only after the age of fifty, and being most likely to arise after the attainment of sixty years. It is very rare for enlargement of the prostate to cause symptoms much before the age of fifty or to begin after the age of seventy. Sir Henry Thompson maintained that 34 per cent. of men over sixty have prostatic hypertrophy, but that only half of them have troublesome symptoms. According to Freyer, 33 per cent. of all men past fifty-five years of age present some enlargement of the prostate.

There are some who oppose the view that prostatic enlargement is essentially a senile change. For instance, Dr. L. Bolton Bangs ("Jour. of Dermatol. and Gen-urin. Dis.," March, 1901) maintains that the change is not senile; that it really begins early in life, but that its effects do not become manifest until during or after middle age. Lydston asserts that it begins during the third decade of life, but the gland does not attain sufficient size to cause symptoms till beyond middle life. Socin and Burckhardt, as a result of 300 postmortem examinations, reached the following conclusions: Between the ages of thirty-six and forty the gland is hypertrophied in 13 per cent. of cases, between forty and fifty in 25 per cent., between fifty and sixty in 31 per cent., between sixty and seventy in 56 per cent., between seventy and eighty in 50 per cent., and between eighty and ninety in 54 per cent. Undoubtedly, the enlargement begins long before it occasions sufficient obstruction to induce symptoms, and the growth progresses very slowly. Guyon and the French school in general maintain that hypertrophy of the prostate gland is always the result of arteriosclerosis, affecting not only the prostate, but also the entire urinary tract. The hypertrophy that ensues affects the bladder walls notably, as well as the prostate, because of distinct growth. Caspar has apparently demonstrated that Guyon's view is not correct. He has shown that in many cases there is no sclerosis of the prostatic arteries, and that frequently there

are no sclerotic changes in other portions of the urinary tract. Another important point made by Caspar is that arteriosclerosis tends to cause degeneration, and not hypertrophy.

Some think that sexual excess is a cause of prostatic enlargement; some assert that antecedent gonorrhea is the cause, but it seems very improbable that either is causal. Belfield blames altered testicular secretion; Hawley believes the cause to be altered prostatic secretion and the "chemical action of pathological proteins resulting from irregular metabolism or derived from disintegration of the secretion, or in the usual action of tissue enzymes" ("Annals of Surgery," Nov., 1903).

In the hypertrophied prostate there is an excessive production of fibrous tissue and of ill-formed glandular tissue, the mass constituting a fibro-adenoma. Fibro-adenoma is the common cause of enlargement (W. Bruce Clarke). Typical adenoma, according to Albarran and Hallé, is found in 14 per cent. of the cases ("Annales des Maladies des Organes Génito-Urinaires," Feb. and March, 1900). Again, in not a few prostates there is no real enlargement, but there is an indurated fibrous mass producing obstruction. Albarran and Hallé (Ibid., 1898, vol. xvi) point out that in an enlargement of the prostate different elements may usually be recognized: soft hypertrophy of the gland; indurated enlargement of the glandular elements; fibrous enlargement; circumscribed tumor-masses; distinct fibromata or myomata; or adenofibromyomata. The real cause of the various forms of prostatic enlargement is not known. Nearly 10 per cent. of cases are cancerous (Oraison), and adenoma is apt to be transformed into cancer.

All the lobes may be enlarged equally; all may be enlarged unequally; the enlarged gland may surround the prostatic urethra like a horse-collar; or one lobe only may be enlarged. Symmetrical enlargement of the entire gland is not so apt to produce symptoms as is non-symmetrical enlargement. In some cases the chief enlargement is into the bladder; in others, into the urethra. An enlarged prostate frequently shows a circular groove about it, due to the constriction exerted by the rectovesical fascia at the vesical neck.

The bridge of prostate which joins the two lateral lobes behind the urethra is known as the *lobe of Home* or the *middle lobe*, and a comparatively trivial enlargement of the middle lobe may cause obstruction. In 1811 Sir Everard Home described the middle lobe. Prostatic hypertrophy causes narrowing and lengthening of the urethra, and gives this tube a tortuous course. The opening of the urethra into the bladder is usually pushed to a higher level, and there forms behind it a pouch in which urine collects. The urine that gathers in this pouch is known as *residual urine*. It cannot be voluntarily expelled. It may, therefore, collect in large quantity, and it is likely to decompose, producing cystitis. Residual urine strongly favors calculus formation. The mechanical resistance to the expulsion of the urine causes congestion of the neck of the bladder and of the posterior urethra and also hypertrophy of the muscles of the bladder. In consequence of the hypertrophy the bladder enlarges, thickens, and becomes fasciculated. When this takes place, micturition becomes very difficult and sometimes impossible. Enlargement of the middle lobe inevitably blocks the flow of urine and causes great distention of the bladder. In hypertrophy of the prostate gland the ureters and the renal pelves and calyces may distend and surgical kidney may develop.

It is useful to divide persons with prostatic hypertrophy into three groups: (1) those in whom there is no obstruction or in whom the urinary symptoms are very trivial; (2) those in whom there are residual urine and disturbances of urinary function, who depend upon the catheter for relief, but who do very well by this method; and (3) those that suffer a complete breakdown during the period in which the catheter is depended upon (Orville Horwitz, in "Phila. Med. Jour.," Nov. 16, 1901).

Symptoms.—In 90 per cent. of the cases there is very trivial inconvenience, the patient merely being annoyed somewhat by episodes of nocturnal, and less urgent diurnal, frequency of micturition. During the day when the man is active the circulation of the prostate is active and so are the muscles. At night, when in bed, there is venous congestion of the prostate and base of the bladder. Hence the vesical irritability. Again, there is usually polyuria in cases of enlarged prostate, and polyuria is most marked at night. The stream of urine is slow to start and falls feebly from the end of the penis. In some cases there is interruption of the stream (stammering). The last drops fall entirely without control. If the patient becomes sexually excited, chilled, or worried, or indulges inordinately in the pleasures of the table or in wine, beer, or alcoholic liquors, nocturnal frequency of micturition becomes for a short time most harassing. Very early in a case the bladder can be completely emptied. In 10 per cent. of all cases the bladder becomes unable to empty itself completely, and residual urine collects. Frequency of micturition comes on during the day as well as at night; the patient has to get up often, several or many times from his bed, the bladder never feels empty; and cystitis is apt to arise. This is known as the second stage. Guyon calls it the stage of "bladder insufficiency." The urine, at first acid and clear, becomes neutral and cloudy, and finally ammoniacal and turbid, and contains bacteria, mucopus, precipitates of phosphates, and blood. Above the pubes there is aching pain, soon spreading to the perineum, and increasing when the bladder is distended and during micturition. The rectum becomes irritable, and piles form or prolapse of the mucous membrane occurs, because of straining in micturition. The second stage may last a year, two years or several years. The second stage passes into the third stage in which attacks of retention of urine may occur. The bladder dilates greatly. With the retention there is usually incontinence (incontinence of retention). "With this overtaxed, overdistended bladder, the sphincter relaxes every few minutes, allowing the escape of a few drops of urine, and when we question one of these old men about his urination, asking if he passes water frequently, and he says, 'Yes, every few minutes'—that always means an overdistended and dribbling bladder" (H. H. Morton, "N. Y. Med. Jour.," Sept. 9, 1916). In about one-third of all cases we can make a diagnosis by rectal palpation. In enlargement of the middle lobe alone or in pure intravesical enlargement rectal touch will fail to make the diagnosis and the cystoscope must be relied upon. The bladder becomes thin and distended, or hypertrophied, rigid, and fasciculated. In rare cases true incontinence is caused by the median lobe growing toward the neck of the bladder and preventing closure. The health breaks down because of pain, restless nights, indigestion, and disorder of the bowels. The urine is of low specific gravity, is low in urea and there may or may not be casts. The patient becomes somnolent and the tongue dry and parched (*urosepsis*). The kidneys may become involved (inflammation of the pelves or calices, or surgical kidney) and suppression may occur. Septic fever may arise. Calculi may form in the bladder. Death is due to exhaustion, suppression of urine, or septic cystitis. A foul catheter is the usual cause of septic cystitis, but micro-organisms sometimes enter by passing along the urethral mucous membrane.

A patient should be examined by rectal touch, by a sound, and by a cystoscope, if possible; the amount of residual urine must be determined, and the condition of the urine is to be carefully studied. The presence or absence of stone should always be determined. After an examination by instruments the patient must remain in bed for twenty-four hours.

Treatment.—There is no known method of preventing prostatic hypertrophy. Many cases of enlargement are treated by regular catheterization, and if this is conducted with careful cleanliness, and if the patient rigidly adheres to hygienic rules, he may be kept comfortable in this way for a consider-

able time. Certain cases of hypertrophy of the prostate gland seem to have been benefitted by radium and the *x*-rays. When a man must depend upon a catheter to empty his bladder he is said to be in *catheter life*. Alexander has formulated several sound rules as to when catheterization is the proper treatment. He says, if the patient is intelligent and dextrous, if cystitis is not severe, if the amount of residual urine is not very large, if obstruction is not great, if the bladder retains considerable expulsive power, and if catheterization is easy and painless, we are justified in relying upon this simple plan of treatment. Prevent cystitis by emptying the bladder each evening with a coudé catheter. If there is trouble in passing the catheter, strengthen the instrument by inserting a filiform bougie as a stylet. It is very seldom that a metal instrument is required, but if it is necessary, a catheter with a large curve is employed. If a soft or semisolid instrument can be passed, teach the patient how to clean it, how to use it, and how to keep it, but never permit the patient to use a metal instrument himself. A dirty instrument may cause fatal infection. It is true that some people use dirty instruments for long periods without trouble, but in most cases there will be trouble if it is attempted. It is absolutely necessary to use perfectly aseptic instruments only. Metal instruments are sterilized by boiling in water. Rubber catheters can be cleansed by washing with soap and running water, wrapping in gauze, and boiling. After sterilization the instruments are kept ready for use in a glass cylinder which contains calcium chlorid.[1] The cleansing of catheters is discussed on page 1457. If there are 3 oz. of residual urine, use the catheter at night only. If there are 6 oz., use it night and morning. If there are more than 6 oz. of residual urine, add one more catheterization a day for every additional 2 oz. present until the catheter is used six times in the twenty-four hours. It should never be used oftener than this. Gradual dilatation with steel sounds is of benefit, but forcible dilatation is not advisable. The sound may be passed once a week. Tell the patient to avoid exercise, cold, damp, sexual excitement, and the use of alcoholic liquors; prevent constipation and indigestion, and direct him to drink milk and plenty of water. A hot hip-bath at night adds to his comfort. Hot enemata are of value. If a large quantity of residual urine exists, or if cystitis begins, wash out the bladder daily with boric acid solution, or normal salt solution, or nitrate of silver (from 1 : 10,000 to 1 : 4000), and give urotropin or salol and boric acid by the mouth (see Cystitis, page 1470). In some severe cases, if a large-sized rubber catheter be tied in the bladder for a few days, great relief is obtained. Retention of urine can usually be relieved by the introduction of a coudé catheter strengthened with a whalebone. In exceptional cases a silver instrument with a prostatic curve must be employed or aspiration must be practised. Many cases occurring among well-to-do people can be kept comfortable by catheterization. Some surgeons still think that only when this fails should an operation be performed. Unfortunately, sooner or later a man who regularly relies upon the catheter will develop cystitis. A poor man cannot give the necessary time and attention to make catheter life safe and operation must be thought of in him sooner than in others. If the symptoms grow constantly worse, if the suffering becomes severe, if the patient cannot empty his bladder without the use of an instrument, if catheterization is painful or impossible, if the patient is too careless or ignorant to trust with a catheter, if only a catheter of very small size can be introduced, if attacks of obstinate retention occur, if there is persistent or recurring cystitis or hematuria, if there are signs of beginning infection of the kidney, if the residual urine gradually increases in amount, operation is called for. Do not postpone operation until the patient becomes really ill. Give palliative measures a reasonable trial, and if they fail, operate. Before determining upon any operation make a cystoscopic examination. This is particularly valuable before a Bottini operation and before a perineal operation. It shows us the condition

[1] R. W. Frank, in "Berliner klin. Woch.," No. 44, 1895.

of the bladder; the nature, size, and situation of the enlargement, the median lobe if present, and a calculus if one exists. This examination may determine the form of operation desirable. Prostatectomy is not to be regarded as a trivial affair certain to result in cure. It is a grave procedure, with a considerable mortality, which may be attended by disastrous complications and from which unfortunate consequences may arise. I agree with James E. Moore that "it is altogether too grave an operation to be resorted to as a routine treatment for every enlarged prostate, and is applicable to properly selected cases only." The operation is contra-indicated if there is advanced disease of the kidneys, and if it is performed in such a case, fatal uremia is to be expected. Age is not in itself a contra-indication if the kidneys and cardiovascular system are sound. An occasional sequel of prostatectomy is incontinence of urine due to injury of the neck of the bladder or to the nerves of the part. A possible sequel is sterility but age has rendered most of the subjects practically sterile before operation.

In the majority of cases in which palliation fails the operative indication is to remove an obstructing mass and to depress the level of the opening from the bladder into the prostatic urethra, so that the prostatic pouch is abolished and the bladder can be thoroughly drained. The surgeon chooses between prostatotomy and prostatectomy. Prostatotomy is usually performed by the galvanocautery (Bottini's operation). Prostatectomy may be suprapubic or perineal, and the latter may be by enucleation without the aid of sight (as in the operations of Nicoll and Alexander) or by open dissection (as in Young's operation). No one routine plan is suitable for all cases. The patient should be studied, and the operation chosen which is safest and best for that individual case. The surgeon who uses one method only must wrong many patients, and he retains consistency at the expense of humanity. It was formerly believed that any operation of total prostatectomy must of necessity produce impotence. This we now know need not be the case. The suprapubic operation is probably less likely to be followed by this than is the perineal, as the former usually spares the ejaculatory ducts. Young's perineal operation spares the ejaculatory ducts. Destruction of the ejaculatory ducts certainly produces sterility and may, but does not of necessity, produce impotence. Willy Meyer ("Med. Record," Oct. 7, 1905) points out that impotence may be caused by damaging important nerves or blood-vessels in advancing through the perineum, and also by the operation producing relaxation of the verumontanum and prostatic urethra, parts necessary in the reflex for erection.

The *perineal operation* is as safe as the suprapubic or safer, and can be rapidly performed. It is the desirable route when the gland can be palpated per rectum, and does not mount high up (when the finger can touch the upper margin of the gland) and when we are dealing with the early stages of soft hypertrophy. Prolonged drainage should be perineal. Permanent drainage should be suprapubic. According to Francis S. Watson ("Annals of Surgery," June, 1904), the mortality in 203 cases was only 2.9 per cent. In 563 cases of removal through the perineum by dissection the mortality was 5.5 per cent. Young's cases in this group number 150 and his mortality was 4.6 per cent.; the mortality of Hartman was 9 per cent.; of Albarran, 4 per cent., and of Murphy, 3.9 per cent. (Schachner, in "Annals of Surgery," August, 1908). In 190 cases of blind enucleation through the perineum the mortality was 4.7 per cent. (Ibid.).

After the performance of the perineal operation the drainage is at the lowest part of the bladder. In a perineal operation every effort should be made to do as little damage as possible to the urethra. If we destroy the entire prostatic urethra the operation becomes easy and rapid and Nature rapidly repairs it, but a traumatic stricture may follow and may make the patient's condition worse than at first. As Moore says, we must destroy a portion of the floor of the urethra, but we can preserve the roof and the side walls. Another point

in the perineal operation is to avoid injuring the rectum. A tear may enter the rectum, or, even if the gut has not been torn, sloughing of the rectum resulting in recto-urethral fistula may occur. The rectum may be opened because the surgeon fails to stick close to the urethra in his dissection, and sloughing may be due to an injudicious use of the retractors. If the rectum is opened, it should be at once sutured with catgut. In most cases it takes about three weeks for the wound in the perineum to heal, and in some few cases a perineal urinary fistula is established. Urinary incontinence may follow this operation. By simply incising the prostate gland the floor of the urethra may be lowered to the level of the floor of the bladder. Simple incision of the prostate in this manner, or by Bottini's method, is known as *prostatotomy*. The mortality is small and the relief is often great. Prostatotomy is performed on old and exhausted patients with damaged kidneys. A large tube should be worn during the healing of the wound.

The *suprapubic operation* is easier than the perineal; it is less safe; it gives excellent results if temporary drainage only be needed. According to Watson ("Annals of Surgery," June, 1904), the mortality in 69 cases was 8.6 per cent. P. J. Freyer reports 600 cases varying in age from forty-eight to eighty-nine years. There were 47 between the ages of eighty and eighty-nine, and 7 were seventy-nine; most of the cases had been entirely dependent on the catheter for periods up to twenty-four years. "Nearly all were in broken health and many apparently dying before operation. Few were free from one or more grave complications, such as cystitis, stone in the bladder, pyelitis, kidney disease, diabetes, heart disease, chronic bronchitis, paralysis, hernia; and in a few instances there was malignant disease of some other organ than the prostate" ("Archives Internationales de Chirurgie," vol. iv, Fascic. 4, 1909). In these 600 cases there were 37 deaths in periods of from six hours to thirty-seven days after operation, a mortality of 6.15 per cent. Suprapubic prostatectomy is indicated in rather young subjects in whom we greatly fear impotence; in cases in which the gland is placed high; in cases in which the gland is not palpable per rectum, but is causing serious symptoms, and in which the hypertrophy is recognized by the cystoscope (Meyer); in cases in which there is a middle lobe; in cases in which cancer exists, or in which calculus complicates the case. It is the most useful operation when the gland is very large and intravesical. It is not a suitable method if the bladder is markedly contracted or if the belly walls are very thick. If prolonged drainage (short of permanent drainage) is required, as it is sure to be in cases with advanced cystitis, the opening is better placed in the perineal operation. If when a suprapubic operation has been performed it is found that prolonged drainage is indicated, a siphon drain (Fig. 968) may be used. If permanent drainage be required in a case, the suprapubic method is the best. After a suprapubic cystotomy has been performed for drainage, the opening may be kept permanently patent by the retention of a tube (Hunter McGuire's operation). It is only in very advanced cases or in cancer that permanent suprapubic drainage is employed. After making a suprapubic incision the floor of the urethra cannot be brought level with the floor of the bladder by a simple incision of the prostate through this incision; it can be brought level by the performance of prostatectomy only. In the suprapubic operation the structures divided are less important, and the drainage is less conveniently placed but better than in the perineal operation. Suprapubic prostatectomy inflicts injury upon the bladder, it may gravely damage the sphincter of the bladder, and is sometimes followed by incontinence or by inability to expel urine (John B. Murphy, "Jour. Amer. Med. Assoc.," March 29, 1902), but disturbance of control is less common than after the perineal operation. The bladder wall may be seriously torn, and if such a wound should be inflicted, it ought to be sutured with catgut. In this operation if the bladder be contracted, the surgeon must exercise great care to avoid injuring the peri-

toneum. The ureters may be damaged and subsequently become obstructed from contraction. If death occurs after prostatectomy it is due to shock, uremia, sepsis, or postoperative complications, usually pulmonary. Schachner ("Annals of Surgery," August, 1908) uses Watson's figures to present the special dangers of each operation. The figures give the percentage of the deaths due to shock, uremia, hemorrhage, and pulmonary complications. The table is as follows:

	Per cent.	
Bottini	2.7	Uremia (or renal insufficiency).
Perineal operations	35.0	
Suprapubic operations	34.0	
Bottini	52.0	Sepsis.
Perineal operations	17.8	
Suprapubic operations	8.6	
Bottini	5.0	Shock.
Perineal operations	21.4	
Suprapubic operations	30.0	
Bottini	8.0	Postoperative pulmonary complications.
Perineal operations	17.8	
Suprapubic operations	22.0	

At the International Urological Congress held in London in 1911 Young presented the records of 484 cases of perineal prostatectomy. The mortality in simple hypertrophy (450 cases) was 3.77 per cent.; 34 cases were cancerous, and of these 2 died. Zuckerkandl's mortality from perineal operations was 9.5 per cent., from suprapubic operations, 18.7 per cent. ("Ann. des Mal. des Org. Gén.-Urin.," 1911, ii). Freyer ("Amer. Jour. of Dermatology and Genito-Urinary Diseases," 1912) reports 1000 cases of suprapubic prostatectomy since 1901. The average age of these cases was sixty-nine. The youngest patient was forty-nine, the oldest was ninety. There were 55 deaths (a mortality of 5.5 per cent.). Freyer's mortality in his first 100 cases was 10 per cent., in his last 100 cases it was 3 per cent. This proves the great value of experience. The less training a man has had, the higher will be his mortality. Prostatectomy is distinctly not an operation for a juvenile surgeon.

Suprapubic Prostatectomy.—Freyer's Method.—The bladder is washed out through a catheter with warm boric acid solution and is then filled to its previously ascertained capacity with the solution. The nozzle of a large syringe filled with fluid is inserted into the end of the catheter. This keeps the bladder fluid from running out and enables the surgeon quickly to distend the viscus more if the occasion arise. The bladder is exposed and opened in the midline and in an area free from veins (see Suprapubic Cystotomy, page 1484). The incision is vertical, is made toward the symphysis, and is about 1 inch in length (it can be enlarged later if necessary). If any calculi are found they are at once removed. A finger is placed in the rectum to raise up the prostate and keep it steady. The finger of the other hand is introduced into the bladder, and by means of the fingernail the mucous membrane is scratched through over "the most prominent portion of one lateral lobe, or over the so-called middle lobe, if there be but one prominence" (Freyer, in "Archiv. Internat. de Chir.," Fascic. 4, 1909). This portion of the gland is covered by mucous membrane only, and when this is scratched through the true prostatic capsule is reached. In doing Freyer's operation the author passes the finger to the extreme anterior limit of the trigone, so that the finger is really within the urethra. At this point he splits the capsule and begins the enucleation, being careful to injure the trigone as little as possible. This precaution greatly lessens the danger of incontinence. The finger is kept in close contact with the true capsule and enucleates the gland by passing first posterior, next outside, and finally in front of one lateral lobe.

"The finger is then swept in a circular fashion from without inward, in front of and to the inner side of the lobe, detaching this from the urethra,

which is felt covering the catheter, and pushed forward toward the symphysis between the lateral lobes, which will, as a rule, have separated along their anterior commissure in the course of the manipulations. The other lobe is attacked and treated in the same manner. The finger is next pushed well downward behind the prostate and the inferior surface of the gland is peeled off the triangular ligament. When the prostate is felt free within its sheath and separated from the urethra, with the finger in the rectum, aided by that in the bladder, it is pushed into the bladder through the opening in the mucous membrane, which, during the manipulations, will have become considerably enlarged" (Freyer, Ibid.). The prostate is removed from the bladder by forceps. If the lobes come away separately, Freyer believes that the ejaculatory ducts are uninjured and remain attached to the urethra. There has been an active controversy as to whether Freyer's operation does or does not destroy the prostatic urethra. It seems certain that even if it is left it must slough for want of blood-supply. In my operations by this method it has come away with the prostate.

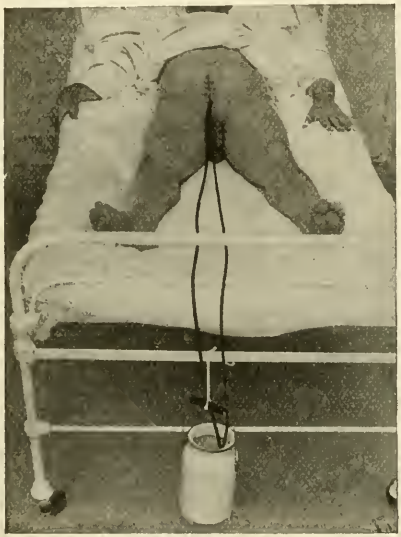

FIG. 1013.

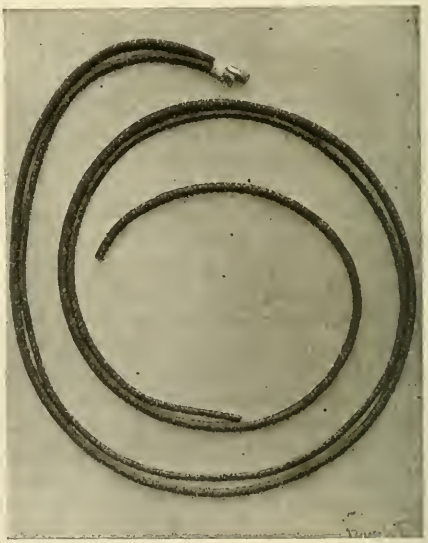

FIG. 1014.

FIGS. 1013 and 1014.—Showing double-tube drainage for suprapubic operation. Fig. 1013 was taken from an elevation to show the termination of the drainage-tubes. Fig. 1014 shows tubes enlarged in separate view.

In Freyer's earlier operations he sought to leave the urethra and accompanying structures behind, but he is now convinced that the prostatic urethra may be torn or removed without ill results. Figure 1013 shows the drainage as I employ it after suprapubic prostatectomy. Figure 1014 shows the drain.

McGill's Operation.—The bladder is opened by a suprapubic incision, the edges of the cut bladder are sutured to the abdominal wound with catgut, and the interior of the viscus is carefully explored by the finger and by sight, an electric light being used for illumination. If a sessile growth exists, the mucous membrane is incised and the growth enucleated by finger or a curet. A pedunculated growth is cut away by sharp-edged forceps. If a mass projects into the bladder, an incision is made to divide it into two portions and each half is enucleated. Hemorrhage is arrested by irrigation with hot salt solution and by compression with gauze pads. In some cases a tampon must be inserted. The bladder is drained for several days or a number of days. As

a matter of fact, a dense fibrous prostate cannot be enucleated and can be removed by scissors or cutting forceps only.

Fuller's Operation.—Open the bladder above the pubes; have an assistant push the gland up by means of a fist in the perineum. The gland can be lifted by two fingers in the rectum. The surgeon makes a small incision through the mucous membrane over the prostate, enucleates the gland by means of the finger, and drains through an incision in the membranous urethra, as well as through the suprapubic opening.

Belfield's Operation.—Belfield performs suprapubic cystotomy, makes a perineal cut to enable the finger to approach the prostate, pushes the prostate up toward the belly, and enucleates it from within the bladder.

Perineal prostatectomy is less bloody than suprapubic prostatectomy. The sphincter of the bladder is not damaged, the entire prostate can be brought into view and removed, and perfect drainage is obtainable after operation.

Nicoll's Operation.—Perform suprapubic cystotomy. Then incise the perineum down to the prostate, split the capsule of the prostate, insert two fingers of the left hand into the bladder, and push the prostate into the perineum so as to bring it within reach. Enucleate the gland from the perineal wound without damaging the mucous membrane of the floor of the bladder.

Alexander's Operation.—Alexander makes a suprapubic incision and uses it for the same purpose as does Nicoll, but he also opens the membranous urethra on a grooved staff. After enucleating the gland he inserts a drainage-tube through the incision in the membranous urethra.

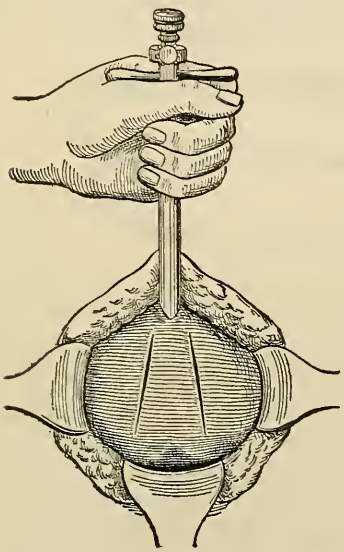

FIG. 1015.—Tractor introduced; blades separated; traction made, exposing posterior surface of prostate. Incisions in capsule on each side of ejaculatory ducts (Young).

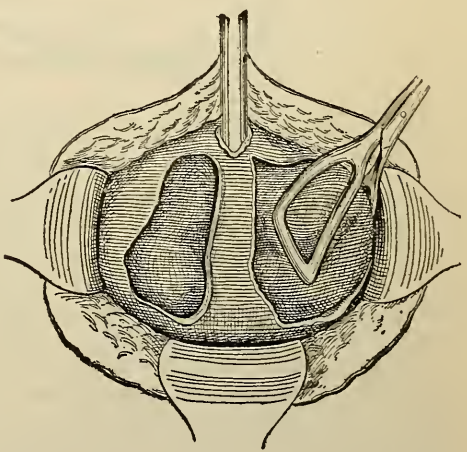

FIG. 1016.—Enucleation of lobes. Forceps in position (Young).

In a very thin subject it may not be necessary to perform suprapubic cystotomy. Alexander has brought the gland into an accessible position in the perineal wound by suprapubic pressure, and Guitéras has done so by making an incision in the linea alba and inserting two fingers into the prevesical space. Syms advocates opening into the peritoneal cavity, inserting the hand, and pressing the prostate into the perineum without opening the bladder above the pubes.

Bryson's Operation.—This is a satisfactory method in some cases. The bladder is irrigated and filled with warm salt solution. A grooved staff is introduced and a median perineal section is made to open the urethra just in front

of the apex of the prostate gland. The knife is pushed back in the groove of the staff sufficiently far to incise the ring at the apex of the prostate; the forefinger is passed into the prostatic urethra and the staff is withdrawn. Then a short tear is made by means of a blunt instrument into the mass of the left lobe and the finger is introduced and enucleates the lobe. The same procedure is carried out on the right lobe, and, finally, if necessary, on the middle lobe. If the middle lobe requires removal, but cannot be reached, a suprapubic cut is made into the cave of Retzius, two fingers are inserted, and the lobe is pushed within reach of the finger below. A large perineal tube is introduced for drainage, a catheter is introduced and tied in place, and bleeding is arrested by packing.

Young's Operation.—This surgeon frequently operates under spinal anesthesia. He places the patient in an exaggerated lithotomy position and introduces a sound. In thin subjects the incision is in the raphé and is carried close to the anus; in short individuals the incision is an inverted V. He incises the recto-urethralis muscle transversely, exposes the membranous urethra, opens it, and inserts his tractor into the opening in the urethra (Fig. 1015).

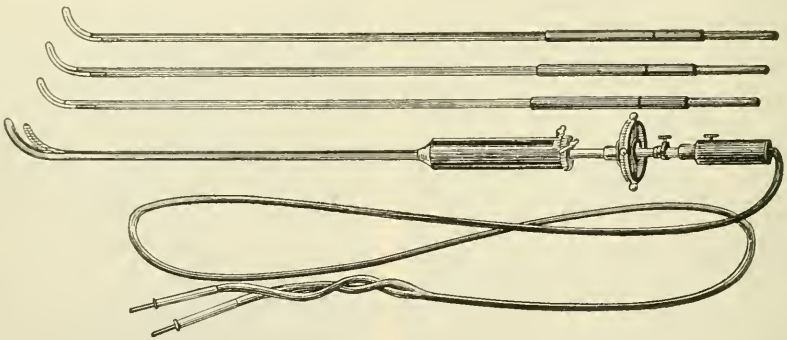

Fig. 1017.—Young's modification of Freudenberg's instrument for prostatotomy by galvanocautery.

The tractor is turned 180 degrees, the blades are opened, and traction is made. The capsule is incised on each side of the ejaculatory ducts and the gland is removed by blunt dissection, the forceps grasping each lobe during enucleation (Fig. 1016). Every effort is made to save the urethra. After removing the lateral lobes the tractor is used to bring a middle lobe, if one exists, into the wound, and it is also enucleated. The bladder is drained for about one week.

Young's punch operation was devised for the removal of small prostatic bars and contractures of the vesical neck involving the prostate. Young reports 200 cases with no mortality. It can be done under local urethral anesthesia; 4 per cent. novocain is employed. The operation is performed by means of a special prostatic punch devised by Young. By means of the punch a portion of the offending bar is removed.

Bottini's Galvanocaustic Prostatotomy.—Bottini, of Padula, in 1874 suggested cauterizing the prostate by means of a special instrument. He sought to burn away a portion of the gland in hope that the contraction of the scar would cause the remainder of the gland to shrink. The instrument of Bottini is shaped like a catheter, and carries a platinum blade which is heated by an electric current. Bottini's early instrument was not satisfactory and the operation never became popular until Freudenberg improved the tools in 1897 (Fig. 1017).

Bottini's galvanocaustic operation is performed as follows: The bladder should be emptied, irrigated, and distended with air, and the posterior urethra must be anesthetized by instillation of cocain or eucain. The current is tried

to see how many seconds it requires to heat the blade sufficiently. The current is broken, the instrument is introduced, the cooling current is set in motion, and one assistant watches this and nothing else. The current is turned on and the surgeon waits the required number of seconds for the blade to become

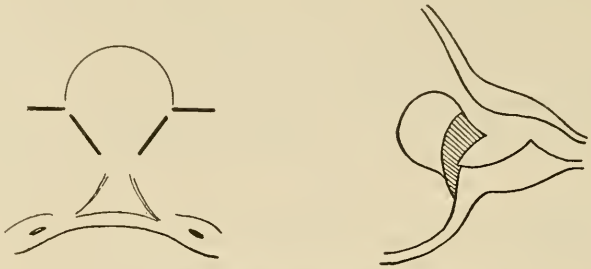

FIG. 1018.—Incisions of the middle lobe (Young).

red hot (twelve to fifteen seconds), and then turns the screw at the handle, and burns a groove in the prostate. A groove should be burned toward the rectum, one to one side, and, if it is thought desirable, one to the opposite side. No groove should be burned toward the pubes. When a groove has been burned,

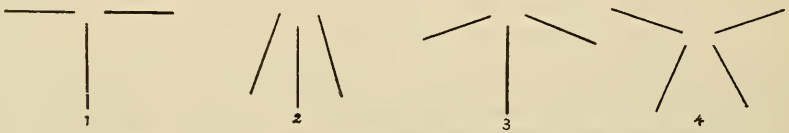

FIG. 1019.—Different incisions of prostate gland in Bottini's operation (after Young).

the blade is returned into its sheath, the current being increased while doing so in order to keep the blade from adhering to the tissue, then the current is shut off. After withdrawing the instrument it is not necessary to introduce and retain a catheter. The patient is confined to bed twenty-four hours only, there is rarely bleeding or fever, and the results are fairly good. The scars contract and the gland atrophies. During the period of healing a steel sound should be passed from time to time (Bangs). It is alleged that fibrous stricture of the neck of the bladder may follow in some cases.[1]

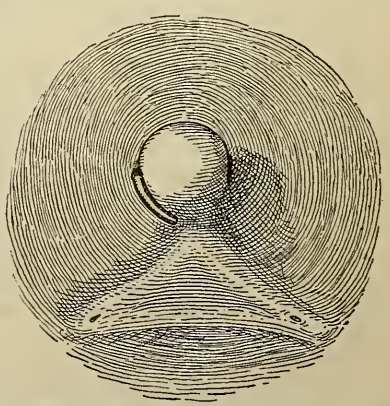

FIG. 1020.—Incising the middle lobe (Young).

Bottini's operation is the procedure to be selected for a sclerotic prostate and for hypertrophy in a feeble and aged individual with damaged kidneys. It is not probable that the cautery operation will ever replace prostatectomy. The best instrument is Young's modification of Freudenberg's instrument (Fig. 1017). Figures 1018 and 1019 show various methods of making the cuts as advised by Hugh H. Young. When there is a distinct and pedunculated median lobe the ordinary plan of burning fails entirely; but, as Young shows (Figs. 1018, 1020), if an oblique cut be made on each side across the base, this lobe

[1] For description of this operation see Freudenberg, in "Berliner klin. Woch.," No. 46, 1897; and Willy Meyer, in "Med. Record" of March 5, 1898, and May 12, 1900.

will drop out of the way and quickly atrophy. Bottini's operation does not gain in public confidence.

Castration and Vasectomy.—In 1886 Sanitzin demonstrated clinically the shrinking of a large prostate after double castration (Hawley, in "Annals of Surgery," Nov., 1903). In 1893 Ramm, of Norway, performed double castration in order to cause shrinking of an enlarged prostate. In 1893, after a long series of careful experiments, J. William White recommended the operation of bilateral orchidectomy for the treatment of prostatic hypertrophy. He proved that removal of the testicles causes a rapid shrinking in an enlarged prostate. Much of this shrinking may be due to diminution of congestion and edema, but true atrophy undoubtedly occurs in the glandular elements. Very remarkable results have been recorded. In some cases the patients become absolutely comfortable and dispense entirely with the catheter. Cystitis ceases, and desire to urinate frequently becomes less marked. Unilateral orchidectomy has been employed, but it is not satisfactory. In 1894 Mears suggested ligation of the spermatic cord. In 1895 Lauenstein suggested division of the spermatic cord. In 1896 Tilden Brown suggested ligation of the vas. Reginald Harrison in 1896 advised section of the vas. Lennander in 1897 proposed exsection of the vas deferens (*vasectomy*). It is slower in its results, but just as certain as castration. In spite of the great simplicity of orchidectomy the mortality has been considerable (from 11 to 18 per cent., according to some authors. Socin and Burckhardt say 16.2 per cent.). In several instances mental disturbance has followed the operation. Castration is now very seldom performed, as vasectomy is just as useful and is safer. Vasectomy is valueless in cases of fibroid prostate, does some good in adenoma, but is most valuable when the prostate is generally hypertrophied and prone to great congestion, causing violent symptoms. The testicle does not atrophy after vasectomy, mental disturbance does not occur because the internal secretion of the testicle is still furnished to the organism, and impotence may not develop, though sterility must.

Other Methods.—Among other operations which have been suggested are: ligation of the vascular elements of the cord; resection of all the cord elements except the vas and its artery and vein (*angioneurectomy*, proposed by Albarran in 1897); parenchymatous injections of cocain into the testicles; and ligation of both internal iliac arteries. Angioneurectomy has a mortality or 5.5 per cent. (Socin and Burckhardt).

Selection of Operation and Results.—The relative merits of these various operations alluded to above are in dispute. It is certain that many cases of prostatic hypertrophy can be kept comfortable by aseptic catheterism. If this procedure fails, or for other reasons must be abandoned, or if the surgeon decides not to employ it, a careful study of the case should be made before selecting a special operation. The Bottini operation for a time had somewhat extensive use. Some applied it to almost any sort of case, claiming that the operation is practically free from danger. Meyer used it for any case of uncomplicated hypertrophy, but if the prostate was very large, ligated the vasa deferentia some weeks before cauterizing the prostate, in order to lessen the danger of thromboses.

A more conservative view is that of Eugene Fuller, who doubts the permanence of the results of the Bottini operation, fears that stenosis of the vesical neck may follow, and would restrict the operation to uncomplicated cases not of a grave character, and in which the bladder has not been seriously damaged. It is the operation of choice if the prostate be fibrous. It is the preferable operation if the patient be old, debilitated, or the victim of kidney disease. Some residual urine usually remains after a Bottini operation. In over 10 per cent. of cases no benefit follows. Vasectomy is used for an engorged and generally enlarged prostate. It may do great good or may fail completely. If the

urine be extremely foul, some operation permitting drainage is advisable. In an adenomatous prostate in which enucleation is easy we should prefer the perineal method. In other cases in which it is probable enucleation will be hard; in cases of uncertain diagnosis; in cases in which a calculus may exist; and in cases in which the middle lobe is at fault, do a suprapubic operation, although sometimes a perineal incision may be made, and a cut be made in the prostate to bring the floor of the urethra level with the trigone.

In old men with great obstruction and with serious disease of the bladder and involvement of the kidneys, and in individuals with prostatic cancer, permanent suprapubic drainage is sometimes the most useful procedure.

The mortality from Bottini's operation is over 5 per cent. Young had 3 deaths in 41 operations.

Vasectomy done early gives a mortality of from 3 to 5 per cent. If performed later, the mortality is 10 to 15 per cent. Socin and Burckhardt estimate the mortality of bilateral vasectomy as 8.3 per cent. The mortality of bilateral orchidectomy is 16.2 per cent.

The mortality of perineal and suprapubic prostatectomy has been considered on page 1529.

Prostatic Fibrosis.—This condition was described by G. J. Guthrie in 1830. He called it a bar at the neck of the bladder. Enlargement of the middle lobe is not the bar, it is hypertrophy. Young calls prostatic fibrosis a median bar formation, Fuller speaks of it as contraction of the vesical neck, Barth designates it atrophy of the prostate, and Guyon names it *vesical prostatisme* (see the elaborate study by Alexander Randall, in the "N. Y. Med. Jour.," Dec. 4, and 11, 1915).

The entire prostate is in a state of fibrosis and the bar forms in the muscular tissue. It impairs the elasticity of the vesical neck which becomes unable to dilate and leads to the gathering of residual urine and the symptoms of prostatic enlargement. The lobes may be enlarged. It can occur in persons in the forties.

Treatment.—Some practise prostatectomy but the patient is still in the age of virility and the operation is difficult and dangerous. Some treat it by fulguration, some by applying the cautery through a perineal incision, some follow Young, and remove the bar by means of a punch (see page 1534).

Malignant Disease of the Prostate Gland.—Primary malignant growths of the prostate are not infrequently encountered, but secondary growths are much more rare than primary growths. When malignant disease does occur it is usually cancerous. Secondary cancer of the prostate finds its most usual antecedent in cancer of the rectum. Epithelioma does not occur. Scirrhus occasionally occurs; but the most frequent form is encephaloid. Carcinoma occurs during or after middle age. The symptoms are those of urinary obstruction. A hard, nodular mass is palpated through the rectum. Sarcoma is very rare, although probably not quite so rare as has been thought. Some cases of prostatic tumor obviously inoperable when first seen by the surgeon are probably sarcomatous. Round-celled, spindle-celled, or mixed-celled sarcoma may develop. Powers says there have been but 31 authenticated cases of primary sarcoma reported ("Annals of Surgery," Jan., 1908). According to Gibson ("Jour. Amer. Med. Assoc.," April 23 1910) there are on record 36 absolutely authenticated cases of sarcoma of the prostate. In 1912, Marcel Descums was able to collect 41 positive cases and Parmenter has recently reported a case. Sarcoma is most frequent in childhood, but may occur at any age. It grows rapidly, is usually soft, and causes difficulty of urination and defecation and pain in the rectum and perineum or pubic region, but early in the case, at least, there is seldom residual urine (Powers, Loc. cit.). In some cases the chief symptoms are rectal (alternations of diarrhea and constipation and abdominal pains) in some vesical (frequency of micturition, slowness in inaugurat-

ing the act, loss of projectile power and dribbling). A mass is detected by rectal palpation and is seen through a cystoscope. The mass may be soft, suggesting abscess, or densely hard. No real cure of carcinoma or sarcoma has yet been reported.

Carcinoma of the prostate my occur at an earlier age than ordinary hypertrophy of the prostate. The latter does not become evident until after the age of fifty; but carcinoma of the prostate may begin at any time after the age of forty, and sarcoma of the prostate may commence in early youth.

At first the carcinomatous growth enlarges slowly; but it soon begins to grow with rapidity. It breaks through the capsule and fungates into the bladder or into the urethra. The pelvic, the inguinal, and the femoral glands become involved early in the course of the disease. It is unusual to find great obstruction to urination or to the passage of a catheter at an early period, but later both these conditions are noted. Early in the case there is pain only when obstruction to urination occurs; later, the pain in the neck of the bladder may be severe, and there may also be pain in the loin and in the sciatic nerves. Hemorrhage usually occurs. In the beginning the hemorrhage is trivial and intermittent, but when fungation exists, large hemorrhages generally take place. The blood is usually mixed with urine, but there is sometimes a large hemorrhage unassociated with micturition. The urine is not likely to contain pus or any large quantity of mucus unless the bladder is involved in the growth.

When the prostate gland is felt by means of a finger in the patient's rectum, it is found to be of stony hardness and to be firmly anchored in place. Reginald Harrison points out that an ordinary hypertrophied gland is not so firmly anchored as a carcinomatous gland; that the bowel moves over it with freedom; and that, although it is firm to the touch, it is not of stony hardness. The patient with carcinoma of the prostate loses flesh rapidly and develops distinct cachexia, and metastatic deposits are likely to form in the vertebral column, in the kidneys, and in other organs and structures.

In making a diagnosis Harrison insists upon the value of the cystoscope. He says that in cancer one does not find much intravesical projection, and that what projection there is is uneven and irregular. In an ordinary adenomatous prostate, on the contrary, the surface is smooth and rounded and projects into the bladder.

Treatment.—Radical operation is out of the question in these cases. Permanent suprapubic drainage is made in most instances, and usually gives the patient great relief. (See "Remarks on Cancer of the Prostate," by Reginald Harrison, in "Brit. Med. Jour.," July 4, 1903.) Radium may be tried.

Tuberculosis of the prostate gland is rarely primary. It is usually secondary to tuberculosis of the kidney. It may follow tuberculosis of the epididymis. In the majority of cases of tuberculosis of the prostate the lungs are involved in a tuberculous process when the patient is first seen by the surgeon. The disease appears particularly between the ages of twenty and thirty years, but it may attack elderly men and even the aged. It begins by the formation of a number of tuberculous nodules in the immediate neighborhood of the prostatic tubules. These nodules caseate and run together, forming cavities and, eventually, tuberculous abscesses, which are prone to rupture into the urethra. In very rare instances a large tuberculous abscess ruptures through the perineum, into the rectum or into the peritoneum.

The disease occasionally undergoes spontaneous cure through fibrous tissue formation or calcification. The tuberculous process is liable to spread to the seminal vesicles, the bladder, the ureters, and possibly to the peritoneum; and in some cases it inaugurates thrombophlebitis and pyemia.

Symptoms.—The patient suffers from pain during micturition; there is frequent micturition, and from time to time the urine contains blood. Attacks

of cystitis take place, and weakness and loss of flesh are greater than is commensurate with any ordinary inflammation. Tuberculosis of the prostate alone is said not to cause marked hectic fever, but when adjacent structures become involved the temperature is definitely elevated and becomes characteristic. When the disease has advanced there is not unusually urinary incontinence, on account of the involvement of the circular muscular fibers about the neck of the bladder. Commonly, there is a mucopurulent discharge, or mucopurulent matter may be obtained by massaging the prostate. This matter may contain tubercle bacilli, and in some cases the urine also contains bacilli. Early in the course of the case rectal examination detects some enlargement of the gland, many nodules, and tenderness; later in the disease it finds marked enlargement and areas of softening.

Treatment.—Early in the case Senn recommends parenchymatous injections of iodoform emulsion, the punctures being made through the perineum. If these fail, operation must be considered. When one takes into account how rare primary tuberculosis of the prostate is, one is impressed with the infrequency with which a radical operation should be attempted. If there is absolutely no evidence that any adjacent organ is involved or that any distant focus of disease exists, it is justifiable to perform perineal prostatectomy. As a rule, however, the only surgical operation performed consists in making, in front of the rectum, a curvilinear incision which exposes the prostate, and permits the surgeon to open and curet caseous foci. If an abscess forms, it should be evacuated by means of a perineal incision and cavities should be curetted and packed with iodoform gauze.

When a patient is convalescent after an operation or if it is determined that no operation is advisable, full antituberculous treatment is employed (see page 255). One should look to the patient's general health, administer urotropin, and avoid using instruments as much as possible; because, as Sir Henry Thompson has shown, instrumentation irritates the prostate, causes a great deal of pain, and makes the disease worse in every case.

Retained and Malplaced Testicle.—The cause of non-descent is unknown. Certain it is that the vaginal process is not a factor in descent. Some think the condition is a reversion to type. Buedinger thinks the gland is restrained by adhesions the result of fetal peritonitis. It has been asserted that a short mesorchium is responsible. Eisendrath ("Annals of Surgery," 1916, lxiv) thinks that the contributing factors are deficiency in the arching fibers of the internal oblique and a weakness of the conjoined tendon which allow of retraction by the cremaster. The normally descended testicle is entirely within the scrotum. In 1 person of 100 there is either undescended or ectopic testis. In 80 per cent. of individuals the testicles have descended at birth; most often it is the right testicle which fails to descend. Sometimes a testicle descends after being retained for months or even years. In Keyes's case it descended in the thirtieth year. Late descent usually causes hernia, and in over 90 per cent. of all cases hernia exists. In not a few cases of non-descent there is hypopituitarism. The testicle may be arrested in its passage to the scrotum (*cryptorchism*, single or double); it may remain in the lumbar region; it may reach the internal abdominal ring; it may lodge in the inguinal canal; it may emerge from the external ring, but fail to enter the scrotum; or it may pass into an unnatural position, as into the perineum or the crural canal (*ectopia of the testis*). The failure of descent may be unilateral or bilateral, but when bilateral the degree of descent is seldom the same on the two sides. The gland may be, but seldom is, functionally active. When retained in the abdomen it never has the power of spermatogenesis. Before puberty the testicle is usually normal, but after puberty there is practically always more or less atrophy. In about 1 case out of 5 there is spermatogenesis for a time. A retained testicle is liable to attacks of orchitis amd may become tuberculous, carcinomatous, endotheliomatous, or

sarcomatous. Coley ("Annals of Surgery," 1915, lxii) reports that among 59,235 cases of inguinal hernia admitted to the N. Y. Hospital for Ruptured and Crippled there were found 737 cases of sarcoma of undescended testicle. In some cases mixed tumors form (sarcocarcinomata). See case of Butt and Arkin ("Jour. Alumni Assoc. Coll. Phys. and Surgeons," 1915, xvii). If both testicles are retained one or both may become the seat of neoplastic formation. In some cases of retention torsion of the cord occurs. In most cases there is neither pain nor tenderness, and the patient presents himself for treatment because a lump has appeared in the groin. In some cases there are sudden attacks of violent pain, accompanied by nausea (Rawling, on "Incompletely Descended Testicle," in "Practitioner," August, 1908). A testicle in the inguinal or crural canal or in the perineum is far more apt to become sarcomatous than one retained within the abdomen. Over 10 per cent. of cases of sarcoma of the testicle are in undescended glands. Russell Howard ("Practitioner," Dec., 1907), out of 57 cases of undescended testicle, found 15.7 per cent. with malignant disease. In double cryptorchism, in which the testicular function has been abolished, there is delayed union of the bony epiphyses and epiphyseal fractures are common, and there may be excessive growth of long bones. The same liability is noted in those subjected to castration in infancy. When such a subject reaches manhood, he may develop some disease of the skeleton which is usually seen in children only (Gross and Sencert, "Rev. de Chir.," No. 11, 1905). In operating on these cases we usually find a well-developed gubernaculum and a vaginal tunic extending below the testicle.

Treatment.—If one testicle is undescended at or after the eighth year of life and before puberty, if it lies in the canal, and if the other testicle is sound, the former should be removed if it is found impossible to draw the gland into the scrotum. Both testicles should not be removed from a child: one should be placed within the abdomen. I would save one testicle in order to have the child certainly enter and remain in the masculine groove. Removal of both testicles is permissible in an adult, because he has definitely become and will remain masculine, and undescended or ectopic testicles, in an adult are or will surely become functionally useless and menaces. If a testicle is retained in the abdomen it should not be operated upon unless it causes trouble. Always try to get a retained gland into the scrotum before the age of puberty. If it is retained after puberty, it will be almost certain to remain so or become functionally useless. An ectopic testicle should be restored to the scrotum if possible; if not, it should be removed. Even when operation is performed to replace the testicle, success is seldom enduring. In Rawling's 29 cases only 4 were permanently successful. Other operators, however, claim better results. For instance, Broca reports 79 cases traced from one to six years, and in 31 of them the result was perfect and permanent. The method I employ is that advocated by Coley, viz., Bassini's incision through the aponeurosis, separation of the cord from the peritoneum (it is usually in the posterior sac wall); removal of the vaginal process, the cremaster and fibrous adhesions around the cord; the making of a scrotal pouch by the fingers, closure of the canal as in hernia; suturing of the cord to the pillars of the external ring, as advocated by Dowd. This is practically Broca's method. Bevan operates for a testicle within the canal by separating and dividing the vaginal process, removing all the coverings of the cord, and leaving the testicle suspended by the vas and spermatic vessels only. This proceeding gives the testicle a very wide range of mobility. A pocket is made in the scrotum by means of the finger, the testicle is placed in the pocket, and remains there without suturing. The canal is now sutured as in a Bassini operation without cord transplantation. There is a certain though small risk of gangrene of the testicle after Bevan's operation. I believe Bevan's method should be employed in the more severe cases. If there is no hernia, operation should not be performed until between the eighth and twelfth years of life.

If an atrophied testicle can be moved into the scrotum it might be proper to take a text from a remarkable case reported by Robert T. Morris ("Jour. Am. Med. Assoc.," Sept. 2, 1916). A boy of 13 lost both testicles as a result of mumps. The scrotum seemed empty. A wedge-shaped graft was secured from the testicle of a hernia patient who was free from syphilis and tuberculosis. One piece of the graft was inserted under the sheath of the right, another under the sheath of the left rectus muscle of the abdomen. The remainder of the graft was placed in the scrotum. As the graft placed in the right scrotum began to disappear the vestige of testicle began to enlarge. About a year later another graft was inserted into the right scrotum. It was then seen that the testicle appeared normal and was about one-third natural size. Evidently the graft stimulated the vestige to development. Lespinasse reports the case of a man who lost both testicles and the power of erection. A graft from the testicle of a live man restored the power of erection ("Jour. Med. Assoc.," 1913, lxi). This is a new principle which might be utilized when a functionless undescended testicle is drawn into the scrotum.

Orchitis is inflammation of the testicle. *Acute orchitis* may follow cold, wet, traumatism or epididymitis, and may follow or develop during gout, mumps, rheumatism, or a specific fever. Mumps seldom attacks the testicle before puberty. Orchitis before puberty may be due to tuberculosis or to cord torsion. The testicle is round, swollen, tender, and very painful, the scrotum is red and swollen, the tunica vaginalis is filled with fluid, and there is fever. *Chronic orchitis* results from the acute form or from a chronic urethral inflammation, and is almost always combined with epididymitis. *Gonorrheal orchitis* is rare and almost certainly results in sloughing of the testicle.

The treatment of the *acute* form consists in rest in bed and applications as for epididymitis (see page 1545). The *chronic* form requires the removal of the causative lesion, if possible, the wearing of a suspensory bandage, applications of ichthyol or mercurial ointment, and the administration of iodid of potassium by the mouth. Strapping with zinc oxid adhesive plaster may do good. Castration may be required.

Tuberculosis of the testicle may perhaps be primary, but in the vast majority of cases is secondary to tuberculosis of the kidney, prostate, bladder, or seminal vesicles. As Keyes ("Annals of Surgery," June, 1907) says, careful examination will show one of three conditions—tubercle bacilli in urine, indurations in the prostate, and vesicles or "a distinct haze in the urine due to prostatic catarrh." Tuberculosis of the prostate or vesicles exists in probably one-half the cases (Barney, in "Boston Med. and Surg. Jour.," March 14, 1912). In about one-third of the cases there is evidence of tuberculosis distant from the genito-urinary organs (especially in the lungs or bones). Patients with tuberculosis of the testicle are nearly always sterile. The disease may be preceded by pulmonary tuberculosis, lymphatic tuberculosis, peritoneal tuberculosis, anal fistula, renal tuberculosis, or tuberculous disease of bones or joints; and primary tuberculosis of the testicle may be followed by near or distant tuberculous lesions. In some cases involvement of the prostate exists, but cannot be detected (*latent tuberculosis of the prostate*); in other cases the prostate is in a state of subacute inflammation. The epididymis is usually involved before the testicle and early chronic lesions are localized there for some time. In most cases the bacilli reach the prostate and vesicles by way of the blood, and reach the epididymis by way of the vas deferens, the lesions of the prostate and vesicles developing first or remaining latent. In some cases tuberculosis of the kidney or bladder is followed by tuberculosis of the testicle. The spead from the prostate, vas, or bladder is by epithelial infection. There is no evidence confirmatory of the idea of ascending infection from the urethra. In a child with an open vaginal process, tuberculous peritonitis may directly cause tuberculous epididymitis. The disease begins in one testicle, but in the vast majority of cases the other

testicle becomes involved after a few weeks or months. If the other testicle remains free for three years its chance of remaining free is good. If but one epididymis is involved the testicle may not be affected for weeks or months. Von Bruns says that in 18 per cent. of such cases the testicle is not involved for six months; in 40 per cent. for over two months ("Archiv. f. klin. Chir.," Bd. 63, H. 4). It usually comes on gradually, but it may begin acutely, as I have seen in two instances during the progress of tuberculous peritonitis. An acute onset or an acute exacerbation of a chronic case usually means mixed infection. The disease may follow a slight injury or inflammation, and is most common in young men, but may arise at any age. The causal influence of antecedent or existing gonorrhea is doubtful. Some maintain that sexual excess predisposes. There is often a family history of tuberculosis. A chronic case begins by swelling of the epididymis. Palpation detects one or two or several rounded nodules, or a diffuse hardening. In the latter case the epididymis is much enlarged, and there is usually a slight hydrocele. Rectal examination

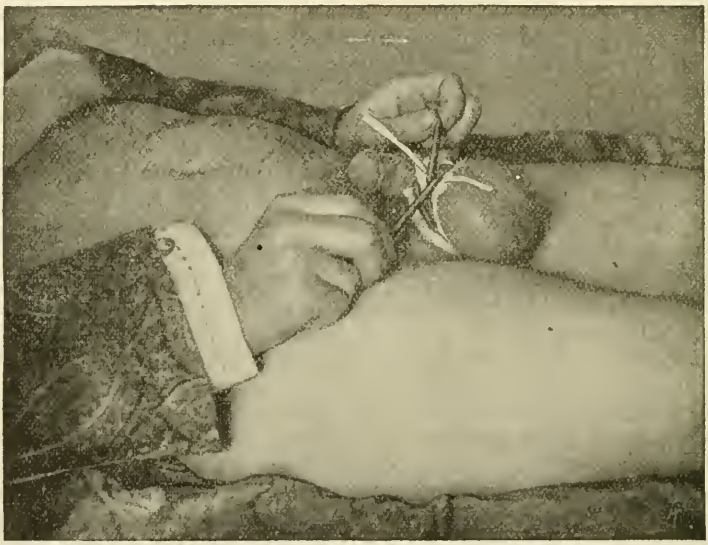

FIG. 1021.—Obstructive hyperemia for the testicles. The ends of the elastic tube are held by the patient, crossed. A piece of tape is placed beneath to be tied by an attendant (Meyer and Schmieden).

commonly detects nodules in the prostate and vesicles. In a few cases there are frequency of micturition, tenesmus, hematuria, and seropurulent fluid can be massaged from the vesicles and prostate and milked from the urethra. In some cases bacilli are found in the urine. In others the urine is hazy. In about 80 per cent. of cases the guinea-pig test will prove the presence of bacilli. In some cases the urine is normal. Sooner or later nodules appear in the testicle. The vas is always swollen and may or may not be palpable. In an acute case one testicle is involved. The testicle is very painful and the epididymis is greatly swollen and smooth. The testicle quickly swells, there is always a hydrocele, and the scrotal skin becomes reddened. In a few days the acuteness of the symptoms subsides, but suppuration occurs soon. In any case of tuberculosis of the testicle nodules tend to soften and run together. After a time the skin may become red and adherent, give way, and expose a caseous breaking-down epididymis or testicle. Caseation can occur without mixed infection, but in many cases in which softening and sinus formation occur there is mixed infection. The duration of the disease is uncertain; 10 per cent. of the 100 cases

carefully studied by Keyes were known to be alive ten years after the beginning of the trouble, and 4 (and not one of them had been operated upon) seemed free from tuberculous lesions anywhere. One-third of the cases that suppurated were apparently well after three years ("Annals of Surgery," June, 1907). Except in the acute cases the testicle is only slightly, if at all, painful, and tenderness is trivial. In one-sixth of the cases a small hydrocele forms. If a hydrocele exists the fluid should be withdrawn by tapping in order that cultures may be made from it.

Treatment.—Before attempting any operation try Bier's method. The patient is placed recumbent, the diseased testicle is lifted upward, cotton batting is placed around the neck of the scrotum, and a rubber drainage-tube of a caliber of 25 of the French scale is wound twice around and fastened with a string or clamp. If both testicles are diseased, both are held up and the neck of the scrotum is embraced by the tube with the required firmness (see Fig. 1021). The treatment is applied for two or three hours a day or longer. The patient had best be recumbent during the application. In the intervals he wears a suspensory and gets about. During the use of Bier's method full antituberculous treatment is required (see page 255). If a cold abscess forms, open it and dress the part antiseptically. Durante injects iodin into the body of the epididymis once a month. If Bier's treatment fails, consider the advisability of operation. An acute case requires unilateral castration. If, in a chronic case the disease is limited to the epididymis or to the epididymis and vas, resect the epididymis (*epididymectomy*) and the vas deferens. If the testicle is diseased, *orchidectomy* is performed. It was long believed that orchidectomy was useless if the vesicles and prostate were involved, but Koenig and others maintain that vesicular and prostatic tuberculosis improves after removing the diseased testicle or epididymis. If the epididymis of each testicle is involved, bilateral epididymectomy should be performed. When both testicles are diseased and other organs and structures are not extensively involved, bilateral orchidectomy is performed or, better, the testicle which is most diseased is removed and the *diseased portion* of the other is extirpated. Cumston points out that when the testicle is diseased the disease may not be detectable even on operative exposure. Hence in doing epididymectomy he splits open the testicle to see if it be diseased. If it be not diseased he sutures it with catgut and removes the epididymis. If it be diseased he considers the advisability of unilateral orchidectomy (Charles Greene Cumston, in "Annals of Surgery," June, 1909).

In many cases after epididymectomy sinuses form. They may remain open for months. In association with and after operation employ antituberculous remedies, order a nourishing diet, send the patient to a good climate, and insist on an open-air life. Tuberculin may prove useful. A considerable percentage of unilateral cases are cured by operation (over 40 per cent.). Some few bilateral cases are cured.

Cysts and Tumors of the Testicle.—Innocent tumors are very rare; in fact, some dispute their existence. The elements of a testicular growth are very complex. A majority of growths is unquestionably malignant. Some are wholly malignant. Many show a mingling of benign and malignant elements. An undescended testicle is liable to malignant growth. Even growths which are not malignant in the beginning have an irresistible tendency to become so. It is believed by many surgeons that fibroma and adenoma can arise and perhaps remain for some time benign. Embryomata are at first benign, but tend, perhaps after years, to become malignant.

Embryomata.—H. Morriston Davies ("Lancet," Feb. 17, 1912) considers embryomata to be "composite tumors containing elements derived from epiblast, mesoblast, and hypoblast." They are "developed in the body of the testicle" and not in the epididymis, though that structure may eventually be

involved. Early in their development these growths are benign, but any or all the layers may become malignant (Nicholson, in "Guy's Hospital Reports," vol. lxi, 1907).

When two or more layers become "malignant" a mixed tumor is the result; when hypoblast alone, the tumor assumes the character of a columnar-celled carcinoma; when mesoblast alone, of a sarcoma or myxosarcoma" (Davies, Loc. cit.). When a dermoid-like growth from the epiblast becomes malignant it resembles chorionepithelioma and, if such a growth arises, the mammary glands may enlarge. Nicholson (Loc. cit.) divides embryomata into solid embryomata (which often contain cysts and are common) and cystic embryomata or dermoids (which are very rare.) Many surgeons regard sarcoma, others carcinoma, as the commonest form of malignant disease. Endothelioma may occur.

Malignant Disease of the Testicle.—It may arise from an embryoma or may be malignant from the start. If a tumor which has long existed, perhaps years, begins to grow rapidly, we may assume that there is malignant change in an embryoma. It is seldom possible to diagnosticate the form of a malignant tumor. Sarcoma may occur at any age, but the period of greatest liability is from twenty to forty. Sarcoma is usually of the small round-celled variety (the type known as lymphosarcoma), but the spindle-celled growth is sometimes seen. It begins in the mediastinum of the gland. The other testicle soon becomes involved in malignancy. The growths disseminate rapidly. In 10 per cent. of cases the testicle is undescended. Any sarcoma is liable to sudden increase in size because of hemorrhage.

Nicholson ("Guy's Hospital Reports," vol. lxi, 1907) divides carcinomata into encephaloid (which is commonest) and scirrhus (which is rare), and regards so-called columnar carcinomata as teratomata. Carcinoma is rare before the age of forty. Davies ("Lancet," Feb. 17, 1912) admirably sums up the clinical picture of malignant disease of the testicle. I have utilized his article extensively below. The tumor may attain a great size (that of a cocoanut). It is usually oval, but may exhibit a few rounded projections "due to the presence of degeneration in the tumor or of fluid in the tunica vaginalis." Early in the development the growth is smooth (except for the projections mentioned); later it breaks through the tunica albuginea and so later has an irregular surface. The epididymis is at first free, but sooner or later becomes part of the tumor. The consistence of malignant tumors is very variable (may be hard, elastic, soft, or fluctuating), and the consistence of a tumor may vary in different parts. In most cases there is an associated hydrocele, in which the fluid may be limited or may be distributed throughout the entire sac. The hydrocele may be translucent, the tumor never is. Pain is seldom severe and tenderness seldom acute in the testicle. I have seen terrible agony when the lumbar glands have been involved. The tumor when raised on the hand feels very heavy. The cord becomes enlarged because of involvement.

The growth finally adheres to the scrotum, and the skin reddens and gives way and fungation occurs. When this happens there is severe pain. Sarcoma of the testicle, unlike sarcoma in most other regions, causes early glandular involvement. The glands along the renal veins are especially liable to invasion. Carcinoma, of course, involves glands. The inguinal glands are not involved unless the scrotum be attacked. The lumbar glands receive the testicular lymphatics. Secondary growths are early and widespread and are common in the skin.

Malignant growth of an undescended testicle causes acute pain in the iliac fossa and later a mass can be felt. Such symptoms, in one whose testicle of that side is not in the scrotum, at once suggest the cause.

H. M. Davies emphasizes the great fatality of malignant disease of the testicle; quotes Chevassu's collection of 100 cases treated by castration, of which 81

died of malignant disease and only 19 were cured, and insists that "early diagnosis and the removal of the testicle and surrounding fascia and the glands in the lumbar region offer the only hope of decreasing so appalling a mortality" ("Lancet," Feb. 17, 1912).

Orchidectomy, or Castration (*Excision of a Testicle*).—Bilateral castration should never be performed without deliberate consideration. It often produces grave mental disorder. This is in part the result of the mental depression attendant on knowing that the highly prized glands are gone for ever, and in part the loss to the organism of the internal secretion of the testicles. A boy castrated before puberty never becomes potent. A man may retain potency for a considerable time after castration. I removed a tuberculous kidney from a man who had been castrated by my colleague, Dr. Horwitz, two years before, and he was still able to have intercourse. Unilateral orchidectomy does not make a man either sterile or impotent and does not produce mental disturbance. In orchidectomy for benign disease an incision is made over the cord, commencing just outside the external ring and runing down over the base of the tumor. Clamp the cord and divide it near the ring, remove the testicle, ligate the spermatic artery alone, and then ligate the entire thickness of the cord. The cord is ligated with chromic gut. The skin is sutured with silkworm-gut. Drainage is not required. It is often advisable to remove a considerable amount of scrotal skin. Orchidectomy for malignant disease must be a much more radical procedure. After the cord has been divided and the testicle removed, as in the ordinary operation, the incision is prolonged along and through the roof of the inguinal canal, and is continued in the same direction to a point a little above the anterior superior spine of the ilium. The incision is then curved and carried up to "the costal margin at the level of the tenth rib" (Davies, in "Lancet," Feb. 17, 1912). The peritoneum is exposed. The cord is traced well into the true pelvis, is tied, and divided. The fascia over the iliacus and psoas muscles is dissected, "together with the contained spermatic vessels and lymphatics," and the glands upon "the inferior vena cava and aorta" are removed (Davies, Ibid.). This operation was first performed by Grégoire in 1905. Davies did the thirteenth operation on record (Ibid.).

Epididymitis, or *inflammation of the epididymis,* is usually due to inflammation of the urethra. It is apt to occur in the stage of decline of a gonorrhea, and in such a case is announced by a notable diminution or a complete cessation of discharge. It may result from the passage of a urethral instrument, the voiding of urine which contains fragments of calculi, or as a complication of prostatic hypertrophy. *Acute epididymitis* is characterized by swelling of the epididymis, severe pain in the groin, and tenderness over the posterior part of the testicle. The pain becomes acute, swelling rapidly increases, and the constitution sympathizes. The swelling is due partly to engorgement of the epididymis and partly to fluid in the tunica vaginalis (*acute hydrocele*). *Chronic epididymitis* is usually linked with orchitis, and it follows an acute exacerbation of a chronic urethral inflammation.

Treatment by aseptic puncture with a tenotome, if fluctuation be marked, will relieve tension and pain. Hagner makes multiple punctures in the epididymis. Leeching over the external abdominal ring, the use of an ice-bag early in the case, elevation, application of guaiacol, and the administration of laxatives and opium constitute the usual treatment in the acute stage. Applications of guaiacol over the cord, epididymis, and testicle seem to relieve pain and distinctly lessen swelling. Two applications a day should be made for one week. At each application paint the scrotum and the skin over the external ring with 15 drops of guaiacol in 1 dram of glycerin or olive oil. Strapping is employed as the inflammation subsides. The treatment of the chronic form is the same as that for chronic orchitis.

Strangulation of the Cord by Axial Rotation.—In nearly one-half of the cases the testicle is undescended or only partly descended. In every case there is a long mesorchium, and if a normal testicle be normally placed torsion of the cord will hardly occur (Chas. L. Scudder, "Annals of Surgery," Aug., 1901). The twisting may be toward the right or toward the left. The symptoms arise suddenly, and usually during exertion. In some cases a hernia also exists. When the rotation occurs, the testicle swells, hemorrhages take place into it, and gangrene may develop. If the cord of an undescended or partially descended testicle twists, swelling and tenderness are noted in the abdomen or groin. If the swollen testicle is in the scrotum, the gland feels nodular and the epididymis is found to be anterior instead of posterior, as it is in a normally placed gland. The symptoms are sudden pain, vomiting, moderate shock and a swelling in the groin or a swollen testicle in the scrotum. The swelling receives no impulse on coughing. The symptoms resemble those of strangulated hernia, but are less violent, and the bowels, though often much constipated, are not obstructed.

FIG. 1022.—Hydrocele.

Treatment.—An incision should be made, and if the twisting has been recent and the testicle is not gangrenous, the cord may be untwisted and the testicle fastened to the scrotum by a catgut stitch. If the testicle is gangrenous it should, of course, be removed. Scudder tells us that in 88 per cent. of cases the testicle is found to be gangrenous. According to Scudder, there are 32 cases on record: 31 were operated upon and 1 was not, but all recovered; in 3 the testicle sloughed and in 2 it atrophied ("Annals of Surgery," Aug., 1901).

Vaginal hydrocele (*chronic hydrocele*) (Figs. 1022 and 1024, *e*) is a collection of fluid in the tunica vaginalis testis. An enlargement of the testis may cause it (*secondary hydrocele*), but in most instances the cause is unknown and no signs of inflammation exist (*primary hydrocele*). The fluid is albuminous, but it does not coagulate spontaneously; it is thin, straw colored, and may contain crystals of cholesterin. The testicle is at the lower and back part of the sac. The pyriform mass fluctuates, is translucent, grows from below upward, and the introduction of an exploring needle permits yellow fluid to flow out. Sometimes a hydrocele has an hour-glass shape. This is the *hydrocele "en bissac"* of the French. In this condition (Fig. 1023) two cavities exist,

usually but not invariably communicating. The constriction between the cavities is due to inflammatory thickening.

Treatment.—In secondary hydrocele the treatment of the diseased testicle is the essential plan. We discuss here the treatment of primary hydrocele. Simply tapping the sac with a trocar is only palliative; air must run in as fluid runs out, and suppuration may occur, which will be dangerous without drainage. Never tap a rigid sac. The injection of irritants should be abandoned, as it exposes the patient to serious danger because of inflammation occurring without provision for drainage. A good plan is to incise the sac, dry its interior by bits of gauze, swab it out with pure carbolic acid, pack it with iodoform gauze, and dress it antiseptically. The packing is removed in twenty-four hours and the wound is allowed to close. In most cases I prefer this method. If the sac is rigid and will not collapse, either stitch it to the skin and pack it or excise a large portion of its parietal layer and insert a drainage-tube (*Volkmann's operation*). Another plan is to tap the sac with a trocar and cannula, leaving the cannula in place as a drain for some days, and dressing antiseptically.

FIG. 1023.—Hydrocele "en bissac." This hydrocele extends up the cord into the inguinal canal and to the internal abdominal ring (Horwitz).

Longuet's operation is easy and is advocated by many surgeons. It is called *extraserous transposition of the testicle.* It was introduced by Longuet in 1898 ("Progrès Méd.," Sept. 21, 1901). Doyen and Winklemann do a similar operation. Jaboulay, too, advocates splitting the sac and turning it inside out. He folds it around both the testicle and cord and stitches it so that the

FIG. 1024.—Varieties of hydrocele: *a*, congenital; *b*, infantile; *c*, funicular; *d*, encysted; *e*, vaginal.

smooth endothelial surface of the tunic will be in contact with the raw scrotal tissue. It will adhere to the scrotal tissue ("Keen's Surgery," vol. iv). A local anesthetic is injected and an incision 2 inches in length is made. The testicle is lifted from the scrotum. The serous and all the other coats except the skin fall together behind and make a sheath for the cord. One catgut suture will hold them behind the cord. A bed is made for the testicle beneath

the inner edge of the skin wound by tearing with the fingers. The testicle is rotated on its long axis and inserted into this cavity. The testicle rests against the scrotal septum, and in front of the gland is the cord covered by the tunic. The skin is sutured and the wound is dressed. E. Wyllys Andrews devised *the bottle operation* ("Keen's Surgery," vol. iv). The unopened tunic (with the testicle) is separated from the scrotum and dislocated through the scrotal wound. A small incision is made near the summit of the funnel-like prolongation of the sac upon the cord. The sac empties and then resembles a bottle or bag with a small opening at the top. The testicle is squeezed through the opening. When this is done the sac is inside out and the edges of the small opening lie closely about the cord. The skin is closed without drainage. In some cases after doing any one of the operations which turn the sac inside out a large tender mass forms, composed of swollen testicle and thickened sac. I have had this experience several times. In such a case it is necessary to excise the thickened sac.

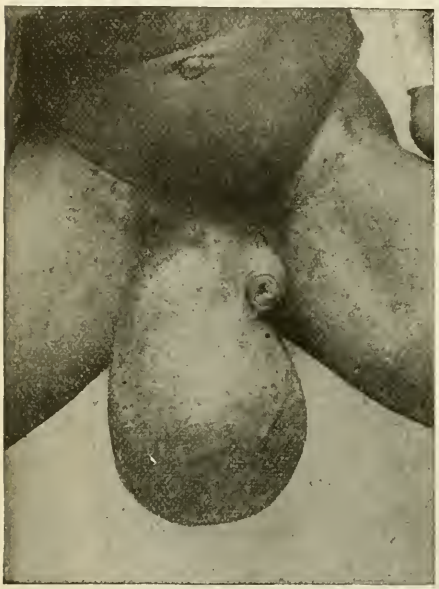

Fig. 1025.—Acute hematocele of tunica vaginalis the result of traumatism (Horwitz).

Congenital hydrocele (Fig. 1024, *a*) is hydrocele through an unclosed funicular process into the tunica vaginalis. If the pelvis be raised the fluid runs back into the peritoneal cavity, from which it originally came.

The **treatment** is the application of a truss to obliterate the funicular process, and when that occurs, if the counterpart of an infantile hydrocele persists, puncture and scarification of the walls of the sac.

Infantile hydrocele (Fig. 1024, *b*) is a collection of fluid in a funicular process of the tunica vaginalis, the funicular process being closed above, but not below.

The **treatment** is to puncture the sac and to scarify the sac wall with a needle.

Funicular Hydrocele (Fig. 1024, *c*).—The funicular process is closed below, but is open above. Raising the pelvis causes the fluid to trickle back into the peritoneal cavity.

The **treatment** is the application of a truss.

Encysted Hydrocele of the Cord (Fig. 1024, *d*).—In this variety the funicular process is obliterated above and below, but it is patent between these two points and fluid collects.

The **treatment** is the same as that for infantile hydrocele. If this fails, incise and pack.

Encysted hydrocele of the testicle and of the epididymis may occur. *Diffused hydrocele* of the cord is simply edema of the cord. *Hydrocele of a hernia* is the distention of a hernial sac by peritoneal fluid.

Hematocele (Fig. 1025).—*Vaginal hematocele* is blood in the tunica vaginalis, the result of traumatism, a tumor, or the tapping of a hydrocele. There is a pyriform swelling which fluctuates, but which gradually becomes firmer; the scrotum is livid and the testicle is below and posterior to the tumor. The *encysted* form of *hematocele of the cord* is a hydrocele of the cord into which bleeding has occurred. The *diffused* form is due to extravasation of blood into the cellular substance of the cord. *Encysted hematocele of the testicle* is due to effusion

of blood into an encysted hydrocele of the testicle. *Parenchymatous hematocele* is extravasation of blood into the substance of the testicle.

The **treatment** of a recent case of vaginal hematocele is to put the patient to bed, support the scrotum, and apply an ice-bag over the testicle. If the swelling does not soon abate, incise, irrigate, and pack.

Varicocele is varicose enlargement of the veins of the venous plexus of the spermatic cord. The veins are thickened, lengthened, dilated, and convoluted. The assigned causes are straining, cough, constipation, and an occupation requiring prolonged standing. Some believe ungratified sexual desire is a cause. Hereditary predisposition is probable. There are more left-sided than right-sided varicoceles, because the right spermatic vein has valves and empties into the vena cava at an acute angle, but the left spermatic vein has no valves and empties into the left renal vein at a right anlge. Varicocele is a very common condition. The elder Senn found it in 21 per cent. of 10,000 recruits. An irregular swelling exists in the scrotum and extends up the cord. This swelling feels like "a bag of earth-worms;" it exhibits a slight impulse on coughing; the scrotal skin and cremaster muscle are attenuated; the testicle lies at the bottom of the swelling and is softer and smaller than normal; the swelling diminishes on lying down and increases on standing or on making pressure over the external ring. The scrotum is pendulous and the scrotal skin frequently contains varicose veins. The testicle may be soft and shrunken. There is usually some discomfort, aching, or dragging in the testicle and the groin, and often neuralgic pain in the cord. There may be no discomfort of any sort. A large varicocele may be free from discomfort and a small varicocele may produce much annoyance, or vice versa. There are sometimes mental depression and hypochondriasis. As a man reaches middle age a varicocele usually ceases to give trouble.

Treatment.—In treating varicocele, reassure the patient: tell him there is no real danger of impotence; order cold shower-baths, correct constipation and indigestion, give occasional tonics, and order the patient to wear a suspensory bandage. If the testicle is undergoing atrophy, if the pain and the dragging are annoying, or if the mind is much depressed, operate.

Operation for Varicocele.—Subcutaneous ligation is no longer practised. The open operation is universally employed.

The patient is placed in a recumbent position. Local anesthesia is very satisfactory. A fold of skin is pinched up over the external ring, and the surgeon transfixes it in the line of the cord, so that he will have an incision about 1½ inches long. The skin and fascia are cut by a scalpel, the veins are well exposed, and the cord is located and held aside. A double ligature of strong catgut or chromicized gut is passed under the veins by an aneurysm needle. The threads are separated 1 inch, tied tightly, and the ends are left long. The veins between the ligatures are excised. The two gut ligatures are tied together and cut. This shortens the cord. The wound is sewed up with silkworm-gut.

Bloodgood points out that it is well to avoid dividing the genital branch of the genitocrural nerve which supplies the cremaster muscle. If this nerve should be divided, the cremaster will become lax and return of the varicocele will be favored. Bloodgood makes the incision over the external ring, draws the veins up, and resects them. A wound so placed heals more certainly and promptly than does a wound of the scrotum. Of late years I have always followed this plan.

XXXVIII. AMPUTATIONS

An amputation is the cutting off of a limb or a portion of a limb. Removal of a limb or a portion of a limb at a joint is known as "disarticulation." Amputation may be necessary because of the existence of severe injury, of gangrene, of tumor, of intractable disease of bones or joints, of ulcer which will not heal, of traumatic aneurysm, etc. A re-amputation may be required because of the existence of a defective stump or disease in the stump.

Classification.—Amputations are classified as follows: (1) As to time of operation after the injury: a *primary* amputation is performed soon after the occurrence of the accident—as soon as the sufferer reacts from shock, and before he develops fever; a *secondary* amputation is performed some time after the accident, suppuration having supervened; and an *intermediate* amputation is performed during the existence of fever, but before the development of suppuration. (2) As to the situation, where the bone is divided or according to which joint is cut through. (3) As to the form and situation of the flap.

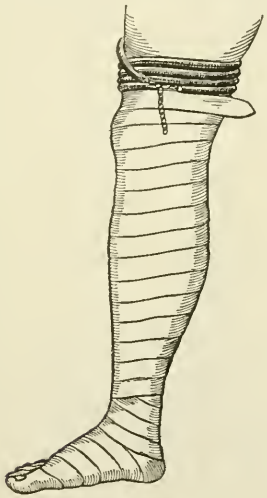

Fig. 1026.—Esmarch's elastic bandage.

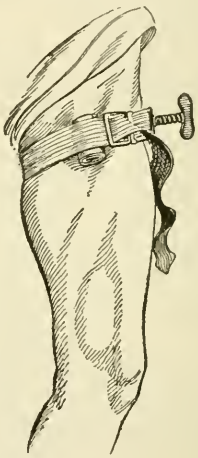

Fig. 1027.—Application of tourniquet.

In performing an amputation maintain rigid asepsis; completely remove the hopelessly damaged portion; sacrifice as little of the sound tissue as possible; prevent hemorrhage during the amputation, and carefully arrest it after the operation; if flaps be used, have enough sound tissue in the flap to *cover* the bone, and enough skin to *cover* the muscles; and secure drainage at a dependent point. In military surgery where gas gangrene is to be expected (shrapnel, condition of soil, etc.) the guillotine, "chop" or other flapless amputation may be used; in civil surgery, however, where gas gangrene is the exception rather than the rule, flaps should always be employed.

Hemorrhage may be prevented by the elastic bandage of Esmarch (Fig. 1026). Ordinarily we can apply this bandage from the periphery to well above the line of prospective incision, encircle the limb with an elastic band (not the thin tube shown in the cut), and remove the bandage. The bandage and band, asepticized before using, are applied to the limb, which has been carefully sterilized. After the band has been applied the limb should not be freely or forcibly moved, because of the danger of tearing muscles which are firmly fixed by the compressing band. When elastic compression has been used in an operation the surgeon, after removal of the band, should be very careful to tie *every visible vessel.* The paralysis of the small vessels induced by

pressure often prevents bleeding, and unless their mouths be found and the vessels be tied reactionary hemorrhage will occur. Reactionary hemorrhage is the great danger after the use of the Esmarch bandage, and paralysis or sloughing may also follow its employment. If there be an area of suppuration or of gangrene or an extra-osseous malignant growth, do not apply the bandage as directed above. One bandage can be applied from the periphery to near the lower border of the area of growth or infection, and another, from near the upper border of this area, up the limb. If the bandages are applied in this manner the contents of the diseased area (tumor-cells and fluid or septic products) are not squeezed into the circulation. In cases like the above the best

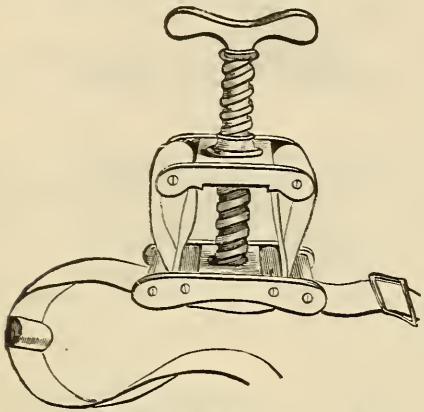

FIG. 1028.—Petit's spiral tourniquet.

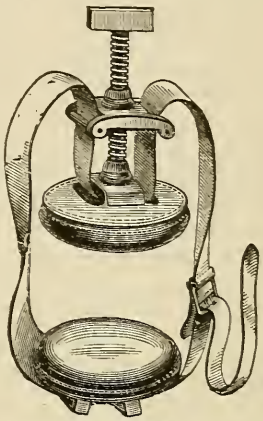

FIG. 1029.—Charrière's tourniquet.

plan is to hold the extremity in a vertical position for three minutes, lightly stroking it toward the body with the hand, and then apply the constricting band. As a matter of fact, this plan satisfactorily empties the limb of blood, and it is not necessary in any case to force the blood out by elastic compression. Some surgeons prefer the tourniquet. Figures 1028 and 1029 show two forms of tourniquet. To apply Petit's tourniquet, place the plates in contact, apply a small, firm compress over the artery and a broad thick compress over the outer surface of the limb, buckle the tapes around the limb so that the plate is over the broad pad, and tighten the tourniquet by separating the plates

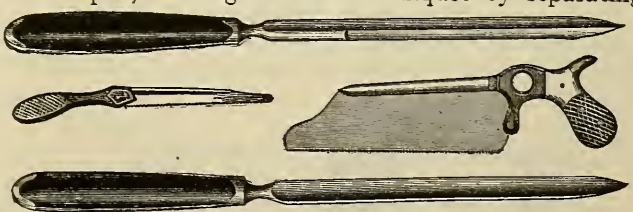

FIG. 1030.—Catlin, long knife, and saws for amputation.

by the screw (Fig. 1027). When a tourniquet is applied to arrest bleeding during transportation, bandage the limb, sew the compress pad to a bandage, and place the plates of the instrument over the pad. Monprofit's all-metal tourniquet may also be used. Signorini's horseshoe tourniquet may be used upon the brachial artery. The extended use (several hours, during transportation, etc.) of the tourniquet is to be deprecated. Frightful gangrene often followed its prolonged application in the recent hostilities. In hip-joint and shoulder-joint disarticulations Wyeth's pins may be passed, and after the limb is emptied of blood the band can be fastened above them. These pins prevent the band from slipping.

The instruments and appliances required for amputation are Esmarch's apparatus or tourniquet, amputating knives (Fig. 1030), a bone-knife, scalpels,

saws (Fig. 1030), a lion-jaw forceps, bone-cutting forceps, a periosteum-elevator, retractors of cloth or of metal (Monprofit's), dissecting, hemostatic, and toothed forceps, a tenaculum, an aneurysm-needle, a probe, scissors, needles, ligatures, sutures of silkworm-gut, dressings, bandages, and solutions. A cloth retractor has two tails for the thigh and arm and three tails for the leg and forearm: it is made by taking a piece of muslin or of linen 8 inches wide and 12 inches long and cutting tails on one side 8 inches in length.

Methods of Amputating.—The *transverse circular* is the oldest method of amputating. The common circular incision is at a right angle to the axis of the limb. Kocher considers also as a circular incision an oblique cut around the limb if the line of incision "continues in one direction" (Kocher's "Textbook of Operative Surgery," translated by Harold J. Stiles). This method is called the *oblique circular amputation.* The *flush circular method* makes no flaps at all. A *racket incision* is formed by adding a longitudinal cut to a transverse circular cut. If the edges are rounded,

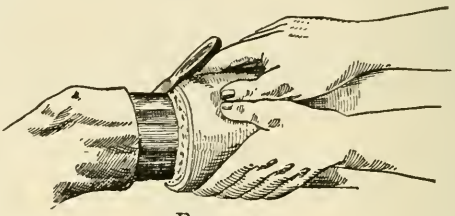

Fig. 1032.

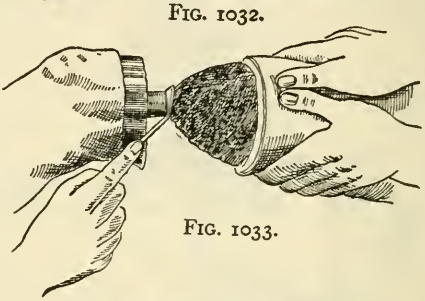

Fig. 1033.

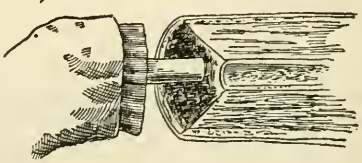

Fig. 1034.

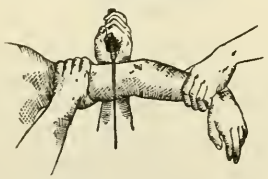

Fig. 1031.—Amputation of arm by the circular method (Druitt).

Figs. 1032–1034.—The steps of a transverse circular amputation (Kocher).

the *lanceolate incision* is formed. *Rectangular* flaps are formed when two longitudinal incisions are added to a transverse circular cut. If the corners of a rectangular flap are trimmed, *rounded flaps* are formed. The three last-mentioned plans are considered under the head of the Modified Circular Amputation (see page 1554).

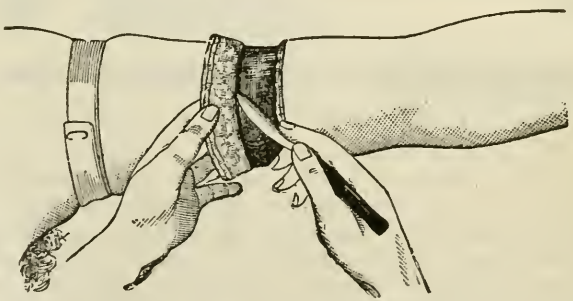

Fig. 1035.—Circular amputation: Dissecting up the skin-flap (Esmarch).

Transverse Circular Method (Figs. 1031–1034).—The surgeon should stand to the right of the limb and use a long amputating knife which cuts from heel to point (Fig. 1031). After an assistant has retracted the skin the operator divides the soft parts by a series of circular cuts. He does not cut at once to the bone,

but divides the skin and subcutaneous tissues. At the retracted edge of the first cut the superficial muscles are divided, and after these muscles retract the

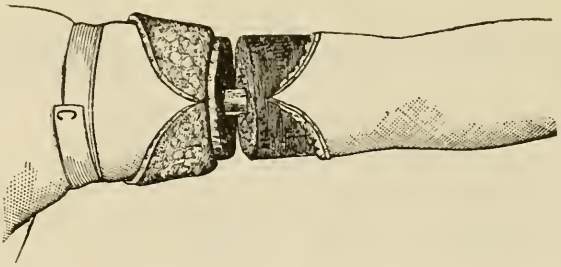

Fig. 1036.—Modified circular amputation: Skin-flaps and circular cut through muscles (Esmarch).

deep muscles are divided. The periosteum is incised by a bone-knife and pushed up by an elevator, and after the application of the retractors the bone is then sawed, the saw starting from heel to point. A periosteal flap can be made to cover the end of the bone, but it is not wise to do so. In this amputation is formed a cone whose apex is the bone and whose base is the skin edge. Figures 1032–1034 from Kocher, show the steps of the operation and the shape of the resulting stump. In one form of circular amputation (*amputation a la manchette*) the retracted skin is cut by a circular sweep of the knife, a cuff of skin and subcutaneous tissue is freed and turned up, and the muscles are cut circularly at the edge of the turned-up cuff (Fig. 1035). The pure circular amputation is performed on the arm and the thigh; the amputation *a la manchette* is performed chiefly through the wrist and the lower forearm.

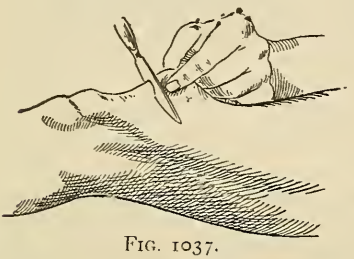

Fig. 1037.

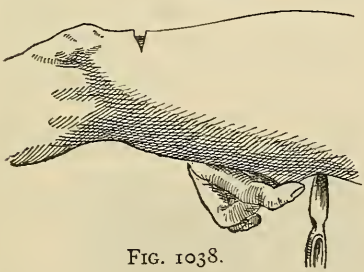

Fig. 1038.

If there is more sound skin upon one

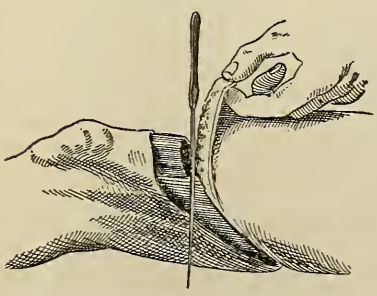

Fig. 1039.

Figs. 1037–1039.—The early steps of an oblique circular amputation (Kocher).

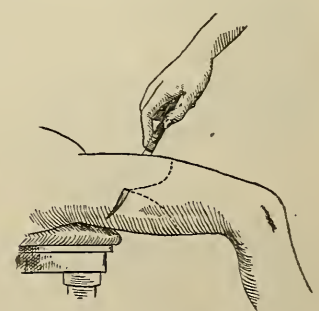

Fig. 1040.—Amputation of the thigh by transfixion (Gross).

side of the extremity than upon the other, the transverse circular incision sacrifices more of the limb than is necessary and the oblique circular is pref-

erable. An objection to the transverse circular incision is that the cicatrix lies directly at the end of the stump and is liable to cause pain when subjected to pressure.

Flush Circular Method.—The skin and superficial fascia are divided as in an ordinary circular amputation. The muscles are divided transversely at the level of the retracted skin. The bone is sawed through at the level of the retracted muscles.. The nerves are drawn down and divided and the vessels are ligated. The wound remains open, dressings are applied and traction on the skin is made by an apparatus like that of Gordon Buck for making extension in hip-joint fracture. The soft parts are thus drawn gradually over the bone. This operation has been practised extensively during the war. It preserves length of limb, diminishes the danger of secondary hemorrhage, and because of the clean transverse incision, free drainage, open wound, and accessibility to disinfection, lessens the danger of gas gangrene, tetanus and sepsis. Kelly ("Brit. Jour. Surgery," 1916, iii) calls it the "flapless amputation," and Watson ("Brit. Med. Jour.," 1916, i), the "flush circular method."

Modified Circular Method.—In this operation the circular skin-cut may be modified by making a vertical incision to join the first wound, the muscles being cut by a circular sweep (racket incision) or by making two vertical skin incisions (rectangular flaps). The lanceolate incision is made by rounding the edges of the flaps which result from a racket incision. Liston's modification consists in dissecting up two short semilunar integumentary flaps and in dividing the muscles circularly (Fig. 1036). This is known as the "mixed method." The modified circular method can be used upon the thigh, the leg, the arm, and the forearm.

Oblique Circular Method (Elliptical Method).—Mark the upper and lower ends of the incision as shown in Figs. 1037–1039. The lowest incision is at a right angle to the cutaneous surface; the highest incision is parallel to the cutaneous surface (Kocher). The skin and fascia are divided so that an incision oblique to the muscles surrounds the limb. The distal elliptical portion of skin is picked up and drawn toward the body and the muscles are divided to the bone, the knife being held transversely (Figs. 1037–1039). Kocher points out that this flap increases in thickness toward the bone. The rest of the muscles are divided on a level with and in the direction of the skin edge. The periosteum is cut transversely and is treated as in the transverse circular operation. The flap of muscle and integument is brought over the wound. This method stands midway between the circular operation and the operation by a single flap, and is employed particularly in certain disarticulations.

Flap Method.—A flap may be composed of *skin* only or of both *skin* and *muscle*, but the skin-flap must always be longer than the muscle-flap, so that the latter will be covered by it. A flap containing much muscle heals badly, but the ideal flap has a moderate amount of muscle (enough skin to cover the muscle and enough muscle to cover the bone). Flaps may be *single* or *double*. Double flaps may be *lateral* or *anteroposterior*, *square* or U-*shaped*, *equal* or *unequal*, and they may be cut by *transfixion* (Fig. 1040), by cutting from without inward, by dissection, or by cutting the skin from without inward and the muscles by transfixion.

Racket Method (if flaps are rounded, is known as the "oval" or "lanceolate" incision).—In an *oval* amputation the incision through the skin and subcutaneous tissue is an oval with a pointed end or a triangle; and the other parts down to the bone are cut from without inward. When a longitudinal incision down to the bone (see Fig. 1052, *a–b*) extends from the point of the oval, the operation is called the "racket" amputation. If the longitudinal cut joins a circular cut, the operation is known as a T-amputation. The oval or racket operation is performed at the metacarpophalangeal, metatarsophalangeal, and shoulder-joints; the T-operation may be performed at the hip-joint.

Completion of an Amputation.—When an amputation has been completed, tie the main vessels, pull down the nerves and cut them high up,

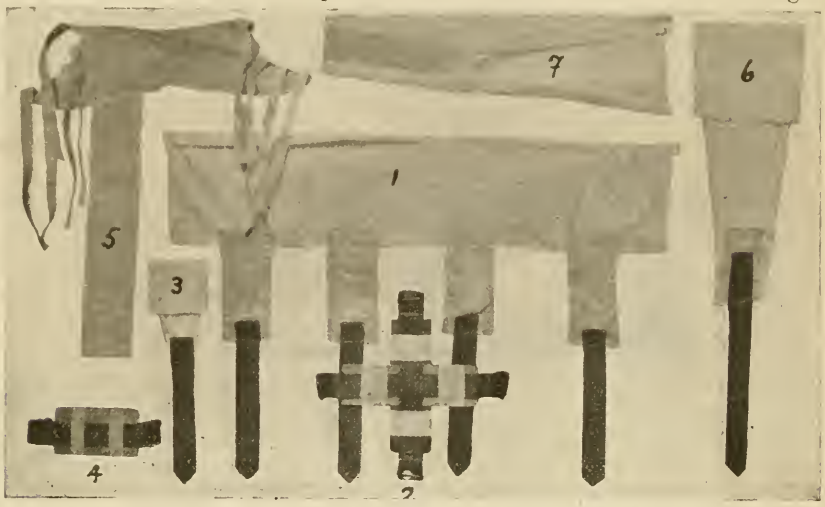

FIG. 1041.—Showing the pattern of the canton flannel extension straps used for the purpose already mentioned. The material used was a medium weight canton flannel. (1) The broad piece, with extension straps, used for the skin traction apparatus. (2) The wooden cross-piece to which the above extension straps are buckled. (3) Cloth, with webbing extension, which is glued to the forearm in the overhead extension treatment of compound fractures of the humerus. (4) Wooden traction piece to which the foregoing webbing is buckled. (5) Cloth anklet used to obtain extension on the foot in cases where the wound in the leg was low down or involved the ankle joint. The horizontal piece is secured over the dressing around the ankle, while the vertical piece turns under the plantar surface and is afterwards pinned to the horizontal piece. (6) Cloth extension strap, with attached webbing, to be glued to the leg in the application of the Blake splint. (7) A double extension cloth, the ends of which are glued to the leg, used as a substitute for adhesive plaster in the application of a Buck's extension (Fauntleroy).

remove the periosteum and bone-marrow for a distance of 2 cm. This may save the patient from a painful stump. It is bad practice to cover the end of the

FIG. 1042.—Showing an old amputation case under treatment with skin traction apparatus. This case improved steadily, and after one month a minor plastic operation completed the cure (Fauntleroy).

bone with periosteum. Smooth the flaps, gradually loosen and finally take off the constricting band, and ligate all bleeding points. Apply to the raw surfaces

pads wet with water at 120° F., and make compression for several minutes. The hot water arrests capillary bleeding. It also restores tone to some vessels of larger size which, palsied by the action of the constriction, have been open but are emitting no blood. Tone being restored, such vessels bleed, and can be seen, picked up and tied. Hemorrhage from the medullary canal is to be arrested by antiseptic wax. Except in amputation of the fingers and toes, drainage tubes are necessary. Take two tubes and fasten an end of one to an end of the other

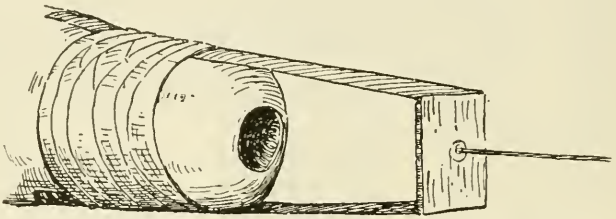

FIG. 1042*a*.—The treatment of an amputation stump by extension. This drawing was sketched from a case of direct circular amputation through the thigh. The soft tissues and bone were cut in one section at the same level. In order to bring the soft parts over the end of the bone longitudinal strips of strapping were placed on the skin and supported by a bandage. The cord passed over a pulley and was attached to a light weight. The effect of the extension was such that the tissues were drawn well over the end of the bone and a good stump resulted. The wound contracted until a comparatively small scar remained, which was drawn well to the back of the limb (Hull).

with a catgut stitch and attach the point of junction to the depths of the wound by a suture of catgut. When the time comes to remove the tubes, one is drawn out from one side of the flap, the other from the other side. Were one tube used removal would necessitate dragging one free end first within and then all the way across the wound. Sutures are now to be inserted. In some cases the deep parts are stitched with a continuous catgut suture and the superficial parts are

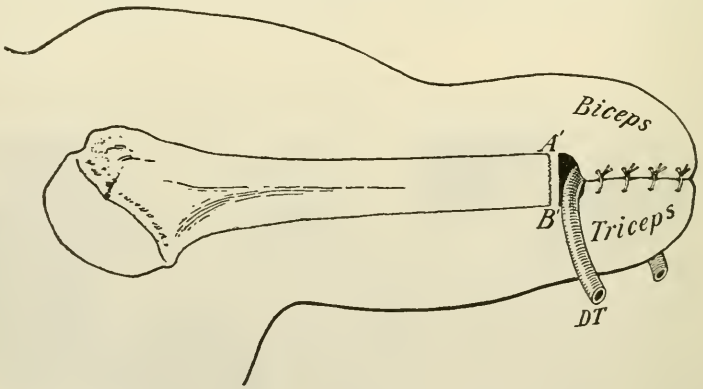

FIG. 1043.—Cinematoplastic amputation. The biceps has been sutured to the triceps and a rubber tube is passed through the loop before dressing the stump (Ashhurst).

closed with silkworm-gut; in other cases the deep parts are not stitched at all, the skin alone being sutured with silkworm-gut. Suture of opposing tendon groups prevents atrophy of the stump.

Painful Stumps.—A painful stump may be due to neuromata. Retraction of the nerves lessens the danger of neuromata. If neuromata form, excision is necessary. A weight-bearing scar causes pain and may necessitate re-amputation. Periosteal irritation causes pain. This is prevented by removing the periosteum and medulla for a distance of 2 cm. If irritation exists a like operation should cure it.

Cinematoplastic Amputations.—Vanghetti devised the method in 1898. The plan is to make a muscular or tendinous loop or muscular or tendinous loops at the end of a stump, so that the movements of the loops can be applied to move an artificial hand. It is not performed as a primary amputation. The stump is allowed to heal. See Fig. 1043.

Special Amputations

Fingers and Hand.—In amputating the thumb and index-finger save every possible scrap of tissue. If it is necessary to amputate a finger above the middle of the middle phalanx, the attachment of the flexor tendons will be cut off and the finger will be liable to project directly backward, so that it is better either to disarticulate at the metacarpal joints or to stitch the flexor tendons to the periosteum. The flexor tendons have fibrous sheaths extending from the proximal end of the distal phalanx to the metacarpophalangeal articulations, these sheaths being thin and collapsible opposite the joints, but being thick and rigid opposite the shafts of the bone. The fibrous sheath is known as the *theca*, and when it is cut in an amputation it should be closed, otherwise it may carry infection to the palm of the hand. The theca does not exist over the distal phalanx, and it is not distinctly visible over the joint between the distal and middle phalanges. To effect closure over the shaft of a bone, strip up the periosteum and pass catgut sutures vertically through the theca and the periosteum (Treves). In amputation of the fingers and the thumb an Esmarch bandage is unnecessary, though pressure may be made upon the arteries at the wrist. Only two or three ligatures are necessary.

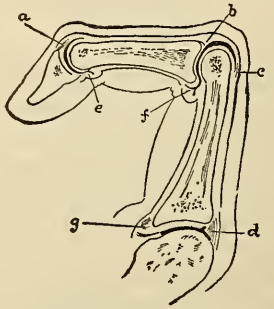

Fig. 1045.—The line of the joints in the flexed position of the finger: *a*, Extensor longus digitorum; *b*, interossei and lumbricals; *c*, extensor longus digitorum and interossei; *g*, interossei and lumbricals; *f*, flexor sublimis; *e*, flexor profundus (Kocher).

Fig. 1044.—Amputation of the finger.

Close with a very few sutures, so as to favor drainage between the stitches.

The distal phalanx is best removed by a long palmar flap (Fig. 1044, A). The plamar flap (A) is marked out by cutting through the skin and subcutaneous tissue. The incisions are next carried to the bone, the flap is dissected from the bone, the finger is strongly flexed, a transverse incision (B) is carried across the dorsum on a level with the base of the third phalanx, the soft parts are pushed back, the joint is opened, the lateral ligaments are cut from within outward, the third phalanx is forcibly extended, and the remaining structures are cut from below upward. Figure 1045 shows the lines of the joints when the finger is flexed. The middle phalanx can be removed by the same method (Fig. 1044, C). The proximal phalanx can be removed by a long palmar flap or by a long palmar and a short dorsal flap (Fig. 1044, D, E).

Disarticulation at a metacarpophalangeal joint is best performed by the oval method. The incision upon the dorsum (A) is begun just above the head of the metacarpal bone, is carried down to beyond the base of the phalanx, and involves the skin only (Figs. 1046 and 1047). One incision sweeps around the finger at the level of the web, going through the skin only (B);

the finger is extended and the palmar cut is carried to the bone; each lateral incision is carried to the bone while the finger is bent in the opposite direction, the flaps are dissected back to the joint, the finger is strongly extended, the joint is opened from the palmar side, and disarticulation is effected. Cutting off the head of the metacarpal bone improves the appearance of the stump, but weakens the hand, hence in a workingman it must not be done unnecessarily. If it be necessary to remove a metacarpal bone, the incision (c) is made from the carpometacarpal joint.

Amputation of the thumb through its distal or proximal phalanx is performed in the identical way employed in amputation of a finger. Amputation of the thumb, with a portion or the whole of its metacarpal bone, is performed by the oval or racket incision (Fig. 1047).

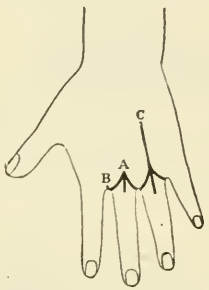

Fig. 1046.—A, Disarticulation of a metacarpophalangeal joint; C, amputation of a finger with the metacarpal bone.

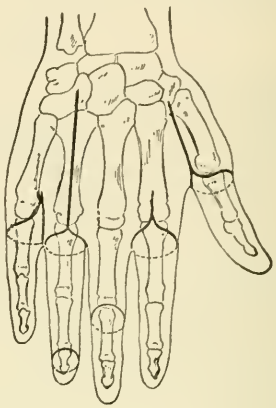

Fig. 1047.—Disarticulation of the little finger and index-finger. Disarticulation of the ring finger with its metacarpal bone. Disarticulation of the thumb with its metacarpal bone (Kocher).

Disarticulation at the wrist-joint can be done by the oblique circular method (Fig. 1048) or by a double flap. In the double-flap amputation a dorsal flap is made by carrying a semilunar skin incision between the styloid processes; the skin is lifted, the wrist is forcibly flexed, the joint is opened

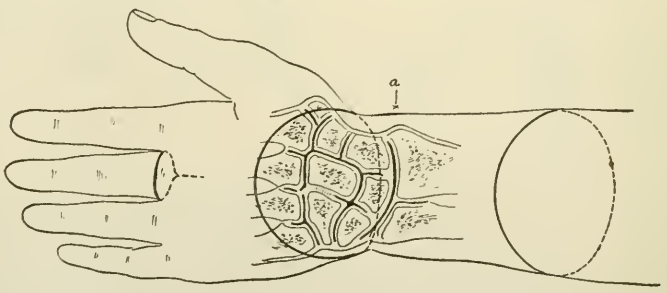

Fig. 1048.—Disarticulation of the middle finger. Disarticulation at the wrist-joint. Amputation through the forearm by the oblique circular method (Kocher).

by a transverse cut, and a long semilunar palmar flap which includes the skin and fascia only is made by dissection. Kocher prefers to amputate by an oblique incision. The lower end of this incision is about the middle of the palm and the upper end is in the line of the wrist-joint (Fig. 1048). The hand is strongly flexed, the extensor tendons are divided, the posterior ligament of the joint is incised, and incisions below the styloid processes divide the lateral ligaments and certain tendons. The flexor tendons are separated from the bone and are divided so as to remain in the palmar flap.

Amputation through the forearm may be effected by the oblique circular method (Fig. 1048), the circular, the modified circular, or the flap operation. The modified circular is an excellent plan. A semilunar dorsal skin-flap and a semilunar skin-flap on the flexor surface are made. The flaps are raised, the muscles are cut circularly (Fig. 1049), the interosseous space is cleared by the knife, a three-tailed retractor is applied, the periosteum is pushed up, and the bones are sawn ½ inch above the flap. In sawing the bones, start the saw upon the radius, draw it from heel to point, make a furrow on the radius and ulna, and saw both bones at the same time. After sawing, cut away any irregular edge with bone-pliers. In the lower third Teale's amputation may be done, the dorsal flap being the long one. In Teale's amputation rectangu-

Fig. 1049.—Modified circular amputation of the forearm (Bryant).

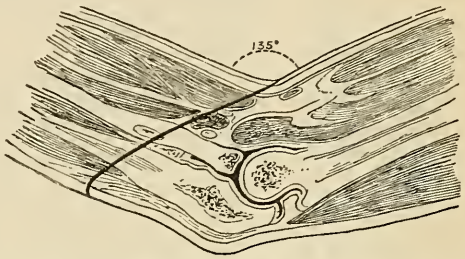

Fig. 1050.—Disarticulation of the elbow-joint by the oblique circular method (Kocher).

lar flaps are made. The long flap is equal in width and length to one-half the circumference of the limb at the point where it is to be sawn. The short flap is equal in width to the long flap, but is only one-fourth its length. The two longitudinal cuts are at first taken only through the skin, but the two transverse cuts go at once to the bone. The flaps are dissected up from the interosseous membrane and the bone. In the middle or the upper third of a fleshy arm two semilunar skin-flaps can be cut from without inward, and the muscles can be cut by transfixion.

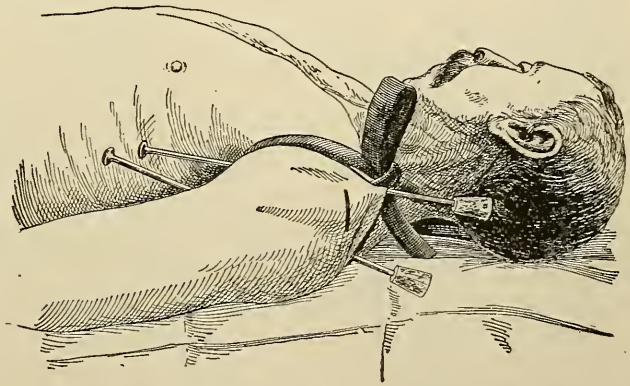

Fig. 1051.—Use of Wyeth's pins in amputation at the shoulder-joint. The acromion is marked by a black line (Keen).

Disarticulation at the elbow-joint can be done by the elliptical method or by a long anterior and short posterior flap. In Kocher's oblique operation the incision begins anteriorly over the joint-line and ends posteriorly a hand's breadth below the summit of the olecranon (Fig. 1050). A posterior flap which contains the integument, the insertion of the triceps, the anconeus, and the periosteum is dissected up until the posterior surface of the humerus is reached. The joint is opened anteriorly by a transverse incision, and the radiohumeral articulation is opened from without inward (Kocher). In the double flap operation the forearm is partly flexed and a skin-cut marks out a long anterior

flap, the knife being entered opposite the external condyle and being withdrawn 1 inch below the internal condyle. The muscles, which are bunched forward, are cut by transfixion. A posterior semilunar flap is made, which separates the attachments of the radius, the ulna is cleared, and the triceps is cut at its insertion (Bell). Gross advocated sawing through the olecranon and the inner trochlear surface.

Amputation of the arm is best performed by marking out with a knife two equal semilunar anteroposterior flaps, the first cut being carried through the skin alone, the muscles being then transfixed with a long knife. Teale's method is shown in Figs. 496 and 497. The circular or the modified circular amputation may be performed.

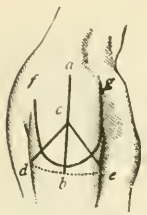

Fig. 1052.—Amputation at the shoulder-joint: *a–b*, *c–d*, *c–e*, Larrey's operation; *f–g*, Dupuytren's operation.

Disarticulation at the Shoulder-joint.—In this operation some surgeons use Wyeth's pins to hold the Esmarch band in place. The anterior pin is entered at the middle of the lower margin of the anterior axillary fold, and emerges 1 inch to the inside of the tip of the acromion. The posterior pin is entered at a corresponding point on the posterior axillary fold, and emerges more posteriorly than the first pin and an inch to the inside of the tip of the acromion. After the extremity has been drained of blood by the Esmarch bandage or by stroking and a vertical position, the Esmarch band is applied above the pins (Fig. 1051). With a competent assistant, however, the pins are not necessary, the surgeon dividing his main vessels as the last step of the operation, and the assistant controling them, before they are cut and until they are tied, with digital compression; or, the main vessels may be ligated as a preliminary step.

Larrey's Operation.—In this method of shoulder-joint disarticulation the limb is held away from the side and an incision is made down to the bone, the

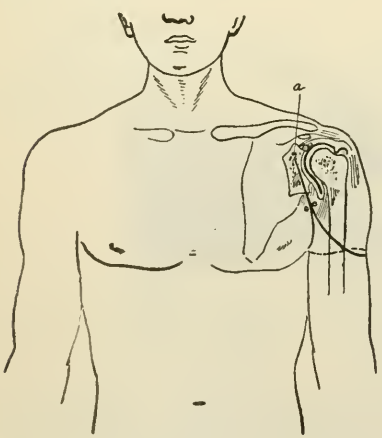

Fig. 1053.—Disarticulation at the shoulder-joint by Kocher's method (Kocher).

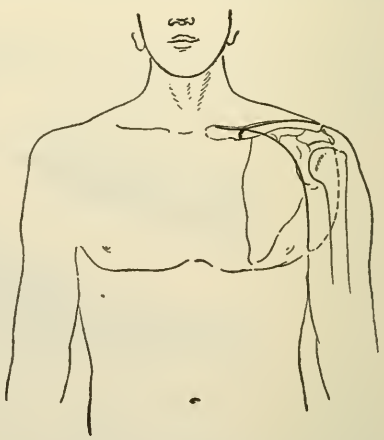

Fig. 1054.—Removal of the entire upper extremity (Kocher).

incision beginning just below and in front of the acromion and running vertically for 4 inches down the outer surface of the arm (Fig. 1052, *a–b*). From the center of this incision an oval incision (*c–d*, *c–e*) is carried around the arm, the inner aspect of the oval reaching as low as the lower end of the vertical cut. The oval incision at first involves only the skin and subcutaneous tissues. The anterior structures are divided close to the bone, and the posterior structures are next cut. To disarticulate, cut the capsule transversely upon the head of

the bone; while the arm is rotated outward cut the subscapularis, and while the arm is rotated inward cut the supraspinatus and infraspinatus and the teres minor. Cut away any tissue holding the humerus to the body, hanging nerves, capsule-fragments and tissue-shreds, insert a tube, and sew up the wound vertically. Bell advises an oval incision with a racket handle. Spence used an anterior racket incision.

Kocher's Operation.—Kocher makes an anterior lanceolate incision (Fig. 1053). The incision begins over the clavicle just external to the coracoid process of the scapula, and is carried downward, dividing, as it advances, the anterior fibers of the deltoid muscle. "Bleeding vessels and the cephalic vein are ligatured. In the upper part of the wound the acromial branches of the acromiothoracic artery are also ligatured. The knife is carried down to the bone at the edge of the deltoid (only the upper fibers of which have been divided). The capsule is divided over the lesser tuberosity and the bicipital groove. The periosteum, the insertions of the subscapularis, pectoralis major, latissimus dorsi, and teres major are detached along with the capsule. The capsule, along with the insertions of the supraspinatus, infraspinatus, and teres minor muscles, is also detached from the upper part of the head and from the great tuberosity. The head of the humerus can now be protruded from the wound. In cutting down over the surgical neck it may be necessary to ligature the circumflex arteries; in any case the anterior vessel must be tied. The racket incision is now completed by dividing the skin circularly at the level of the axillary folds. The vessels and nerves are then easily isolated, the former being ligatured and the latter divided" (Kocher's "Text-book of Operative Surgery," translated by Harold J. Stiles). Kocher cautions us to avoid the circumflex nerve which supplies the deltoid, as the deltoid is the muscle of the stump.

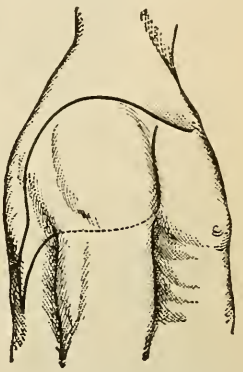

Fig. 1055.—Removal of the whole upper extremity.

Dupuytren's Operation.—In Dupuytren's shoulder-joint disarticulation a U-shaped flap is marked out by a skin-incision (Fig. 1052, *f–g*). If the amputation is to be at the right shoulder, the arm is carried across the chest; the knife is entered at the root of the acromion, follows the margin of the deltoid, and is withdrawn at the coracoid process, the arm being gradually abducted and pulled off from the chest. If the left shoulder is to be amputated the procedure is reversed (Treves). The knife next cuts through the deltoid and raises a flap composed of this muscle, the shoulder-joint is exposed, and disarticulation is effected as in Larrey's method. The knife is passed down back of the bone and a short internal flap is cut.

Lisfranc's amputation is by transfixion with the formation of an anterior and a posterior flap, and can be performed very rapidly by a skilful surgeon.

Amputation of the Entire Upper Extremity.—Berger's Operation.—*The Interscapulothoracic Amputation.*—This operation, which is an amputation above the shoulder-joint, was described by Berger in 1887. By it are removed the arm, the scapula, and a portion of or the entire clavicle. It is occasionally employed in cases of malignant disease and of severe injury. The operation is attended with profuse hemorrhage, and as a preliminary the subclavian vessels should be ligated. The incisions must be varied according to the necessities of the case. In this operation Berger divides the clavicle at the junction of its outer and middle thirds, and resects the middle third of the bone; ligates and divides the subclavian vessels; cuts the anterior flap; divides the brachial plexus; marks out the posterior flap; and completes the operation by dividing the structures which hold the shoulder-blade to the chest.

It is in this last step that bleeding is profuse. Figure 1055 shows Berger's incisions for the operation. Figure 1054 shows Kocher's incisions.

The usual procedure of tying the third part of the subclavian artery as a preliminary measure possesses certain disadvantages. The artery is very deeply situated at this point, is in close relation with the pleura, and is covered to a considerable extent by the vein, and the phrenic nerve is very near. Le Conte resects the entire clavicle before tying the vessels. He maintains that then one of two courses may be taken: The veins may be severed first, and

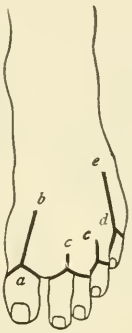

Fig. 1056.—Amputation of the toes with and without the metatarsal bones.

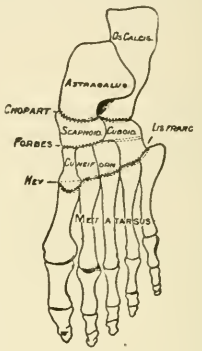

Fig. 1057.—Lines in amputations of the foot (Gross).

afterward the artery may be exposed and tied. When this is done, the amount of blood remaining in the arm is lost. The procedure that he selects as the best, however, is to expose the axillary artery as high up as possible, and place a temporary ligature around it; then elevate the arm, empty it of blood, place a permanent ligature around the third part of the subclavian artery, and divide the artery in this portion of its course (Robert G. LeConte. "Annals of Surgery," Oct., 1902). If the scapula be involved in the tumor, the mortality is something over 23 per cent. (Berger, "Revue de Chir.," Aug., 1905). I have twice performed the operation successfully and in each case followed LeConte's plan.

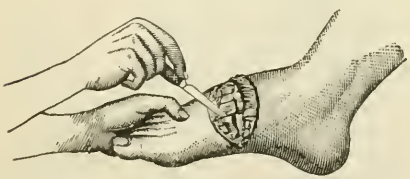

Fig. 1058.—Lisfranc's amputation: First step in disarticulating the second metatarsal bone (Guérin).

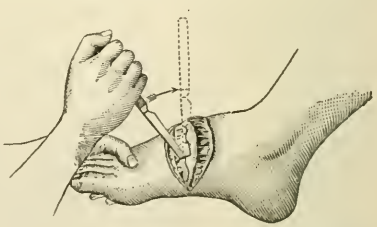

Fig. 1059.—Lisfranc's amputation: Second step in disarticulating the second metatarsal bone (Guérin).

Amputation of the Toes and the Foot.—Only through the great toe is *partial* amputation performed, and it is effected by the formation of a long plantar flap, just as a long palmar flap is formed from a finger. Amputation at a metatarsophalangeal joint is performed by an oval or racket incision (Fig. 1056, *c*, *c*). Amputation of a toe with removal of its metatarsal bone is shown in Fig. 1056, *a*–*b* and *d*–*e*.

Disarticulation at the Tarsometatarsal Articulation.—Lisfranc's Operation (*after Treves*).—In order to amputate the right foot by this method begin an incision on the outer border of the foot, behind the tubercle of the fifth metatarsal bone; carry the incision forward 1 inch and sweep it across

the foot ½ inch below the tarsometatarsal articulations; bring the incision to the inner edge of the foot, ½ inch in front of the articulation of the tarsus with the first metatarsal bone, and carry the cut straight back along the inner margin of the foot until it reaches a point ¾ inch above the articulation of the metatarsal bone of the great toe. A very short semilunar dorsal skin-flap is thus formed. Figure 1062 shows the flaps as cut by Kocher. After the skin-

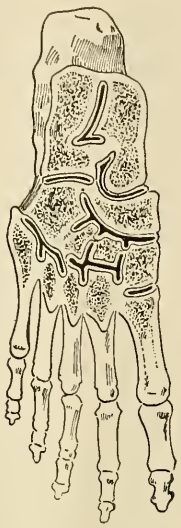

FIG. 1060.—Anterior intertarsal disarticulation (Kocher).

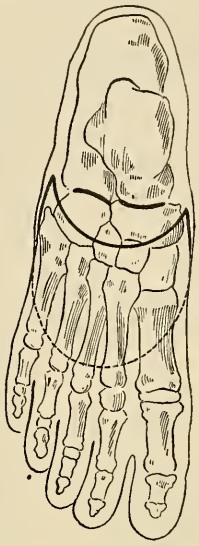

FIG. 1061.—Chopart's amputation (Kocher).

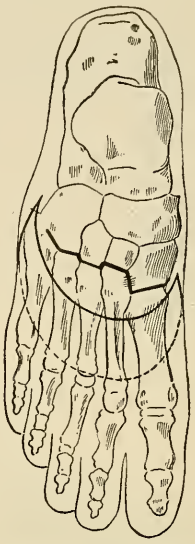

FIG. 1062.—Lisfranc's amputation (Kocher).

flap has been dissected back for ¼ inch the tendons are divided, and the flap, which now contains all the soft parts, is dissected back to *above* the joint. A long plantar flap is cut, reaching from the origin of the first flap to the necks of the metatarsal bones. The skin-flap is dissected up until the hollow behind the heads of the metatarsal bones is reached, when, with the toes in extension, the tendons are cut across and a flap composed of all the soft parts is dissected

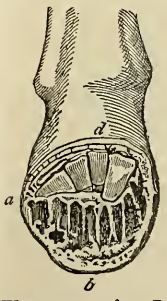

FIG. 1063.— The parts after Lisfranc's amputation (Bernard and Huette).

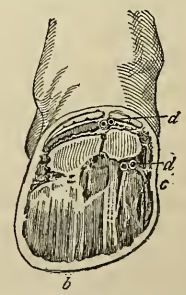

FIG. 1064.—The parts after amputation by Chopart's method (Bernard and Huette)

up to above the tarsometatarsal joint. Figures 1057 and 1062 show the line of Lisfranc at the tarsometatarsal articulation. The joint is opened from the outer side according to the following rule: in separating the fifth metatarsal direct the edge of the knife toward the distal end of the first metatarsal; in separating the fourth metatarsal direct the knife toward the middle of the

first metatarsal; in separating the third metatarsal carry the knife almost directly across. The separation is facilitated by bending down the toes and the foot, and at the same time the tendons of the peroneus brevis and tertius are divided. Open the joint between the first metatarsal and the inner cuneiform bone, turning the knife toward the middle of the shaft of the fifth metatarsal, and at the same time divide the tibialis anticus muscle. Treves says that in disarticulation of the second metatarsal the knife is to be held as a trocar, it is to be thrust between the base of the first and second metatarsal bone until the point strikes bone (Fig. 1058), and is then to be raised to a perpendicular and the cut is to be made toward the external malleolus to sever the ligament of Lisfranc (Fig. 1059). Divide any remaining ligaments, and also the tendon of the peroneus longus muscle. The skin-incisions in the *left* foot are begun on the inner side, and, in disarticulating, the tarsal joint of the great toe is first opened. Figure 1063 shows the parts after disarticulation in the line of Lisfranc. After Lisfranc's amputation a patient can walk with very little limp.

Hey's Operation.—In Hey's method the incision is practically the same as that for Lisfranc's amputation. The four external metatarsal bones are disarticulated, but the first metatarsal is removed by sawing a portion of the internal cuneiform bone. Guérin advised sawing all the bones across. Skey advised the division of the head of the second metatarsal. Figure 1057 shows the line of Hey.

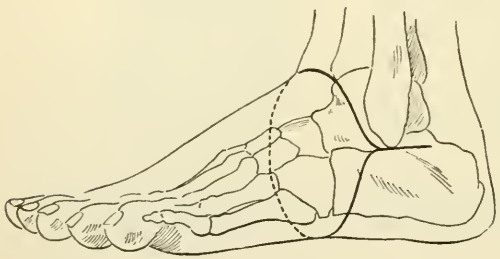

Fig. 1065.—Subastragaloid disarticulation (Kocher).

Anterior Intertarsal Disarticulation (Amputation of Forbes, of Toledo).—The disarticulation is effected between the three cuneiform bones in front and the scaphoid behind, and the cuboid is sawn across. Figure 1057 shows the line of Forbes. The incision of the soft parts is as for Lisfranc's amputation (Fig. 1060).

Disarticulation Through the Middle Tarsal Joint.—Chopart's Operation (*Posterior Intertarsal Disarticulation*).—Make a transverse incision through the skin of the instep, 2 inches below the ankle-joint, cut the tendons and muscles, expose the tarsus, and make on each side a small longitudinal incision reaching to below and in front of the corresponding malleolus. The flap thus formed is retracted. The plantar flap is made as in Lisfranc's amputation. The flaps as made by Kocher are shown in Fig. 1061. Open the astragaloscaphoid joint, then the calcaneocuboid joint, and disarticulate. Figures 1057 and 1061 show the line of Chopart. Figure 1064 shows the parts after Chopart's disarticulation. Chopart's amputation seldom gives good results. A secondary operation is usually necessary.

Subastragaloid Disarticulation.—A circular incision is carried around the foot at the level of the middle tarsal joint and a racket incision is added to it running below and posterior to the tip of the external malleolus (Fig. 1065). "The joint between the astragalus and scaphoid is opened upon the dorsum, without opening the calcaneocuboid joint. A narrow knife is then passed backward and slightly upward beneath the head of the astragalus so as to divide the strong interosseous ligament between it and the os calcis. The soft parts are then dissected off the os calcis, first from its upper surface, then from its outer and under surfaces, and lastly from its inner and posterior surfaces. The greatest difficulty is met with at the inner side in clearing the projecting sustentaculum tali" (Kocher's "Text-book of Operative Surgery," translated by Harold J. Stiles).

Disarticulation at the Ankle-joint.—Syme's Method.—The foot is held at a right angle to the leg, and a skin-incision is carried, from just below the external malleolus, straight across or a little backward across the sole to a corresponding point on the opposite side. Do not take this incision near to the inner malleolus, as to do so will endanger the posterior tibial artery. The incision is carried to the bone, the flap being pushed back and separated from the bone by means of a strong knife and the thumb-nail until the tuberosity of the os calcis has been reached. The foot is now extended and a transverse cut is made across the dorsum, joining the two ends of the first incision; the ankle-joint is opened, the lateral ligaments are cut, disarticulation is effected, and the foot is finally completely removed by severing the tendo Achillis. A thin piece of bone including both malleoli is sawn from the tibia and fibula. The flap is perforated posteriorly to secure drainage (Fig. 496). The patient will be able to walk with very little limp.

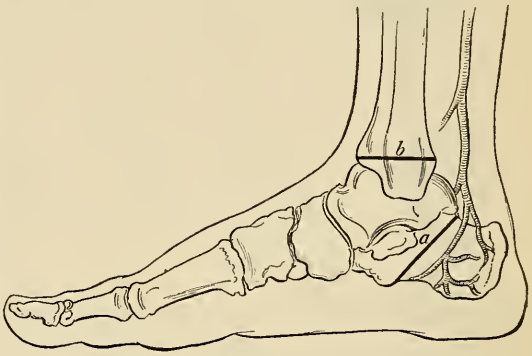

Fig. 1066.—Lines of section of the os calcis and the bones of the leg in Pirogoff's amputation.

Pirogoff's Method. — Flex the foot to a right angle with the leg. "Make an incision from the tip of the internal malleolus across the sole, a little in front of the long axis of the tibia, to a point in front of the apex of the external malleolus down upon the bone."[1] Dissect the flap backward from the calcaneum for ¼ inch, but do not dissect the flap from the posterior portion of the os calcis. Join the extremities of the first incision by another cut which reaches to the bone, and which is "½ inch in front of the lower extremity of the tibia" (Bryant); but saw off this bony projection obliquely and leave it adherent to the tissues. The saw is used after disarticulation of the ankle-joint; it is passed behind the astragalus, cutting downward and forward, sawing the os calcis obliquely, and leaving a considerable portion in place in the flap. The lower ends of the tibia and fibula are well exposed by raising the anterior flap slightly; the sawing is begun anteriorly just above the articular surface, and is completed ½ inch above the articular surface posteriorly. The lines *a* and *b* (Fig. 1066) show the sections made by the saw. The sawn surface of the os calcis is brought into contact with the sawn surfaces of the tibia and fibula, and the flaps are sutured.

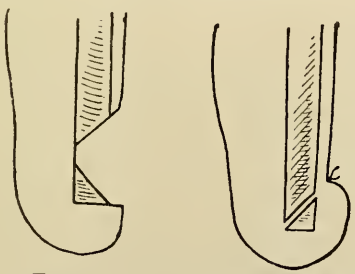

Fig. 1067.—Diagrammatic representation of amputation of the leg after the method of Bier.

Amputations of the Leg.—The so-called "point of election" is at the upper part of the middle third of the leg. Seventy-five years ago Liston advised surgeons not to amputate in the lower third of the leg because of the scantiness of the soft parts, because the stump is apt to ulcerate, and because it is uncomfortable in an artificial leg. These views have been much modified. The amputation near the ankle is safer than the amputation near the knee, and artificial legs are now made which may be worn with comfort. Binnie ("Annals of Surgery," 1914, lx) maintains that in order to get a proper stump for a good artificial leg the lowest point considered

[1] "Operative Surgery," by Joseph D. Bryant.

for amputation should be 8 inches from the ground and the highest point 4 inches below the lower margin of the patella. The circular incision seldom gives a good, weight-bearing stump because the scar is over the end of the bone. The flap method should be used if possible. The removal of the periosteum and bone-marrow for a distance of 2 cm. tends to prevent a painful stump. In amputations of the leg by the *long anterior flap*, cut through the skin, dissect up the anterior muscles with the flap and cut all the posterior tissues with a single transverse sweep. Amputation by the *rectangular flap*, Teale's method, is very useful (see page 1559). The long flap is anterior, and is in length and breadth equal to one-half the circumference of the limb. The short flap is one-fourth the length of the long flap. The flaps are dissected up, the bones are sawn, the long flap is turned upon itself, and its edges are sutured to the edges of the short flap.

Fig. 1068.—Sédillot's amputation of the leg (Wyeth).

Bier suggests a plan (Fig. 1067) to increase the supporting power of the stump after a leg amputation. After the wound has healed, a wedge-shaped piece of bone is removed above the level of the stump. The lower extremity is turned forward and upward through an arc of 90 degrees, and unites in this position (Zuckerkandl's "Operative Surgery"). Thus the medullary cavity is closed and the skin which must bear pressure is healthy and free from cicatrices; and as the muscles are still attached to the bone, they do not undergo atrophy.

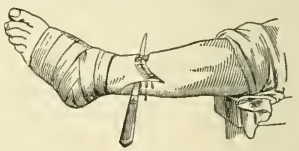

Fig. 1069.—Amputation of the leg by a long posterior flap (Gross).

Sédillot's leg amputation (Fig. 1068) is by a long external flap. A longitudinal incision is made along the inner edge of the tibia, the tissues are drawn

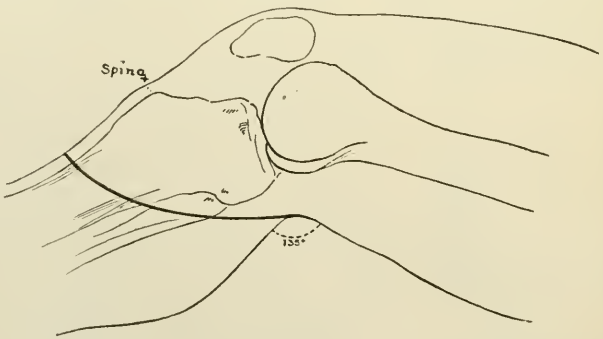

Fig. 1070.—Kocher's oblique incision for disarticulation at the knee-joint (Kocher).

toward the fibula, a knife is introduced and passed to the outer edge of the tibia, just touching the fibula, and is brought out posteriorly, thus transfixing the calf-muscles and cutting an external flap. A convex incision is made on the inner side, the bones are cleared and are sawn 1 inch above the flaps, ½ inch more being taken from the fibula than from the tibia, and the tibia being bevelled anteriorly.

Modified Circular Amputation of the Leg.—Cut semilunar skin-flaps, lay them back, and cut circularly to the bone at the edge of the turned-up flap. Another method of modified circular amputation is by adding to the circular cut a vertical incision down the front of the leg. In sawing the bones of the leg the

surgeon, who stands to the outer side of the right leg or to the inner side of the left leg, divides the fibula first, and at a higher level than the tibia, and bevels the anterior surface of the tibia. In sawing the left fibula the saw points to the floor; in sawing the right fibula it points to the ceiling.

Amputation of the Leg by a Long Posterior and a Short Anterior Flap.—In this operation a posterior U-shaped flap is made equal in length and breadth to the diameter of the limb. The skin-incision is begun 1 inch below the point where the bone is to be sawn, and behind the inner edge of the tibia, and is carried to a point posterior to the peronei muscles. The gastrocnemius muscle is divided transversely at the level of the flap, the soft parts on either side in the line of the flap being cut to the bone. Through these vertical cuts the muscles are lifted from the bones and are divided through their lower part by cutting from within outward. The anterior flap is formed by making a semilunar skin-flap and by cutting the muscles across at its retracted edge (Fig. 1069).

Amputation of the leg by lateral flaps is not a popular operation, as it offers too much encouragement to subsequent protrusion of the bone.

Amputation Just Below the Knee.—The seat of election is 1 inch below the tuberosities. No muscle is needed in the flap. Cut two flaps of skin, equal in size and of semilunar shape, these flaps beginning anteriorly 2 inches below the tuberosity of the tibia. One flap is antero-external and the other is

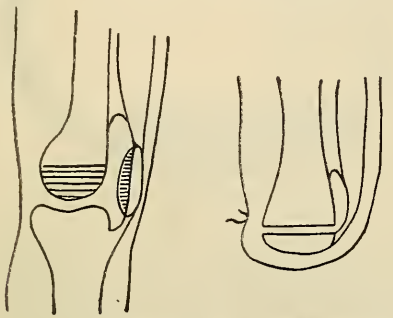

FIG. 1071.—Diagrammatic representation of Gritti's operation.

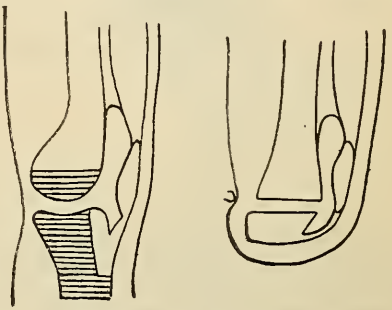

FIG. 1072.—Diagrammatic representation of Sabanejeff's operation.

postero-internal. The flaps are pulled up, the anterior muscles are cut as high up as possible, and the posterior muscles are cut through the middle of the portion exposed (Bell). The bone is sawn 1 inch below the tuberosity.

Disarticulation at the Knee.—In disarticulation by the long anterior flap make a long anterior skin-flap, incise the ligament of the patella, turn up a flap containing the patella, open the joint, and complete the disarticulation by cutting from within outward and downward. The knee may be disarticulated by means of a long anterior and a short posterior flap. Kocher prefers the oblique incision (Fig. 1070). This secures an anterior flap. The leg is so held that it makes an angle with the thigh of 135 degrees and "the incision falls in the continuation of the long axis of the thigh" (Kocher's "Text-book of Operative Surgery," translated by Harold J. Stiles). The posterior part of the incision is opposite the line of the joint and the anterior part of the incision ends four fingers-breadth below the tibial tubercle.

Amputation through the Femoral Condyles.—*Syme's Method by a Long Posterior Flap.*—Carry a skin-incision, with a very slight downward curve from one condyle to the other, across the middle of the patella. Cut down to the bone, retract the flap, and cut the quadriceps above the patella. Insert a long kife at one angle of the wound, pass it back of the femur, and make it emerge at the opposite angle, cutting a posterior flap 8 inches long. Retract the posterior flap, clear for sawing, and section the condyles horizontally.

In *Carden's method* a long anterior flap of skin and fat is cut, all other soft parts are divided transversely and the bone is sectioned through the base of the condyles. The patella is, of course, removed. In children Buchanan showed that we can easily separate the lower femoral epiphysis. In *Gritti's amputation* an oblique incision is made. The upper end of the incision is posterior and just above the condyles. Its lower end is anterior and two fingers' breadth below the patella (Kocher). The ligament of the patella is cut, the flap is turned up, the femur is sawn at the level of the adductor tubercle, the articular face of the patella is sawn off, the sawn patella is placed upon the sawn femur and the flaps are sutured (Fig. 1071). In *Stokes' amputation* (which is really a supra-condyloid amputation) the femur is di-

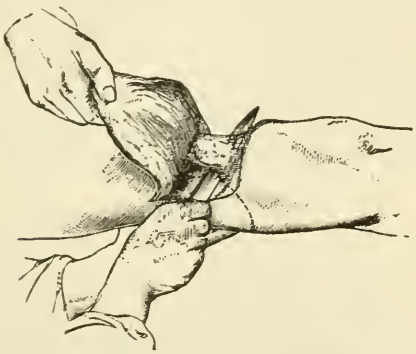

Fig. 1073.—Amputation of the thigh (Bryant).

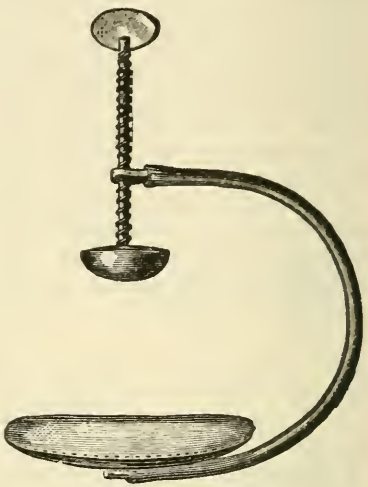

Fig. 1074.—Pancoast's aorta tourniquet.

vided about three-quarters of an inch above the condyles and the sawn patella placed against the surface so formed. In Gritti's amputation the remaining portion of the patella is apt to be pulled forward and to tilt. Stokes's operation corrects this tendency and the two bone surfaces are nearly equal in size. Sabanejeff makes an anterior flap, opens the knee-joint from behind, saws the

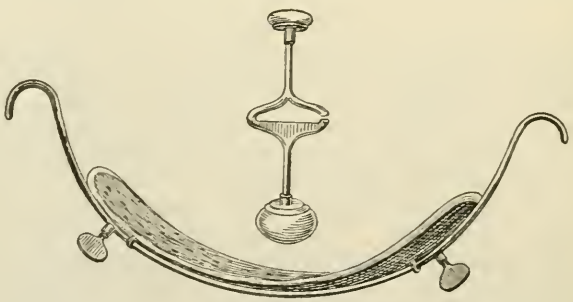

Fig. 1075.—Von Esmarch's aorta tourniquet.

condyles at their broadest part, takes a bone-flap from the anterior portion of the tibia, and fastens it to the femur (Fig. 1072).

Amputation of the Thigh.—In amputation high in the *lower third* either a flap or a circular operation may be performed. In a double-flap operation a semilunar skin-incision should be made from without inward, and the muscles should be cut by transfixion (Fig. 1073). In the lower third Teale's flap or the long anterior flap may be employed. The amputation by a long anterior flap consists in making a lengthy skin-flap, reflecting it, cutting the anterior struc-

tures to the bone, again entering the long knife at one angle of the incision, pushing it back of the femur, bringing it out at the outer angle, and cutting the structures behind the bone directly backward. Bell amputates by a long anterior semilunar flap and a short posterior flap. In amputations in the *upper two-thirds* of the thigh the best plan is to mark out equal anterior and posterior semilunar skin-flaps, divide the skin with a scalpel, enter the long knife at one angle of the anterior flap, bring it out at the other angle, and cut the muscles by transfixion. Cut the posterior flap in the same manner. Some surgeons prefer a long anterior semilunar flap and a short posterior semilunar flap. The purely circular amputation is not adapted to the thigh.

Disarticulation at the Hip-joint.—Various methods have been employed to prevent or limit hemorrhage during this formidable operation. Abernethy used digital compression of the external iliac artery or of the femoral artery. This is an extremely tiresome procedure; the finger is liable to slip; and, in any

FIG. 1076.—Macewen's method for compression of the abdominal aorta ("American Text-book of Surgery").

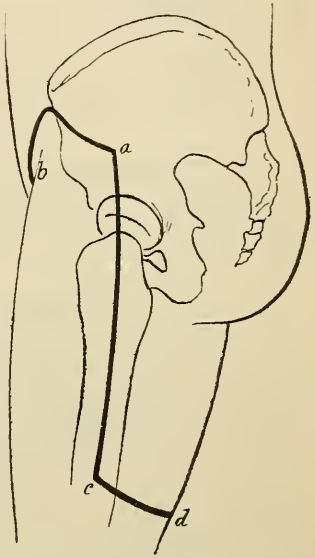

FIG. 1077.—Posterior flap in author's unusual case requiring hip-joint amputation: *a–b*, The anterior incision; *a–c–d*, the external incision and the beginning of the posterior cut.

case, compression so situated fails to intercept the blood-current in a number of large vessels.

Various other methods have been employed. It was formerly the custom to compress the aorta by means of an abdominal compressor (Figs. 1074, 1075). A tourniquet is very likely to be displaced during the operation. The intention is to compress the artery against the spine, but in effecting this the circulation in a portion of the intestine may be impaired. In any case, as Senn says, the circulation is cut off from half the body, and the patient is exposed to grave danger from "sudden vascular engorgement of important internal organs" (Senn). Again, an abdominal compressor of this sort does not arrest venous bleeding. A number of years ago Davy suggested that a suitable cylindrical piece of wood, about 25 inches long, and shaped like a cone at the end, might be introduced into the rectum and used to compress the common iliac artery upon the pelvic brim. This appliance is known as *Davy's lever*. It is apt to slip, and may do serious damage to the rectum.

Some surgeons have practised preliminary ligation of the common femoral artery or of the external iliac artery, and others have tied the vessels while making the flaps. I employed preliminary ligation of the common femoral with perfect satisfaction in 2 of my 4 cases of amputation at the hip-joint for sarcoma of the femur. If any form of compression be used, that recommended by Macewen, of Glasgow, is the most successful and satisfactory (Fig. 1076). The weight of the assistant's body is thrown upon the patient's aorta by the right fist, placed slightly to the left of the umbilicus. McBurney has suggested the prevention of bleeding by making a small abdominal incision and having an assistant make direct digital pressure upon the iliac artery. I employed McBurney's method in one case and found it most satisfactory. In this case a sarcoma of the thigh reached up so far that no band could be applied above it and I was obliged to make the posterior flap shown in Fig.

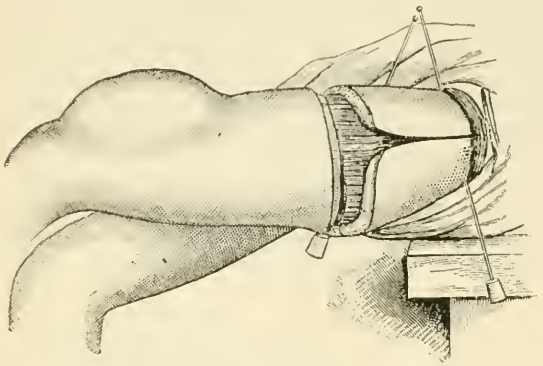

Fig. 1078.—Amputation at the hip-joint: Wyeth's bloodless method.

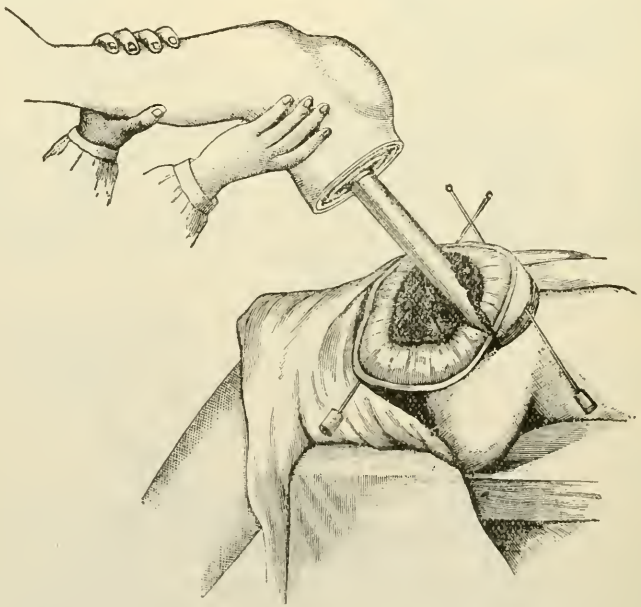

Fig. 1079.—Wyeth's bloodless amputation at the hip-joint: Cuff of skin and subcutaneous fat turned back, muscles divided at level of small trochanter, bone partly stripped, and large vessels exposed for ligation.

1077. If the constricting band of Esmarch be applied by the ordinary method, it is certain to slip. It may remain in place if applied as a figure-of-8 of the thigh and the pelvis, but even then it is uncertain.

A satisfactory method in many cases is Wyeth's, in which the constrictor is held in place by the preliminary passage of two steel pins (Fig. 1078). Tren-

delenburg's method consisted in passing one pin and winding an elastic tube about it. Wyeth applied the principle and greatly improved the method. The outer pin is inserted 1½ inches below and a little internal to the anterior superior spine of the ilium, and is brought out just back of the great trochanter. The inner pin is entered 1 inch below the level of the crotch and internal to the saphenous opening, and it emerges 1½ inches in front of the tuberosity of the ischium. A sterile cork may be pushed on the end of each pin, to save the surgeon from wounding himself upon the sharp points. A cork is apt to come off during the course of the operation. Because of the insecurity of the cork I have devised pins with removable points. After a pin has been passed, the point is unscrewed and a knob is screwed on in its place. After the limb has been emptied of blood by holding it in a vertical position for five minutes and stroking it from the periphery toward the body, the constricting band is fastened about the limb above the pins.

In the *bloodless method of Wyeth* (Figs. 1078, 1079), after passing the pins, draining the limb of blood, and applying the band of the Esmarch apparatus, the amputation is proceeded with. The hip is brought well over the edge of the table, a circular incision is made down to the deep fascia, 6 inches below the constricting band, and is joined by a longitudinal skin-cut reaching from the band to the level of the circular incision, and the cuff is reflected to the level of the lesser trochanter. The muscles are cut by a circular sweep at the level of the retracted cuff, the capsule of the hip-joint is opened freely, the cotyloid ligament is cut posteriorly, the thigh is bent upward, forward, and inward to dislocate the head of the bone, and, using the thigh as a handle, the round ligament is incised and the limb removed. After ligating the vessels and introducing drainage-tubes the flaps are sewn together vertically. The old transfixion operation is practically extinct. A *T-amputation* may be employed. It consists of an external straight incision down to the bone, starting over the great trochanter, down the outer side of the limb, and a circular incision through the skin 5 inches below the constricting band, the muscles being cut by a circular sweep at the level of the retracted skin. This method affords easy access to the joint. The bloodless method of Wyeth, as applied to the hip-joint and shoulder-joint, is a notable advance in the art of surgery.

Senn's Bloodless Method.—The elder Senn has devised a method of preventing hemorrhage during amputations through the hip-joint. He makes a straight incision, about 8 inches in length, in the direction of the long axis of the femur and directly over the center of the great trochanter. This incision reaches about 3 inches above the upper margin of the great trochanter. The muscular insertions are divided close to the bone, and the thigh is flexed, strongly adducted, and rotated inward. The capsular ligament is divided at its upper and posterior aspect. While the thigh is brought into a position of slight flexion the remaining portion of the capsular ligament is cut. Then the thigh is dislocated outward, and the ligamentum teres is cut. If this cannot be accomplished, the head of the bone is forcibly dislocated upon the dorsum of the ilium. After dislocating, the lesser trochanter and the upper part of the femoral shaft are cleared. The limb is now brought down in a straight line with the body, the thigh is slightly flexed, a long and stout pair of forceps is inserted into the wound behind the femur and on a level with the normal situation of the lesser trochanter, and the instrument is pushed downward and inward, 2 inches below the ramus of the ischium and just behind the adductor muscles. As soon as the point can be felt under the skin, an incision 2 inches in length is made upon it, and the instrument is forced through the opening. The tunnel in the tissues is enlarged by opening the forceps. A piece of rubber tubing ¾ inch in diameter and 4 feet in length is caught about the middle with the forceps and is withdrawn. The rubber tube is cut in two at about the point at which the forceps have held it, and half of the tube is used to constrict the anterior seg-

ment of the thigh (Fig. 1080) and the other half to constrict the remaining portion of the thigh (Fig. 1081). Before the constricting bands are tied the limb

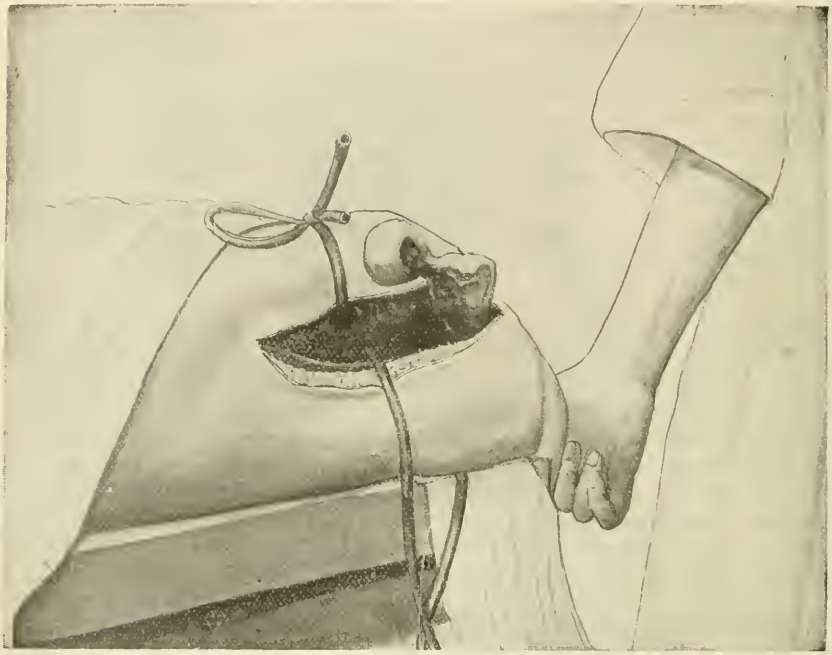

FIG. 1080.—Senn's method of performing bloodless amputation at the hip-joint. Dislocation of head of femur and upper portion of shaft through straight external incision. Elastic constrictors in place, the anterior one tied (Senn).

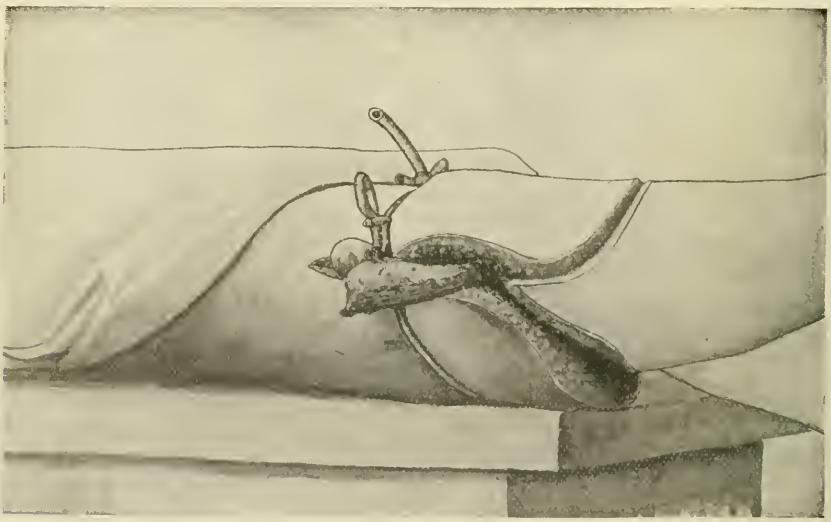

FIG. 1081.—Elastic constriction completed by constricting the posterior segment of the thigh. Flaps formed, including all the tissues down to the muscles (Senn).

is held vertically for a sufficient length of time to make it practically bloodless; the amputation is then completed (Senn's "Practical Surgery").

Other Methods.—John G. Sheldon ("Amer. Med.," April 19, 1902) has modified Senn's method as follows: He disarticulates the head of the femur and frees the upper part of the femur from its attachments. He then introduces a pair of long, stout artery-forceps behind the femur and clamps the femoral vessels. He forms the flap, removes the limb, and ligates the vessels. In this operation the surgeon can work rapidly and can make a flap of any size or shape, and is not hindered by a constriction apparatus; but this method does not cut off the bleeding from the obturator and the sciatic arteries.

Larrey amputated by lateral flaps, and Liston by anteroposterior flaps. Forneaux Jordan's method consists in dividing the soft parts low down, tying the blood-vessels on the face of the stump, shelling out the femur from the soft parts, and disarticulating.

FIG. 1082.—Keen and DaCosta's method of interilio-abdominal amputation ("International Clinics," vol. iv, 13th series).

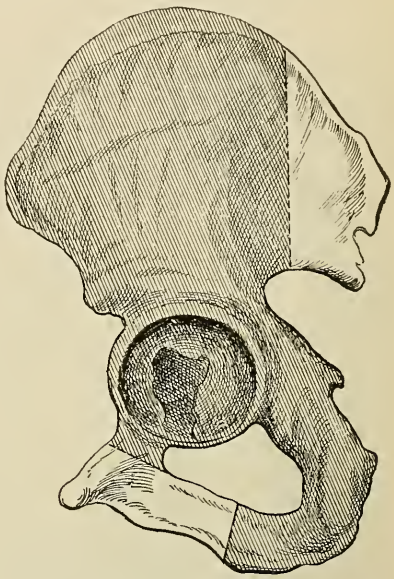

FIG. 1083.—Keen and DaCosta's case of interilio-abdominal amputation. The shaded portion of the bone was removed ("International Clinics," vol. iv, 13th series).

Interilio-abdominal Amputation.—This very formidable operation is occasionally performed for sarcoma of the ilium. The operation was first performed by Billroth in 1891, and the patient died. Prof. Keen and I collected 19 cases, including 1 of our own. Five of these cases recovered (W. W. Keen and J. Chalmers DaCosta, in "International Clinics," vol. iv, 13th series). Our patient perished in thirty-three hours from suppression of urine and with gangrene of the parts supplied by the internal iliac artery. J. H. Pringle has collected 43 cases and has performed the operation 5 times personally. The mortality in the series was 58.1 per cent. Pringle had 3 recoveries out of 5 cases, ("Brit. Jour. Surgery," 1916, iv). In some cases the entire innominate bone has been removed; in others, portions of it have been left. In our case we made the flap shown in Fig. 1082, tied the internal iliac artery after rolling up the peritoneum, but spared the external iliac, kept the femoral in the flap, and sawed through the bones as indicated in Fig. 1083, leaving in place the portions shown in white.

XXXIX. DISEASES OF THE MAMMARY GLAND

Hypertrophy of the Breast (Fig. 1084).—This is a rare condition. It may affect one breast or both. It is most apt to appear at the age of puberty, but it may appear in childhood, adult life, or old age. The breast may attain enormous size. In Porter's case the breasts of a woman of thirty-seven were

so very large that they were carried hung upon a frame ("Boston Med. and Surg. Jour.," March 3, 1892).

These very large breasts are not composed of true gland tissue, but rather of fat and connective tissue ("Diseases of the Breast," by A. Marmaduke Sheild). Hypertrophy may also occur in the male breast. In some cases hypertrophy occurs so rapidly as to merit the name *acute*. Such cases may prehaps be sarcomatous.

Treatment.—Be sure it is hypertrophy and not sarcoma, adenoma, or lipoma. Try recumbent posture, dry diet, pressure, and iodid of potash (Sheild, Ibid.). If these means fail, amputation is the only recourse.

Fig. 1084.—Hypertrophy of breast.

Mammillitis and Fissure.—The nipple may inflame as a result of injury, but the condition is rarely encountered except in a woman who is nursing a baby. It is most common after a first pregnancy, when the nipple is deformed or when the skin is delicate. The nipple is slightly injured during nursing, and the epithelium is macerated by the milk and saliva. If the inflammation be not arrested, a spot excoriates or an irritable ulcer forms (a fissure). A fissure is often surrounded by an area of acute inflammation, and nursing causes intense agony. Because of the pain the mother is apt to extend the intervals between nursing, and as a consequence the breasts become swollen with retained milk. The ulcer not unusually bleeds when the breast is taken by the child. Besides the fact that a fissure causes pain to the mother, it often leads to grave trouble. It is a suppurating area, and as such may lead to abscess of the mother's breast, or may impair the health of the nursing child.

Prevention of Fissure.—During pregnancy the nipples should be carefully attended to. They should be washed often in sterile water and bathed in alcohol, and if retracted, ought to be drawn out repeatedly. During the period of lactation the nipples are washed in sterile water, dried, and dusted with borated talc powder as soon as an act of nursing is completed. Washing the nipples regularly with the following solution tends to prevent the formation of a fissure: iodid of mercury, 2 gr.; alcohol, 1½ oz.; glycerin and distilled water, of each a pint (Lepage). If a small abrasion appears, order the woman to wear a nipple-shield during nursing, and after each act of nursing to wash the part with hot sterile water, to dry it and to dust borated talc over the surface. If a fissure forms, wean the child at once, and dry up the milk on both breasts. It is useless to try to dry it up in one breast. Milk may be dried up by applying ointment of belladonna locally, and administering iodid of potassium internally; by strapping the breasts with adhesive plaster (Parker); or by applying to the nipples six times a day a 5 per cent. solution of cocain in equal parts of glycerin and water (Joise). The fissure is not treated by ointments. These preparations are septic, prevent drainage, and aggravate maceration. Wash

the fissure twice a day with peroxid of hydrogen, dress it with gauze wet in boric acid solution (10 gr. to 1 dram of water), and cover the dressing with waxed paper. If the fissure resists treatment, touch it with lunar caustic.

Acute Mastitis and Abscess.—Acute inflammation of the breast, as a result of injury of the breast or nipple, may occur in either sex at any time of life. Very commonly in both sexes a few days after birth the breast becomes distended with a material which in reality is milk. The fluid is usually small in quantity. The process is physiological, and, as a rule, ceases spontaneously (Guelliot). If it lingers, the application of belladonna ointment will stop secretion. If the nurse meddles with the glands and tries to squeeze out the fluid, acute mastitis is apt to arise in one gland, or occasionally in both. The skin of the breast reddens, the gland swells and becomes tender and painful, the child loses its appetite and becomes feverish, restless, and sleepless. Such a condition is treated by the local use of alcohol. If pus forms, the local signs and constitutional symptoms are aggravated. Evacuate the pus, dress with hot antiseptic fomentations, and be sure that the child is well nourished. Tonics and stimulants are indicated.

A condition identical with the secretory activity of the glands of the newborn may occur in either sex at puberty. The methods of treatment are the same in both cases. As a matter of fact, at this time of life rarely more than one lobule inflames, and suppuration is most unusual.

Acute mastitis is most usually met with in a woman who is nursing a child, and is due to bacterial infection. Primiparæ are particularly liable to develop mastitis. So are women with deformed nipples. In most cases an abrasion of the nipple exists, and through this breach of continuity bacteria gain entrance to the breast-tissue. The abrasion may be so slight that it can only be detected when the nipple is examined through a magnifying-glass (Marmaduke Sheild). Streptococcic infections are very generally due to inoculation of a fissure of the nipple. Bacteria may pass up the milk-ducts, coagulating the milk and penetrating through the walls of the acini. Staphylococci not unusually pursue this route in reaching the breast-tissue. Occasionally causative bacteria reach the breast through the arteries (in septicæmia and in septic wounds of the genital organs).

Symptoms.—There are pain, swelling, and tenderness in the breast, and in most cases a fissure or abrasion exists. There is a febrile condition. Occasionally a chill ushers in the attack.

If a case supposed to be acute mastitis proves utterly rebellious to treatment the suspicion should arise in the surgeon's mind that the condition is acute or inflamed cancer (carcinoma mastitoides, see page 1586). If such a doubt arises, a piece of tissue must be excised for microscopical study.

Treatment.—Order the patient to suspend nursing. The physician endeavors to arrest the secretion of milk. Treat the nipple as advised on page 1574. Support the breast and apply ichthyol ointment.

Mastitis may undergo resolution; it may terminate in organization and induration; it may eventuate in suppuration.

Acute abscess of the breast follows acute mastitis. There may be but one area of suppuration, or multiple foci may exist, which eventually fuse. The symptoms of mastitis, local and constitutional, are greatly aggravated. After a time the skin becomes dusky and edematous. The axillary and superficial cervical glands enlarge. The abscess will eventually open spontaneously at one or more points, leaving branching fistulæ. A superficial abscess is situated just beneath the nipple, and pus may flow from the nipple.

An intramammary abscess is in the depths of the gland. There are often multiple foci of suppuration. Nodules are felt in the gland, pus may run from the nipple, but cutaneous redness is late in appearing.

Retromammary abscess is a rather rare condition. It may occur alone or be

associated and connected with an area of intramammary suppuration. It may result from metastasis or from caries of a rib. The breast is lifted up by the fluid beneath it.

Treatment.—Open a superficial abscess by an incision radiating from the nipple. Treat as any other acute abscess. An intramammary abscess should be opened by a radiating incision, and pockets of pus should be broken into with the finger. An examination is made to determine if a retromammary abscess also exists. If this is found to be the case, an incision is made at the point of junction of the thorax and mammary gland, and at the lower border of the gland. The gland is raised from the chest wall, the pus evacuated, a drainage-tube is inserted, and a few sutures are introduced. If retromammary abscess exists alone, make the last-named incision in the first place.

Chronic Mastitis.—This condition may be present in only a portion of the breast, or may attack many lobules (lobar mastitis). The ordinary form may arise after weaning a child, or may be due to a blow, to the pressure of corsets, or to numerous slight traumatisms. It may occur in the young, the middle aged, or the old. The patient has slight pain at times in the gland. Examination detects a firm, elastic area, which is somewhat tender and does not possess distinct margins. The skin is not adherent to the mass unless suppuration occurs. If the mass be pressed against the chest by the surgeon's fingers, it becomes evident that no real tumor exists.

Treatment.—Remove any cause of irritation. Support the breast by a spica bandage. Apply ichthyol ointment. During the night employ a hot-water bag. If pus forms, treat as before directed.

Chronic lobular mastitis is a condition in which numerous lobules become indurated. The real cause of this condition is unknown. It may occur at any age after puberty, and often attacks both breasts. Such a breast is apt to be painful, especially at the menstrual periods; it feels unnatural, solid, and careful examination detects numerous indurated areas, each of which is of small size. At the menstrual period the breast enlarges and new nodules may be detected. In some of these cases violent neuralgic pains are present in the gland (*mastodynia*). Chronic lobular mastitis is apt to lead to cyst formation. When cysts form fluid may occasionally discharge from the nipple.

Treatment.—Support the breast and apply ichthyol ointment or belladonna ointment. Examine the generative organs and correct any existing abnormality. Improve the general health by good food, tonics, and open-air life. In cases in which multiple cysts are known to exist the question of treatment is uncertain. There seems to be little doubt that such cases tend in some instances to eventuate in cancer. I believe that the proper treatment when multiple cysts exist is extirpation of the breast.

Tuberculosis of the Mammary Gland.—Sir Astley Cooper in 1829 wrote on "scrofulous swellings" of the breast, and Velpeau also referred to them. Nevertheless, Virchow, in his treatise on tumors, stated that the mammary gland was not subject to tuberculosis. Durbar first proved the existence of the condition by histological and bacteriological observations. Primary tuberculosis of the breast is a rare condition. If we are to judge from English and American literature, it is a very rare condition. In 1902 Bindo de Vecchi was able to report 1 case and collect 77 from literature ("Extratis della Clinica Chirurgica," No. 8, 1902). Braendle in 1906 reported 11 cases from the Tübingen clinic ("Beit. zur klin. Chir.," vol. i, 1906). Powers, of Denver, reported 4 cases ("Annals of Surgery," Feb., 1913). About 80 cases confirmed by bacteriological findings and histological study have been reported. It is seldom that both glands are involved. Tuberculosis of the breast may be secondary to tuberculosis of the skin, of related glands, of the rib, etc. It may result from some distant tuberculous lesion of bone, of joint, of lung, etc. It

may be a part of general miliary tuberculosis. We consider here primary or, as Geissler named it, solitary tuberculosis, tuberculosis apparently limited to the breast in an individual free from evidences of antecedent tuberculosis, and of tuberculosis elsewhere. It occurs usually in those of excellent general health. The route of infection may be by the blood, by the lymph-ducts, and perhaps by the lymphatics from the skin or nipple. The lesion begins in the periacinous and periductal connective tissue. The ducts and acini become involved later. E. M. Von Eberts ("Amer. Jour. Med. Sci.," July, 1909) states that there is no reported case before the age of puberty, that the most advanced case reported was fifty-three years of age, that maturity of the gland and lactation predispose, and that the reported cases show the proportion of the married to the unmarried as 4 to 1. It is vastly more common in women than in men. In many cases there is a history of antecedent inflammation or abscess during lactation. In some cases there is a history of traumatism. There are two forms of the condition, and in each form, sooner or later, degeneration occurs, and fistulæ from a cold abscess arise (see page 267); these forms are *nodular* and *confluent* (von Eberts, Ibid.). In the *nodular* form a nodule, several nodules, or many nodules arise in the glandular tissue. There is little or no pain. If nodules are under the nipple retraction may occur. The condition is very slow in progress and a year or several years may elaspe before degeneration occurs. Degeneration results in cold abscess (see page 262) and often in fistula formation. Schley has pointed out that cold abscess is a termination more common in the confluent than in the nodular type ("Annals of Surgery," 1903). In the confluent form the condition develops much more rapidly, is associated with pain, is most apt to arise during lactation, is particularly prone to abscess and fistula formation, and is liable to acute exacerbation from secondary pyogenic infection. The axillary glands are found enlarged in three-fourths of all cases of primary tuberculosis. Cases have been reported of carcinoma and of adenoma associated with tuberculosis.

Treatment.—In a very slowly developing nodular case, in which it is certain lactation will not arise, it may be considered proper to treat the condition with tuberculin, etc. (see section on Tuberculosis). In the confluent form and in cases of the nodular form in which tuberculin treatment has failed, or in which we cannot exclude the possibility of pregnancy, the breast should be removed and the glands and fat should be removed from the axilla. Most of the cases recover permanently after radical operation (Braendle, of Tübingen, in "Beit. zur klin. Chir.," 1906, Bd. 1). Powers ("Annals of Surgery," Feb., 1913) advises the thorough removal of the breast, pectoral fascia, and axillary contents, and with this recommendation I am in accord.

Cysts and Tumors of the Nipple.—Tumors are rare in the nipple, but do sometimes occur. The following growths are occasionally seen: fibroma, angeioma, papilloma, myxoma, myoma, and epithelioma. Sebaceous cysts of the nipple and areola are not very unusual. A cancer of the nipple may be a primary growth, or may be secondary to gland cancer. Primary epithelioma of the nipple presents the same general characters as epithelioma in any other part. It begins as an indurated area in the areola, or an excoriation of the nipple. Ulceration soon occurs. The ulcer is irregular in outline, has hard edges, and furnishes a foul, red, sanious, and fetid discharge. The mammary gland becomes infiltrated at an early period. The subclavian glands enlarge, and later the axillary glands. Such a growth must not be confounded with a chancre of the nipple.

Treatment of Tumors of the Nipple.—Innocent tumors are to be excised and the breast need not be removed.

Epithelioma of the nipple requires the complete extirpation of the breast, and also the clearing out of the lymphatic contents of the axilla, and possibly of the subclavian triangle.

Paget's Disease of the Nipple (*Malignant Dermatitis*).—Sir James Paget made a report upon 15 cases of this rare disease ("St. Bartholomew's Hospital Reports," vol. x, 1874). Over thirty years previous to Paget's paper Velpeau described a like or identical condition ("Leçon orales de Clinique Chirurgicale," 1841). It is a rare condition. Only about 150 cases have been reported (Jopson and Speese, "Annals of Surgery," August, 1915). Paget's disease is held to be a peculiar chronic inflammation of the epithelial layer of the nipple and areola occurring in women beyond middle life, and is regarded as a not unusual precursor of epithelioma of the nipple and of duct cancer. Paget's disease is not a simple eczema, it is not associated with the usual causes and attendants of eczema, either local or constitutional, and is not cured by remedies which control the ordinary disease. It begins in the cells of the Malpighian layer, which grow downward but do not invade tissue like cancer cells, and it causes proliferation of cells of the acini and milk-ducts.

The diseased area is raw and red, and from it exudes copiously a thick, yellow discharge. In some cases inflammation of the nipple and areola is secondary to duct cancer, auto-infection of the nipple having been effected by the fluid flowing from the ducts but true Paget's disease is a primary affection. Practically always cancer follows. In rare cases squamous-celled epithelioma arises on the nipple or areola. Commonly duct or gland cancer follows.

Treatment.—Removal of the entire breast and clearing out of the axilla.

Tumors and Cysts of the Mammary Gland.—These tumors may be innocent or malignant. Tumors may occur in childhood (angeioma, sarcoma, fibro-adenoma). Malignant tumors are very rare before the age of twenty-five.

Innocent Tumors of the Mammary Gland.—The innocent tumors are: *Periductal fibroma*, *fibrocystadenoma*, *papillary cystadenoma*, *simple adenoma*, *periductal fibromyxoma*, *myxoma*, *angioma*, *lipoma*, and *enchondroma*. It is maintained by most authorities that any innocent tumor of the gland may and is apt to become malignant.

Periductal Fibroma, Fibro-adenoma.—The nomenclature of fibro-adenomata is in a state of great confusion. The name fibro-adenoma was given by Cornil and Ranvier to the same sort of growth which the younger Gross called a fibroma, Billroth an adenofibroma, and Sir Astley Cooper a chronic mammary tumor. It is doubtful if a pure fibroma ever occurs in the mammary gland. A fibro-adenoma consists of acini surrounded by fibrous tissue. Each of these structures proliferates, but the fibrous tissue does so much more rapidly than the glandular. Bloodgood ("Amer. Jour. Med. Sci.," Feb., 1908) says, "the fibro-adenoma microscopically is nothing more than an encapsulated area of normal breast tissue, in which the parenchyma, in the early stage of the tumor, is greater in amount than the normal breast. Later the parenchyma undergoes pressure atrophy and the tumor may become calcified." A growth of this character is surrounded by a capsule and is movable. It is firm, elastic, lobulated, superficially situated, and of slow growth. It is unassociated with retracted nipple, glandular enlargement, adhesion to the skin, or cachexia, and may occur at any age up to fifty, but is most common between twenty and thirty (Sir. J. Bland-Sutton). Such a tumor is rarely very painful, but it may be tender on rough handling and may be painful at the menstrual period. As a rule, there is but one of these tumors in the mammary gland, but the tumors may be multiple in one gland, or one or more may exist in each gland. It is not very common for sarcoma or carcinoma to arise.

Periductal Fibromyxoma.—It is most common in young women. It may be multiple in one breast or both. It is an encapsulated, lobuled, and elastic growth, which is seldom painful, is usually small, and often remains quiescent indefinitely or even disappears. It may enlarge and even attain a great size. When it enlarges it is apt to become cystic and sarcomatous.

Treatment of Periductal Fibroma and Fibromyxoma.—The tumor should be extirpated. If a supposedly innocent growth, removed by a limited operation, has been really the seat of beginning malignancy, the wound will soon thicken after healing and recurrence will be rapid. Halsted has shown that in such a case re-operation, however extensive, will not obtain a cure. Hence, it behooves us in doubtful cases, if we err at all, to err on the side of radicalism. In a case recognized as doubtful, when the growth is removed a frozen section should be made at once and be studied then and there, and the surgeon should suspend operation while he waits for the report. If the report shows that the growth is malignant, at once remove the breast radically and clean out the axilla. A tumor known to be innocent may be removed through an incision made along the junction of the mammary gland and chest, at the lower margin of the gland, as Thomas proposed, or, better, at the edge of the outer hemisphere, as advocated by Warren ("Annals of Surgery," June, 1907). The incision exposes the fibers of the great pectoral muscle, the gland is raised from the muscle, and its posterior surface exposed. Any growth is exposed by an incision from center to periphery and this incision is exploratory. Warren removes an innocent tumor, a cyst, or cysts by a V-shaped incision, the apex of the V being at the center of the gland, and he wisely insists that the tumor is not to be dissected out. Several radiating incisions may be necessary to explore a cystic breast. The V-shaped space from which the tumor or cyst has been removed is closed by a double row of catgut sutures. Incisions for exploration seldom need to be closed by suture. The gland is sutured to the outer edge of the pectoral fascia, and a row of sutures is inserted through the deep layer of the superficial fascia. Warren calls this operation *plastic resection of the breast.* It leaves the patient free from deformity.

Fibrocystadenoma or **cystic adenoma** (**adenocele**) is a rare form of slowly growing tumor, which is apt to attain a large size, which is nodular in outline, hard to the touch, and firmly attached to the mammary gland, but mobile upon the chest. A cystic adenoma has a distinct capsule. This form of tumor is painless, and is most apt to occur in women between thirty and forty who have borne children. The growth is adherent to the skin, but the cutaneous surface is not discolored, the cutaneous veins are not distended, the axillary glands are not enlarged, and the nipple is not retracted. From the walls of the dilated acini papillomatous growths are apt to arise (intracystic vegetations). The growth may be a precursor of cancer.

Treatment.—Radical removal of breast and clearing of axilla.

Papillary Cystadenoma.—This condition is often called villous papilloma or duct papilloma. There is much more epithelial proliferation than in the fibrocystadenoma, and the warty masses project into the cyst cavities. These growths are firm, grow slowly and painlessly, and seldom fluctuate. They do not adhere to the skin, attain a large size, or cause glandular enlargement. They are situated near or under the nipple, and occur particularly in middle life. Discharge of serous fluid from the nipple is a common symptom. In many cases there is a bloody discharge. The condition tends to become cancerous.

Treatment.—The danger that duct cancer will arise is so great that the old operation of excision of the tumor should give way to radical removal of the breast. In any duct growth with a serous discharge from the nipple it is wise to remove the breast and to clear the axilla. If the discharge be bloody that radical procedure is imperative.

Simple Adenoma.—This is a very rare tumor. It occurs in young and middle-aged women. It is soft, nodular, and freely movable. It does not adhere to the skin and does not cause lymphatic involvement. It consists of glandular acini and a very delicate stroma of connective tissue. It tends to become cancerous.

Treatment.—Extirpation of the tumor. Touch the wound with chlorid of zinc solution (10 gr. to the ounce) in order to destroy cells which might lodge and grow.

Myxoma is a rare tumor, and only occurs in a person of middle age or beyond. The growth is solitary, is soft, may be round or lobulated, and occasionally fungates. The nipple is not retracted, the superficial veins are not distended, and the axillary glands are not enlarged.

Treatment.—Removal of the mammary gland.

Angioma.—This form of tumor is very rare. It may arise secondarily to a nevus of the skin (Sir. J. Bland-Sutton). The diagnosis of angioma of the skin is readily made. In a cavernous angioma of the breast it will be found that the tumor can be lessened in size by pressure, and will be increased in size by coughing, laughing, and holding the breath. Pulsation may be detected and a bruit may be audible.

Treatment.—For treatment of nevus see page 419. If a cavernous angioma exists in the mammary gland, it will be necessary to extirpate the gland.

Lipoma and *enchondroma* occasionally occur in the breast.

Cysts of the Mammary Gland.—Involution cysts (*cystic degeneration of the mamma*) occur in women who are approaching the menopause. Such cysts occur earlier in those who are sterile than in those who have borne children, and may arise after chronic mastitis. The parenchyma of the gland undergoes atrophic change, but the ducts remain, become blocked and dilated. Numerous small cysts form, and both glands, as a rule suffer. Villous growths may arise in the walls of the ducts. In some cases there is much white fibrous tissue between the cysts (cystic fibroma).

The subjects of this disease are often nervous, hysterical, and despondent. One or more ill-defined indurations are detected. Frequently there is a history of discharge from the nipple and of attacks of lancinating pain in the breast. Cystic breasts are dangerous, because the intracystic vegetations are liable to eventuate in duct cancer. One-fourth of these cases are cancerous when first seen (Speese, quoted by Primrose in "Amer. Jour. Med. Sci.," Jan., 1913).

Treatment.—In such cases, after confirming the diagnosis by an exploratory incision, remove the entire breast.

Lacteal cyst (**galactocele**) is an accumulation of milk brought about by blocking of some of the milk-ducts. It usually arises soon after the delivery of the child, but may not be noted for months or even several years after childbed. It grows rapidly from the time it is first detected. A large quantity of milk may collect, and rupture of the cyst walls may occur, the fluid passing into the glandular connective tissue.

A galactocele is rounded, fluctuates distinctly, and increases in size during nursing. There is little or no pain. In some cases the contents of the cyst coagulate and a solid mass is formed.

Treatment.—Incision and drainage.

Hydatid cysts are rare, but do occasionally occur. There are 33 positive cases on record (Le Conte, in "Amer. Jour. Med. Sci.," Sept., 1901). A small, hard, movable, and painless mass appears in the mammary gland. Usually it gradually increases in size, but it may grow rapidly for a time and then remain apparently almost stationary for a period. If rapid growth takes place there is always pain, and pain is usual in any case when the cyst attains considerable size. Fluctuation is often absent and crepitation is never obtained (Le Conte). Suppuration is apt to occur and sinuses may form.

Treatment.—A small and recent cyst may be extirpated. If the cyst is not recent, but is fairly large and adherent, incise, evacuate, and pack with gauze. If the cyst is large and adherent, but is surrounded by considerable breast tissue, partially amputate the breast. If the cyst is large and the breast

practically destroyed, or if the nipple adheres to the cyst, remove the mammary gland (Le Conte, Ibid.).

Malignant tumors of the mammary gland are ten times more common than innocent tumors. We should regard every palpable tumor in the gland as malignant until it is proved to be innocent. In other words, we reverse the rule of jurisprudence. We regard every tumor as guilty of malignancy until its innocence is proved. If the mistake is made of regarding an innocent tumor as malignant, the woman loses her breast needlessly. If a malignant tumor is regarded as innocent the woman loses her life needlessly. "The fact that malignant degeneration of benign growths in the breast is of frequent occurrence is obviously another convincing argument for the removal

FIG. 1085.—Scirrhous carcinoma (J. Collins Warren).

of all breast tumors. A recent study of Speese showed that no less than 26 per cent. of the cases of chronic cystic mastitis (that is, that form of 'abnormal involution' occurring at the menopause) examined by him showed malignancy. So, too, cyst adenomata are found associated with carcinoma, the frequency of such association being placed by some authors as high as 15 per cent. Inflammatory conditions of the breast resulting in mastitis are often found in the early history of cancer cases. All these facts point conclusively to the frequent occurrence of malignant degeneration in benign growths of the breast" (A. Primrose, Loc. cit.).

Sarcoma of the mammary gland is a very rare growth (not over 3 per cent. of breast tumors). It may occur at any age from puberty to old age. It was

long thought to be most common from twenty to thirty-five years of age, but Rodman's investigations show that one-half the cases occur in the fifth decade of life (Rodman on "Diseases of the Breast"). The growth may be composed of round cells or spindle cells. The spindle-cell growth is the most common. Both round and spindle cells may be present, and myeloid cells may be found. Myxomatous change may occur. Circumscribed sarcoma arises usually between the ages of twenty and thirty; it is firm to the touch, as it contains much fibrous tissue, is painless, does not grow very rapidly, glands are seldom involved, and there is no cachexia. The nipple is not retracted. The growth may adhere to the skin. If it be composed of giant cells or spindle cells it will rarely return after extirpation of the breast.

Diffused sarcoma is composed of small round cells, arises in the center of the breast, and grows with great rapidity. It is most commonly met with about the age of thirty-five, and a history of injury can often be elicited. The tumor is soft, some parts being softer than others because of cyst formation. It is usually mobile upon the thorax, though it soon becomes adherent to the skin. The tumor reaches a very great size, and soon fungates through the skin. There is little or no pain. The cutaneous veins over the tumor are distended, the nipple is not retracted, and the axillary glands are not often enlarged. Diffuse sarcoma is apt to recur after removal.

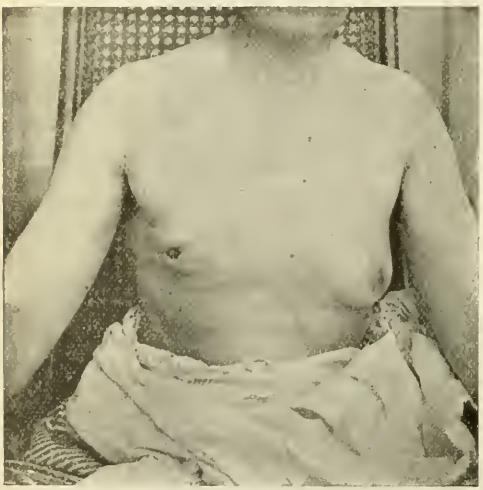

Fig. 1086.—Scirrhous carcinoma of right breast showing retraction of nipple (Dr. Blanck's patient).

Treatment.—Remove the breast, and if the muscles of the chest wall are infiltrated, remove them. The axillary glands should be removed whether they are enlarged or not. Operation will not cure when metastases exist. If the case be inoperable, we can try the use of Coley's fluid. If the toxins of erysipelas fail to arrest the progress of the disease, keep the patient as comfortable as possible by the administration of cocain and morphin.

Endothelioma.—This is a very rare tumor. I have had 1 case of it. The diagnosis cannot be made from carcinoma.

Treatment.—As for cancer.

Carcinoma or Cancer of the Mammary Gland of the Female (Fig. 1085).—The great majority of mammary tumors are cancerous. Cancer is due to proliferation of the epithelium of the acini (acinous cancer) or of the ducts (duct cancer).

Acinous cancer is vastly more common than duct cancer. Usually there is much connective tissue and but little parenchyma in the growth (scirrhous cancer). In some cases there is little connective tissue and much parenchyma (encephaloid or medullary cancer). If colloid degeneration of the parenchyma or stroma occurs, the growth is spoken of as colloid cancer.

Scirrhus (Figs. 1085 and 1086), the common form of acinous cancer, is almost as hard as stone. On section it is concave, and Sutton says "resembles an unripe pear." The tumor is without a capsule, and the epithelial cells are surrounded by masses of fibrous tissue. Portions of tissue, even some distance away from the tumor proper, contain foci of proliferating embryonic epithelial

cells. In atrophic or withering scirrhus the fibrous stroma contracts and epithelial cells undergo fatty degeneration.

Halsted in 1898 described *adenocarcinoma*. It is the initial movement in the direction of unrestrained epithelial proliferation, and sections of the tumor show the formation of tubular acini. The most characteristic sections resemble adenoma. Adenocarcinoma is not the common form of breast cancer. In the common form the proliferating epithelium attains no resemblance to glandular structure, but multiplies irregularly in connective-tissue spaces or lymph-spaces.

Causes and Symptoms.—Scirrhus is more common among women who have borne children than among those who have not. Heredity is manifest in only about 10 per cent. of cases. The younger Gross found it in 1 case out of 9. Trauma has no apparent influence in producing cancer. The disease is rare before the age of thirty-five, and is most common between forty-five and fifty. The author operated for scirrhus of the breast on a woman only twenty-seven years of age. Henry saw a woman of twenty-one with cancer. It is frequently

FIG. 1087.—Carcinoma of right breast. Lesion first noticed six months before photograph was made.

met with in the aged. These tumors are rare in the negro race. A hard nodule is found in the breast, usually under the nipple, but possibly far away from it. The growth is nodular, and is immobile from the beginning. In a large, fat breast there is often a deceptive sense of mobility, because some of the breast tissue moves with the tumor. The cancer may have been present for a considerable time before being discovered. Sometimes widespread lesions develop from a small or an undiscovered breast cancer (pleural effusion, enlarged glands of the neck, disease of the spinal cord, of bones of the skull or brain). In obscure lesions of bones and viscera examine the mammary glands, because the trouble may be due to metastasis from an undiscovered carcinoma of the breast. The glands of the armpit always and soon become diseased, the glands above the clavicle often enlarge, and the arm may swell. Growth may arise within the chest, either by lymph regurgitation from the axillary and subclavian glands, or directly through the chest walls to pleura and lung or to mediastinal glands. Oelsner and Poirier show that there is a lymph tract running from the breast to glands within the thorax, passing through the great pectoral muscle and "the fourth interspace at the level of the costochon-

dral articulation" (Primrose, in "Amer. Jour. Med. Sci.," Jan., 1913). "Fortunately, these glands are not frequently involved, a circumstance which may be accounted for by the atrophy of this channel in senile mammæ, in which cancer usually develops (Poirier)" (Primrose, Ibid.). Retraction of the nipple is present in over one-half of the cases. It occurs when the growth is near the nipple, and is due to the contracting fibrous tissues of the tumor pulling in the milk-ducts. If the growth be far away from the nipple, a dimple is apt to form in the skin of the breast because of the pulling upon the suspensory fibers. Neither retraction of the nipple nor a cutaneous dimple proves the existence of cancer. One or both may be noted in a breast containing a scar (from a wound or a healed abscess), in tuberculosis of the breast, and in mammary syphilis. The dimple is not due to adhesion between the tumor and the skin. It is noted even when the tumor is far away from the skin. It may not be obvious unless the gland be moved to and fro or unless the skin

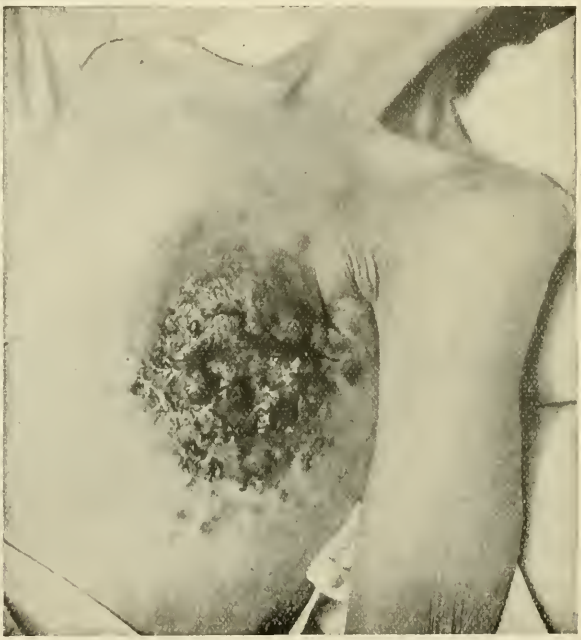

Fig. 1088.—Recurrent carcinoma. Cancer en cuirasse.

over the breast be pushed in various directions. When this is done it becomes evident that the skin, at a certain point, is held inward. The dimple is a very valuable early symptom.

Glandular carcinoma in the axilla soon follows the appearance of a scirrhus although there may be no palpable enlargement for a considerable time. The glands become very hard and adherent. In over 60 per cent. of persons the glands of the axilla are felt to be enlarged when the patient first comes for treatment. Because the surgeon cannot feel enlarged glands is no proof that they do not exist. As a matter of fact, the glands are usually involved within two months of the beginning of the disease, but the involvement can rarely be detected externally until months later. Enlargement of the axillary glands is followed by enlargement of the glands in the posterior cervical triangle and in the mediastinum. Herbert Snow has shown that the blocking of the axillary glands often leads to regurgitation of lymph containing cancer-cells, the cells being thus deposited in the head of the humerus and in the thymus gland. Cancer

in the thymus and in the mediastinal lymph-glands, after a time, causes a projection of the sternum (the *sternal symptom*). When the axillary lymphatics are extensively involved the arm swells from obstruction to the lymph-flow (lymphedema) or pressure upon the vein. If there be lymphatic obstruction the skin of

Fig. 1089.—Cancer en cuirasse.

the breast becomes pitted and resembles *pig skin*. The skin is actually cancerous or soon becomes so by infiltration. Each pit is the opening of a sweat-gland. The sweat-duct is held down by contracting fibrous tissue. This condition is termed *peau d'orange*, or pigskin saddle appearance. The tumor usually grows rather slowly unless lactation is established, when it grows with frightful rapidity. As it grows it infiltrates adjacent structures (the pectoral fascia, pectoral muscles, subcutaneous cellular tissue, and skin). When a tumor becomes adherent to the skin the skin becomes congested and of a dark purple hue. When the skin is destroyed, an ulcer forms, and around this ulcer the skin becomes red and filled with cancerous nodules, which feel like shot in the skin. Metastases are apt to occur in the bones, liver, brain, pleura, lung, spine, thymus gland and rarely the eye. The pleura and lung may be attacked by direct spread of the growth through the chest wall, from infected mediastinal glands, or by lymph regurgitation from the axillary and subclavian glands.

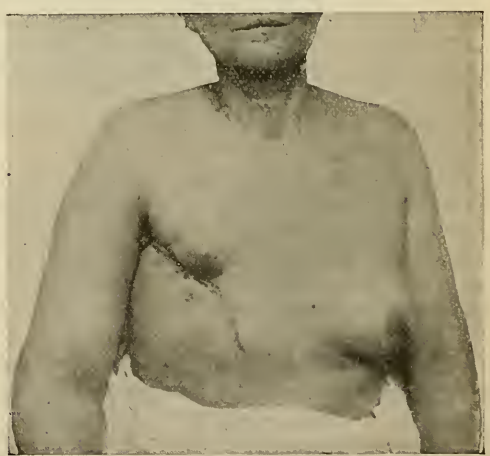

Fig. 1090.—Recurrent carcinoma of the breast.

Pain, absent at the start, is usually present later in scirrhous carcinoma.

It is lancinating and neuralgic in character, and not brought on or increased by handling. It ceases if colloid degeneration begins. The general health is usually unimpaired until ulceration takes place, when cachexia arises. In 1792 Howard described the condition to which Velpeau called particular attention in 1838 as a deep cancer of the integument due to a cancerous state of the deep cutaneous lymphatics. Velpeau named it *ligneous cancer* and also *cancer en cuirasse* (Figs. 1088 and 1089). The cancer en cuirasse of Velpeau is a condition in which the lymphatic vessels of the skin are distended because of obstruction. The skin thickens as in elephantiasis. The blocked-up lymph contains cancer cells and the skin early becomes nodular and cancerous. In most cases the condition is secondary, but primary cases have been reported. The condition may arise from cancer in the breast or may follow an operation for cancer of the breast. The skin of the chest becomes thick and rigid like a leather cuirass. The growth adheres and the soft parts, after a while, adhere to the chest wall. The skin is very extensively invaded. In this condition the chest wall is fixed, respiration is difficult, temperature is commonly somewhat elevated, and there is probably a pleural effusion. The corresponding upper extremity is usually the seat of great swelling from hard edema.

Fig. 1091.—Ulcerating scirrhous carcinoma.

In *atrophic* or *withering scirrhus* the breast becomes very small. In some cases the contraction is so great that it seems as though the mammary gland had been removed. The duration of scirrhus, when left to run its course, varies, but the disease generally produces death within two and a half years. Occasionally it causes death within a year. In atrophic scirrhus the patient may live for many years.

Duct cancer is not a common growth. It arises from the duct walls in conditions of cystic degeneration of the mammary gland. The tumor is softer than the acinous growth and is not nodular. There is no pain, no retraction of the nipple, no skin dimple. Serous or bloody fluid may often be squeezed from the nipple. A duct cancer grows and infiltrates less rapidly, and involves adjacent glands later than does an acinous growth.

Cancer beginning in an *outlying lobule* of the breast may be very deceptive. Such a lobule may be in the side of the chest in the axillary line, in the axilla, just below the clavicle, over the front of the sternum, or over the lower ribs.

Carcinoma mastitoides, acute cancer, brawny cancer, or *inflamed cancer* is a condition originally described by Volkmann in 1875 under the name of *mastitis carcinoma.* It comes on almost suddenly, grows very rapidly, causes violent

irritation, and hence widespread infiltration by small cells. The condition resembles inflammation (Edward A. Schumann, in "Annals of Surgery," July, 1911). In this condition the surgeon cannot make out the outlines of a distinct tumor, but the entire breast is hardened and enlarged, and the skin of the breast is reddened, infiltrated and edematous, and adheres to the gland. There is often pain and heat.

Anatomically related glands enlarge. The disease is most apt to arise late in pregnancy or during lactation and is most common in rather young women. It may be limited to one breast, but both breasts may be involved, successively or simultaneously. The nipple may or may not be retracted. Slight elevation of temperature is usual.

There is rapid metastasis, profound toxemia, and early death. Death occurs in less than a year, perhaps in a few weeks. Billroth's case died in six weeks after the discovery of the cancer.

Any persisting case of supposed acute mastitis should make us suspicious. In such a case excise a piece of tissue for examination. In cutting out the piece small abscess cavities may be discovered even when the condition is cancerous. Schumann (Ibid.) says there are only 13 reported cases of carcinoma mastitoides. Since Schumann's paper Morris Booth Miller reported a case ("Annals of Surgery," May, 1913). I showed a case to the class at Jefferson Hospital in the winter of 1912–13. The woman was pregnant and both breasts were involved. She perished miserably a few months after the onset of the disease and a few weeks after her confinement.

Cancer of the Male Breast.—This condition is seldom met with, though I believe it to be more common than is generally supposed. I have seen 5 cases within the last ten years. Each patient was in the early forties; none complained of pain. In one, the breast had been extremely large from early years. In each case the growth was indurated, but in none was there any retraction of the nipple. The condition in each patient was sirrchus carcinoma. Warfield has collected 32 cases from literature and has added 5 others ("Bull. of Johns Hopkins Hosp.," Oct., 1901). The patients were between forty and seventy years of age; 8 gave a history of injury; in 9 cases there was pain, and in 12 the nipple was retracted. Palermo has collected 750 cases of tumor of the male breast ("Semaine Médicale," May 20, 1908) and 649 of them were cancerous.

Treatment of Carcinoma of the Mammary Gland.—The treatment is early and thorough operation; the earlier and the more thorough, the better. The older surgeons operated simply to prolong life a few months; the modern surgeon operates with the hope of curing the patient. The mortality of the operation is surprisingly small. It is certainly under 2 per cent. Rodman's statistics (2133 operations performed since 1893 by twenty-one American surgeons) show a mortality of less than 1 per cent. I have personally lost 5 patients in over 250 operations. In 1878 Billroth's statistics showed only 8 cures in 143 cases. In 1896 W. Watson Cheyne reported 12 cures out of 21 cases (57 per cent.). His cases now show 54.8 per cent. alive and well from six to thirteen years after operation. Depage's statistics show that 48 per cent. of cases passed the three-year limit ("Presse Médicale," Oct. 21, 1908). Greenough, Simmons, and Burney consider 320 cases operated upon radically " Annals of Surgery," July, 1907); 88 cases passed the three-year limit.

E. S. Judd ("Jour. Amer. Med. Assoc.," April 27, 1912) publishes the following statistics from the Mayo Clinic. He says: "The prognosis as to the probability of a cure in a case of carcinoma of the breast will depend—1, on the length of time the neoplasm has been developing; 2, on the degree of outlying involvement; 3, on the activity of the gland, which will be determined by the age of the patient and the relation to a period of lactation; and, 4, on the thoroughness of the removal of the gland-bearing fascia.

"Data Collected from the Mayo Clinic on 518 Cases of Carcinoma of the Breast, From January 1, 1890, to January 1, 1900:

Average age	55 years, 6 months.
Oldest	75 years.
Youngest	21 years.
Number of cases operated on over ten years before:	
Alive and well	21 (23.5 per cent.).
Dead	23
Not heard from	45
Total	89
Number of cases operated on over five years before:	
Alive and well	74 (30 per cent.).
Dead	76
Not heard from	89
Total	239
Number of cases operated on over two years before:	
Alive and well	233 (44 per cent.).
Dead	134
Not heard from	151
Total	518"

Bloodgood ("Amer. Jour. Med. Sci.," Feb., 1908) sets forth Halsted's statistics: "The statistics in Halsted's Clinic up to the present time show that among 210 cases, in which three years or more have passed since the operation, 42 per cent. are apparently well. If we consider the cases in which the axillary glands, studied microscopically, showed no evidence of metastasis, 61 cases, or 85 per cent., are well. In cases in which the axillary glands showed metastasis (110), 30 per cent. remained free from recurrence for three years. When the glands in the neck showed metastasis (40 cases), only 10 per cent. remained well for three years. In all of these groups metastasis has been observed after an interval of three years of apparent cure. Such late metastasis may take place up to eight years after operation. Excluding these cases of late recurrence, the number of definitely cured in these three groups is reduced to 75, 24, and 7 per cent. respectively, or, for all cases together, 35 per cent. I have not time to give the facts, but there is evidence to indicate that when the microscope fails to demonstrate metastatic cancer cells in the lymphatic glands in the axilla, this is not a positive proof that metastasis has not taken place, and for this reason and others, which space prevents me from stating, there should be no restriction in the complete operation for carcinoma of the breast." It will be observed that of these 40 cases, with involvement of neck and axilla, only 4 passed the three-year limit. If they had not been operated upon, statistics would have been bettered. The surgeon who would not operate on such cases would have a higher percentage of cures for his statistics, but he would have sacrificed to statistical glory these 4 cases. If there be the *slightest* doubt of the diagnosis, make an exploratory incision before making the incisions for the removal of the breast (see Dawbarn's remarks on the deceptive signs given by thick-walled abscesses, in the "Annals of Surgery," March, 1908). A frozen section can be made and examined in a few minutes, and this procedure is demanded in a doubtful case. If the mass proves to be cancer, I always pack in a piece of gauze from which boiling water has just been squeezed and go on at once with the removal of the breast. As Dawbarn shows, this method seals up the open mouths of lymphatics. A radical operation should remove the breast and much of the skin above it, the pectoral fascia, the pectoral muscles, the fat and glands of the axilla, and the fascia over the serratus magnus. As Cheyne says, remove all the glands along the axillary vein and lift up the vein at the apex of the axilla and remove the

glands and fat behind it. The sheath of the vein should always be removed. Cheyne points out that the line of spread must be traced upward along the vessels and nerves and downward along the external respiratory nerve of Bell ("Lancet," March 12, 1904). Cancer of the male breast is to be treated exactly as is cancer of the female breast. If three years after an operation there has been no return, we regard the case as cured (Volkmann's limit). As a matter of fact, recurrences are noted after five years, and this limit should be used instead of three years. It is true that 80 per cent. of those passing the three-year limit remain free from recurrence. Over 90 per cent. of those passing the five-year limit remain free. Coley reported 65 cases of recurrence—15 per cent. recurred after three years and 6 per cent. after fourteen years. Ransohoff collected 10 cases of recurrence during the seventh and eighth years, 2 each after the ninth, tenth, eleventh, twelfth, and fifteenth years, and 1 each after various intervals, from fifteen to twenty-five years. Martin suggests that these later so-called recurrences are really new growths in persons predisposed to cancer ("Annals of Surgery," Oct., 1908). Certain cases are unsuitable for a radical

FIG. 1092.—Halsted's operation for carcinoma of the breast: The first incision.

operation: cases in which metastases exist; cases of *cancer en cuirasse;* cases with mediastinal involvement; cases where axillary involvement is very great. Cheyne would also rule out cases in which large glands may be felt above the clavicle, believing that in such cases the mediastinal glands must be cancerous.[1] Operation is well-nigh useless for carcinoma mastitoides.

Halsted's Operation.—Halsted performs a very radical operation. He removes suspected tissue *in one piece,* and thus prevents carcinoma cells from falling into the wound, for it is well known that if such cells fall into the wound they may grow just as may a graft of healthy epithelium. The neck, shoulder, arm to the elbow, the entire surface of the chest down to the waist, both breasts, the axilla, the side and the back of the diseased side must be sterilized. It is necessary to have, besides scalpels and the ordinary instruments for an operation, a great number of hemostatic forceps (80 to 100). Place the patient recumbent, with a sand-pillow under the shoulder of the affected side. The shoulder is right at the edge of the table and a nurse holds the arm from the side, keeping it at a right angle with the body. Halsted's operation is performed as follows:[2] The skin-incision is made as shown in Fig. 1092, and is carried at once through the fat. The triangular skin-flap (*a*, *b*, *c*) is turned down. The costal insertions of the great pectoral muscle and the muscle are split between

[1] See "Objects and Limits of Operation for Cancer," by W. Watson Cheyne.
[2] "Johns Hopkins Hosp. Reports," vol. iv; "Annals of Surgery," Nov., 1894.

the clavicle and costal portions and up to a point opposite to the scalene tubercle, and at this point the clavicular portion of the muscle and the tissue overlying it are cut through close to the clavicle, and the apex of the axilla is at once exposed. The cellular tissue under the clavicular portion of the muscle is dissected from the muscle, and the splitting of the muscle is continued on to the

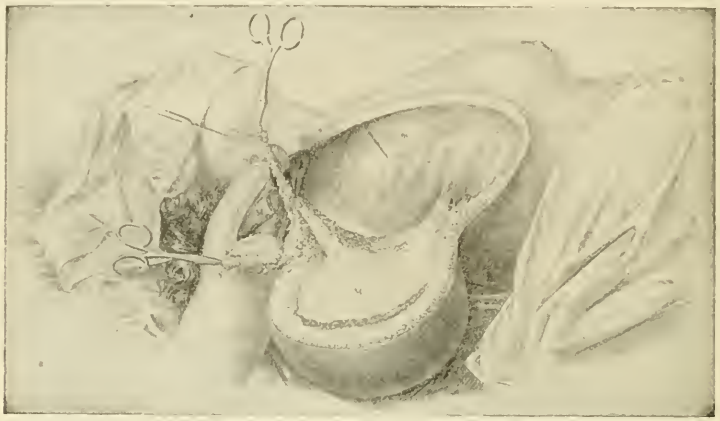

FIG. 1093.—Halsted's operation for carcinoma of the breast: The mass turned down.

humerus. The part of the muscle to be removed is cut through close to its humeral insertion. The whole mass circumscribed by the first incision (skin, breast, areolar tissue, and fat) is raised with considerable force in order to put the submuscular fascia on the stretch as it is stripped from the thorax close to the ribs. It is well to include the delicate sheath of the pectoralis minor muscle. The lower and outer boundary of the lesser pectoral having been passed and exposed, the muscle is cut at a right angle to its fibers and a little below the middle. The tissue over the pectoralis minor muscle near its coracoid insertion is divided as far out as possible, and is then reflected inward to prepare for the reflection upward of this part of the minor muscle. The upper portion of the minor muscle is retracted upward. Some surgeons do not remove the lesser pectoral muscle. I believe it should be removed, because the axilla can then be more easily and rapidly cleared. The removal of the muscle does not impair arm movements, and its retention leads to the formation, when healing is complete, of a cord-like band in front of the axilla. (See Douglas Drew, in "Brit. Med. Jour.," May 17, 1902.) The small blood-vessels under the minor muscle are carefully separated from it, are dissected out very clear, and are ligated close to the axillary vessels. Having exposed the subclavian vein at the highest possible point below the clavicle, the contents of the axilla are dissected away with a sharp knife and the vein and its branches are stripped absolutely clean. The loose tissue about the artery and the nerves should also be removed. When the vessels are cleared, the axillary contents are rapidly stripped from the inner walls of the axilla and the lateral wall of the thorax (Fig. 1093). The fascia which binds the mass to the chest is cut loose from the ribs and the serratus magnus muscle. Just before reaching the junction of the

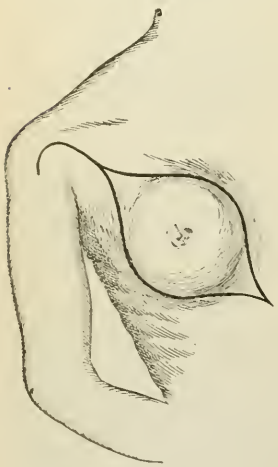

FIG. 1094.—The younger Senn's incision for amputation of the breast.

posterior and lateral walls of the axilla an assistant draws the triangular flap of skin outward in order to spread out the tissue which lies upon the subscapularis, teres major, and latissimus dorsi muscles. The operator cleans the posterior wall of the axilla from within outward. The subscapular vessels are clearly exposed, and are caught before they are cut. In some cases the subscapular nerves are removed, in others they are permitted to remain. Having passed these nerves, the mass is turned back into its normal position and severed

FIG. 1095.—Jabez N. Jackson's incision for removal of the mammary gland.

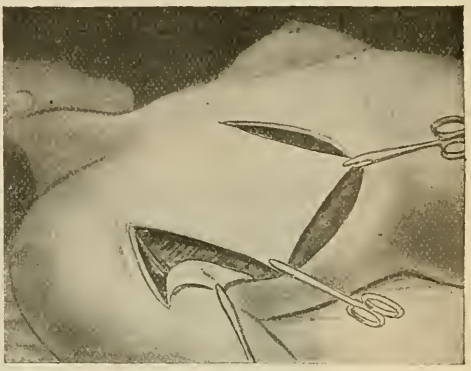

FIG. 1096.—Method of approximating flaps after breast amputation.

from the body of the patient by a stroke of the knife from *b* to *c*, repeating the first cut through the skin. Every bleeding point, however small, is tied with fine silk. From 60 to 100 ligatures or even more may be required.

After the completion of the operation the wound into the axilla is closed with a subcuticular stitch of silver wire; if a cut has been carried above the clavicle, it is closed in the same manner, and the edges of the elliptical opening are brought nearer together by a purse-string subcuticular stitch. Thiersch grafts cut from the patient's thigh are used to cover the gap. Silver-leaf is placed over the wound, this is covered with gauze, bandages are applied, and the dressing is overlaid by a plaster-of-Paris bandage, which includes the head, neck, chest, and arm. The area from which grafts have been taken is dressed with sterile gauze or an ointment containing boric acid.

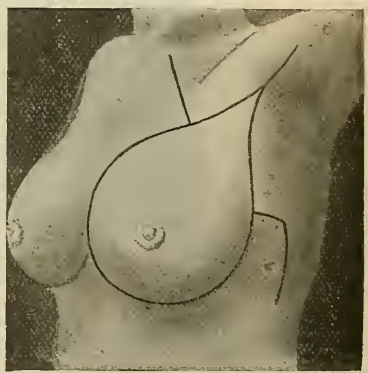

FIG. 1097.—Warren's incision for removal of the mammary gland.

Formerly I did not open the subclavian triangle. I believed that these glands were involved from the axillary lymphatics only, that when they were involved the mediastinal glands were sure to be affected (the route to them being more direct) and that operation was certain to be useless. When the subclavian glands are involved from the axillary lymphatics this is true, but in some cases they are involved by way of the direct lymph paths from the mammary gland. In such a case the mediastinal glands may be free, and cleaning out the subclavian triangle may save the patient. I always open the subclavian triangle and clear out fat and glands if no glands or only a few small glands have been palpable before operation. If there be a large glandular mass in the triangle, operation is useless. I always open the triangle if the tumor of the mammary gland is in the upper hemisphere, or if I discover enlarged glands at the apex of the axilla, whether there are or are not small palpable glands

above the clavicle. An *x*-ray examination of the mediastinum should be made, before deciding upon operation (see page 1612).

The Younger Senn's Incision.—A very useful incision is that described by the younger Senn, and shown in Fig. 1094. The breast is circumscribed by two curvilinear incisions which meet above, at the border of the great pectoral muscle. The incision is continued a little internal to the outer border of the muscle to about 1 inch above the apex of the axilla, when it is curved outward in the deltoid region, and terminates at the level of the apex of the axilla. The breast is removed from the wall of the chest, and is then suspended by axillary glands and fat, which are removed *en masse*.[1] This incision gives a free exposure, opens the axilla from in front, enables the surgeon quickly to locate and freely to expose the axillary vein, and the resulting scar does not materially limit the motions of the arm.

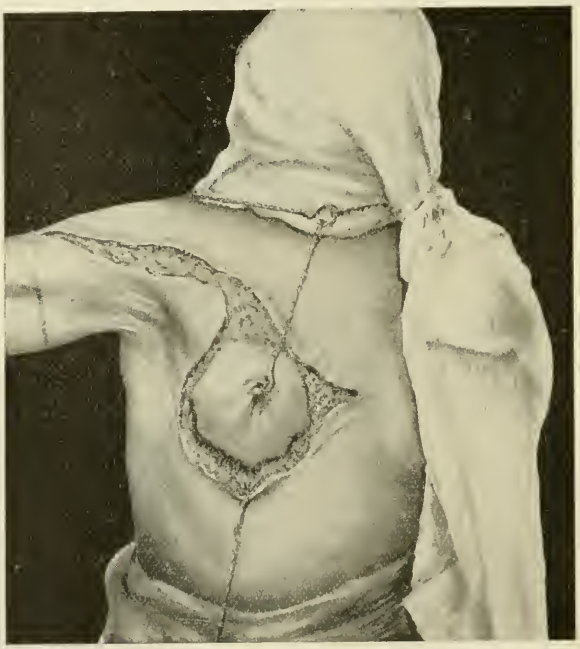

FIG. 1098.—Willy Meyer's operation for carcinoma of the breast. Skin incision as practised since 1898.

Jackson's incision (Jabez N. Jackson, "Jour. Amer. Med. Assoc.," March 5, 1906) is shown in Fig. 1095. The axilla is entered from above, a quadrilateral flap of skin is raised, and is subsequently pulled down to inclose the wound (Fig. 1096).

Warren's incision is shown in Fig. 1097. It enables the surgeon to close the wound.

Willy Meyer's Operation ("Jour. Amer. Med. Assoc.," July 29, 1905).—For the last few years I have been performing the operation devised by Willy Meyer. I consider it a most excellent procedure, with distinct points of superiority over other plans. We owe to Gerster the principal of opening the axilla in the beginning of the operation in order to prevent the diffusion of cancer cells and thus diminish the chance of rapid recurrence. Gerster's paper was published in the "Amer. Jour. Med. Sci." in 1888. The younger Gross, in his later

[1] See the younger Senn in "Jour. Amer. Med. Assoc.," May 27, 1899.

years, used to open the axilla first when there was an axillary mass, but he did it in order to determine in the beginning of the operation if the axillary mass was really removable. Willy Meyer emphasizes the value of his procedure in lessening hemorrhage. In Meyer's operation two flaps are formed by the skin-incision (Fig. 1098)—a lower and an upper flap. The incision for the formation of the lower flap begins at the point of insertion of the great pectoral muscle on the humerus, and is carried downward and inward ½ inch above the border of the muscle and parallel to it. When the incision reaches the base of the mammary gland, it is carried along the lower margin of the gland, and it ends over the sternum, a little beyond the midline (Fig. 1098). The lower flap is separated and turned down, a quantity of subcutaneous fat being allowed to remain attached to the breast. This turning down is carried to the border of the latissimus dorsi muscle, to the axillary cavity, and to the chest wall.

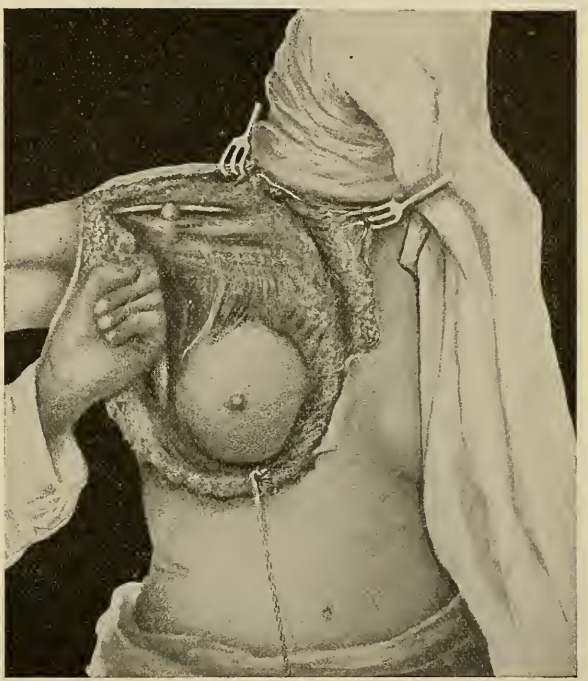

Fig. 1099.—Willy Meyer's operation for carcinoma of the breast. Insertion of pectoralis major muscle exposed. Operator's left index-finger encircling its tendon.

Meyer then directs that the border of the latissimus dorsi be followed down to the serratus anticus major, and upward to the mass of fat that enters the bicipital sulcus of the arm. The fat is removed from the anterior border of the muscle by blunt dissection. This anterior lower wound is then packed with gauze.

The surgeon next forms the upper flap by uniting the inner and outer ends of the first incision with another incision carried along the upper margin of the breast (Fig. 1098). In this flap, as in the other, the surgeon leaves as much subcutaneous fat adhering to the breast as he can spare without inducing the danger of skin necrosis. This upper flap is raised progressively until the cephalic vein is reached and there is exposure of the lower surface of the clavicle with the sternoclavicular articulation. Meyer directs that the tissues covering this articulation shall not be disturbed.

After the formation of these two flaps the next step in the operation is the division of the tendons of the two pectoral muscles and the exposure of the

axillary and subclavian veins. Meyer advises that the cephalic vein be followed up until the insertion of the great pectoral muscle into the humerus is found. The tendon is fully exposed, care being taken to bare it of axillary fat. The arm is then carried a little nearer to the side to relax the great pectoral muscle. This tendon is cut off close to the humerus (Fig. 1099). The muscle is pulled downward and inward and is loosened from the cephalic vein. It is then cut off near the lower border of the clavicle and the sternoclavicular articulation. It is necessary to divide the nerves that enter the pectoral muscle, and all the vessels that come into view are divided between two clamps and tied.

The next step is to divide the tendon of the lesser pectoral muscle near the coracoid process (Fig. 1100). Just beneath this tendon lies the subclavian vein. The surgeon now makes a transverse division of the fascia over the axilla, and thus exposes the axillary and subclavian veins (Fig. 1101).

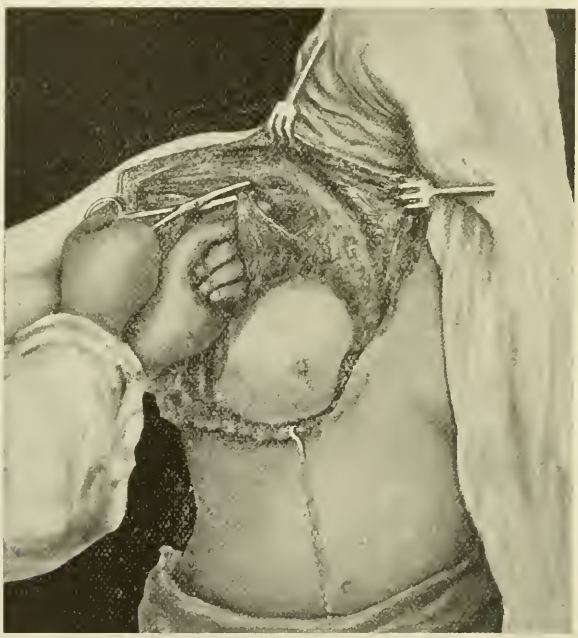

Fig. 1100.—Willy Meyer's operation for carcinoma of the breast. Finger under tendon of pectoralis minor muscle. Above, cut surface of clavicular portion of pectoralis major parallel to clavicle is visible (in the living the belly of the pectoralis major is not so thoroughly detached from that of the pectoralis minor. It is done here to show the latter's tendon).

Meyer's third step is to split the axillary fat over the upper portion of the latissimus dorsi up to the axillary vein, "thus dividing it from the mass of fat that enters the sulcus bicipitalis brachii."

Next, the axillary and the subclavian veins are followed up to where the subclavian passes below the clavicle, and every vessel that evidently must be cut is divided between two ligatures and tied. This procedure saves a great amount of hemorrhage. Meyer directs us to be careful to preserve the two superior subscapular nerves, although the third subscapular must be sacrificed.

The next step in the operation is to have the assistant hold up the mass of partly loosened tissues without pulling upon them; for if he does pull upon them, Meyer truly says, he is apt to tear off pieces of periosteum or perichondrium; and such bare spots are liable to become necrotic. The surgeon now cuts to the wall of the chest, being careful not to damage the great serratus

muscle. Meyer cautions us at this step to hold the blade of the knife horizontal; that is, "perpendicularly toward the thorax." "If he (the surgeon) should not thus turn the blade of his knife, but cut perpendicularly downward toward the subscapular muscle, he would enter the fat covering and enveloping the nerves and blood-vessels of this region, thus running the risk of unnecessarily causing considerable hemorrhage and of injuring the subscapular nerves. In the general run of cases this region need not be explored; only in very advanced cases did I find a few infected glands in this area."

The pectoralis major muscle is now divided close to the wall of the chest, the cuts being parallel to the ribs, and almost level with them; and the mass being gently drawn toward the sternum. By watching carefully, one may

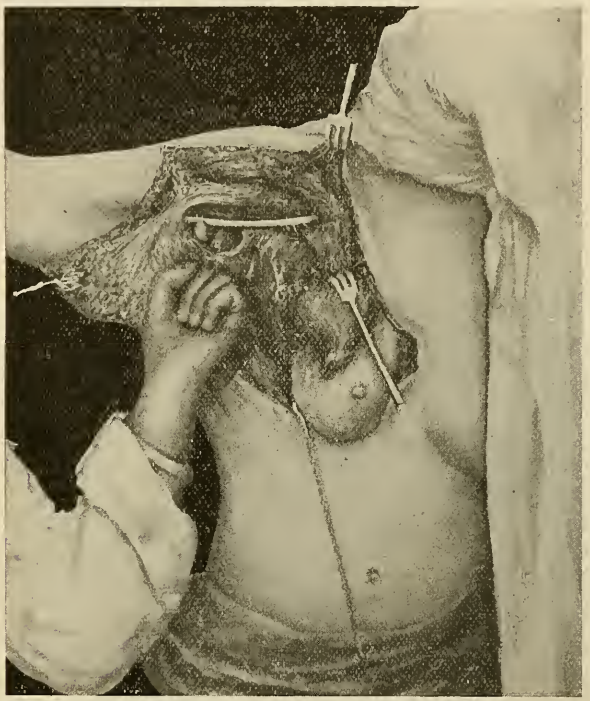

FIG. 1101.— Willy Meyer's operation for carcinoma of the breast. Subclavian and axillary veins fully exposed. So far, glands and fat tissue not removed; smaller vessels still in connection with main trunks. Finger under fat toward sulcus bicipitalis, its nail resting on axillary vein.

see the perforating arteries and veins drawn out by traction before cutting them, and may usually catch each of them with two clamps and divide between the clamps. If this be impossible, they are divided and quickly picked up. The last tissue that holds the mass to the chest wall is composed of the muscle-fibers from over the sternum. These are divided close to the sternum (Fig. 1102). The final steps consist in tying all blood-vessels, draining, and suturing the wound. The draining is done through a perforation in the posterior flap. It may be tubal or by gauze. Gauze has the advantage of restraining oozing of blood.

This operation has noteworthy merits. It can be performed far more rapidly than any other method that I have ever employed. The loss of blood is comparatively trivial, because in this operation the chief blood-vessels are divided early, are cut close to the axillary artery, and are tied. In removing the

mass from the chest wall there is little bleeding, except which comes from the perforating vessels, hemorrhage from the branches of the axillary being entirely absent; and even many of these perforating vessels are tied before being *divided*. We are far less apt by this method, than by the usual plan, to milk lymph which contains cancer cells into the wound, or in aberrant directions through the lymphatics. As Dawbarn says, the squeezing "of the breast by the retractors during its oblation, as also its handling when separated, save for its attachments to the armpit," are real dangers and may be responsible for rapid recurrence of the growth ("Annals of Surgery," March, 1908). The drain is removed in from thirty six to forty-eight hours. The patient is placed in a sitting posture on emerging from ether and is allowed out of bed on the fourth or fifth day.

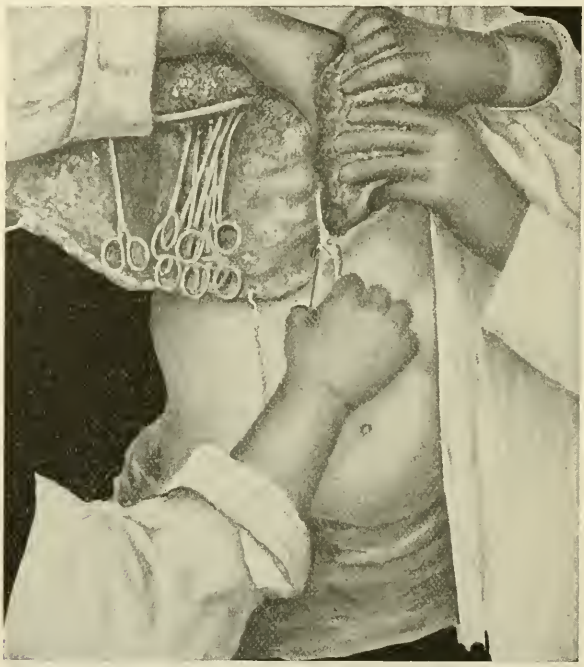

FIG. 1102.—Willy Meyer's operation for carcinoma of the breast. Pedicle of mass over sternum ready to be cut off.

Stewart's Operation (Figs. 1103–1107).—My colleague Prof. Francis T. Stewart removes the breast by a transverse incision. He attacks the axilla first. The incision gives free exposure, does not pass into the arm or across the axilla (in either of which regions a scar may impair function, or press upon vessels or nerves), and, with the aid of extensive undermining can nearly always be closed ("Annals of Surgery," August, 1915).

Dressing and After-treatment.—After operating for cancer the dressing must be wide and ample. Fluffed up gauze is pushed into the axilla to obliterate the dead space and the arm is bound to the side for forty-eight hours. When the binding is removed, the extremity is placed on a pillow in a position of moderate abduction, and is abducted a little more each day. If the incision has been placed well above the axillary border the mobility of the arm will be such that in two weeks the patient can place the hand on the back of the head. Of late I have been placing the arm, immediately after the operation, in abduction (upon a pillow or a triangular splint which rests upon the side). This is un-

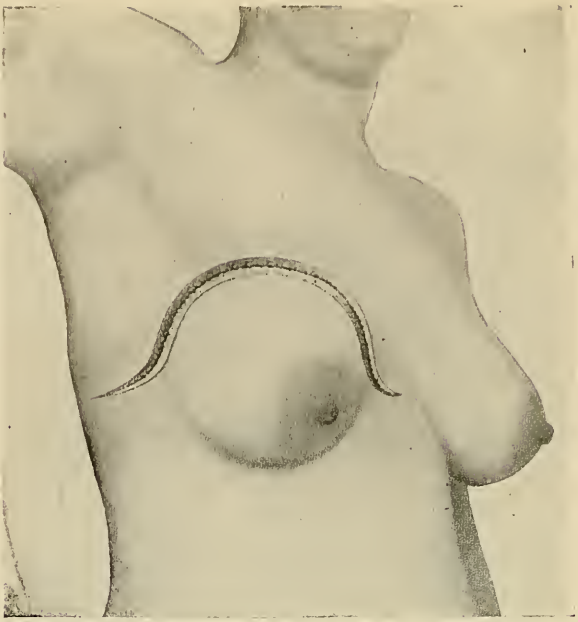

Fig. 1103.—Primary incision. The towels which should be attached to the margins of the wound are not shown (Stewart, in "Annals of Surgery.")

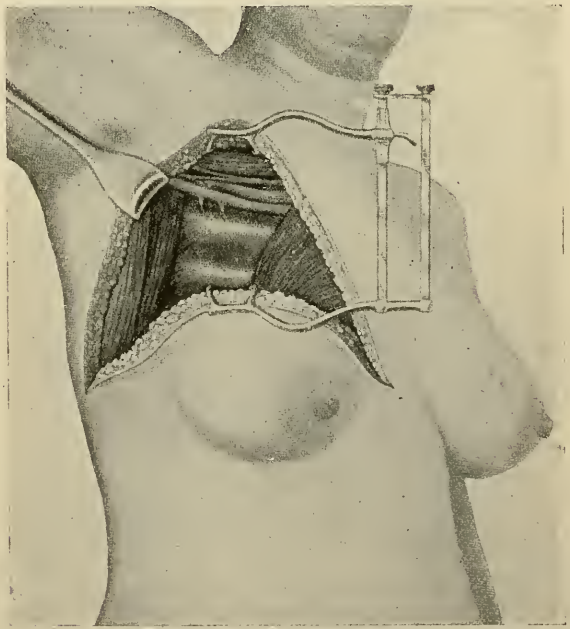

Fig. 1104.—Dissection of axilla (Stewart, in "Annals of Surgery.")

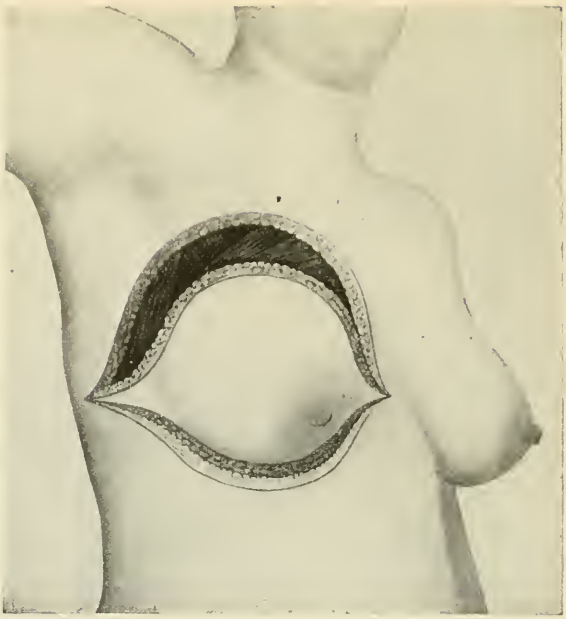

Fig. 1105.—The lower incision is made after evacuation of the axilla (Stewart, in "Annals of Surgery.")

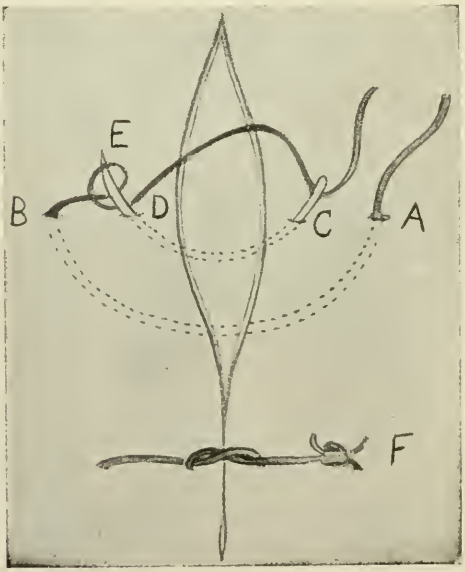

Fig. 1106.—Combined retention and coaptation suture. The needle is inserted a couple of inches from the edge of the wound (A) and brought out at a corresponding point on the opposite side (B). It is then reinserted close to the wound (C) and, on emerging from a corresponding point on the opposite side (D), is passed through the loop E. When the suture is tied (F) the edges of the wound are held firmly together and inversion of the skin does not occur (Stewart, in "Annals of Surgery.")

necessary if the incision does not run on to the arm but is in front and above the anterior axillary margin. If the old incision in the axilla be used, abduction and all other plans will fail to prevent decided limitation of movement.

Inoperable Malignant Diseases of the Breast.—This term implies that a radical operation looking to cure is impossible. The conditions in which it is impossible have already been specified (see page 1589). Even if the case be judged inoperable from the radical standpoint, it may be wise to remove the mammary gland, in order to free the patient from a hideous, ulcerating area, violent pain, or harassing hemorrhage.

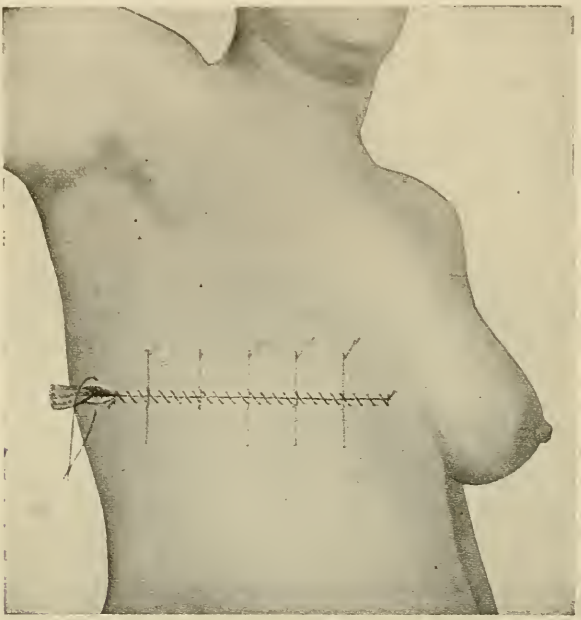

FIG. 1107.—Incision closed (Stewart, in "Annals of Surgery.")

It has been suggested that some cases inoperable by ordinary methods may be subjected to removal of the entire upper extremity or to disarticulation at the shoulder-joint with some prospect of cure. My own view is that when a case has advanced so far that it is not amenable to ordinary operative treatment, neither of the above-mentioned procedures offers any reasonable chance of success. If the pain is extremely violent in an inoperable case, the surgeon may relieve it by dividing the brachial plexus, or perhaps by disarticulating at the shoulder-joint.

Some inoperable cases may be greatly improved—for a time, at least—by the use of the *x*-rays; and even when the condition is not benefited in other ways, this force sometimes mitigates or greatly relieves the pain. It is said that in some cases radium is more efficient than the *x*-rays, but it is probable that most improvements by radium could have been obtained by the *x*-rays. In cases of lymphatic recurrence it is advisable to administer thyroid extract during the *x*-ray course (Woods, in "Brit. Med. Jour.," July 1, 1911).

Beatson's Operation, or Double Oöphorectomy.—It has been pointed out by Sir George Thomas Beatson that there is a certain similarity between the formation of cancer in the mammary gland and the process of lactation. In each there is an enormous production of embryonal epithelial cells; but in lactation the epithelial cells undergo fatty degeneration, and in cancer formation they do not do so, but penetrate into the tubules and the acini and

infiltrate the gland structure. Beatson further points out that when a lactating cow is spayed, it continues to give milk indefinitely. This seems to indicate that removing the ovaries favors the fatty degeneraion of the epithelial cells. This operation has been performed in cases of inoperable carcinoma of the breast in the hope of bringing about degeneration in the tumor mass. In the great majority of cases it fails utterly; but now and then it secures a notable improvement, and in a very few cases outward evidence of the disease disappeared, the general health improved, and there was gain in weight. The cure is apparent, but not real. The improvement is only temporary. Abbe obtained an apparent cure in 2 patients. It was at first thought that the operation would only be applicable to persons that had not passed the menopause, but one of Abbe's patients was over seventy years of age. Butlin, however, says that there is no genuine cure secured by this operation on record, and Beatson makes the same statement. The operation is not to be considered if visceral deposits exist. My own view is that the procedure offers but little prospect of success, but that, as it does offer some, the exact facts should be placed before the patient, and she should be permitted to choose whether or not she wishes the operation performed.

XL. THE X=RAYS IN SURGERY. RÖNTGENOGRAPHY; RÖNTGENOSCOPY; RÖNTGENTHERAPY; RADIUM AND RADIOTHERAPY; ELECTROCOAGULATION

(Dr. George E. Pfahler did me the honor to rewrite this section.)

History of the Röntgen or X-rays.—In 1858–59 Gessler obtained violet, blue and red colors by passing alternating currents through glass tubes of low vacuum ($\frac{1}{1000}$ of an atmosphere). The cathode rays were discovered by Hittorf in 1869, while passing an induction current through a vacuum tube. Crookes, of London, greatly improved the vacuum tube and obtained a rarefaction which left in the tube but one-millionth of an atmosphere. This last-named observer found that when an interrupted current of high potential is passed through a vacuum which is nearly perfect, fluorescence takes place. In Crookes's tube the positive electrode is placed at some indifferent point, and the current at the negative electrode produces what is known as the cathode stream or cathode rays. These do not flow toward the positive pole unless it be in direct line with the stream of rays, but are thrown directly toward the opposite wall of the tube, and at this point a phosphorescent glow is detected.

In 1895 William Konrad Röntgen, of Wurzburg, while making a study of cathode rays as developed in Crookes's tubes, discoveed the energy which he named the *x*-rays. Both Jackson and Lenard were on the very eve of making the discovery a year before. Röntgen while at work was called from the room and laid an energised vacuum tube upon a book. Within the book was a key placed there as a marker and the book rested upon a photograph plate holder containing plates. He returned to the laboratory, removed the tube, took some plates for a camera trip, departed, and took some pictures outside. When he developed the plates he found the picture of the key. By reproducing the conditions he made the discovery (E. E. Burns, in "Popular Science Monthly," 1908). Röntgen showed that at the wall of the Crookes tube opposite the negative electrode a new and hitherto unknown energy was generated. Because of the uncertain character of this energy he gave to its manifestation the name of the *x*-rays or unknown rays. Since then, in honor of their discoverer, these rays are more generally known as the Röntgen rays, and from this root word, Röntgen, the other words used have been derived, and are as follows: Röntgenology, the science of the Röntgen rays; Röntgenography, the photographic effect of the Röntgen rays; Röntgenoscopy, the use of the Röntgen

rays in fluoroscopy; Röntgentherapy, the use of the Röntgen rays in the treatment of disease, etc.

Physical Properties of the Röntgen Rays.—The Röntgen rays or *x*-rays are a form of ethereal vibration akin to light, but of extremely short wave length, and belong to the invisible portion of the light spectrum. They have been refracted by passing through salt crystal, but in practical work they can be neither refracted, reflected nor concentrated, nor deflected by a magnet. The rays cannot be polarized, travel with the velocity of light, and cause fluorescence in certain substances, notably in the tungstate of calcium (Edison), platinocyanid of barium (Röntgen) and the platinocyanid of potassium. The rays have a marvellous power of penetration, and move in a straight line from their source until absorbed. The rays are absorbed by the substance through which they pass in proportion to the density and thickness of the object. The density is measured by the atomic weights of the elements composing the object. For example, aluminum is of low atomic weight, and lead of high atomic weight. Therefore, aluminum is relatively very transparent to the *x*-rays, while lead is very opaque, but since the thickness of a body comes into consideration in estimating the total absorption it is possible to have a layer of aluminum so thick that it will cast as much shadow as a thin layer of lead. The above physical observations are of practical importance because it is possible to place a pin, or other dense body, on or near the surface of a thick muscular portion of the body, such as the thigh, and while in itself it is very dense it may not be demonstrable on a photographic plate or fluorescent screen if the part be examined in one position only and the pin be on the opposite side from the plate or the screen. It is the property of differentiation of tissues, according to their density, which makes the Röntgen rays of value in medicine and surgery. The bones are relatively opaque as compared with the surrounding soft tissue because of their greater density, the density being due chiefly to the calcium salts. Even soft tissues can be differentiated if there be any variation in their density. For example, the heart can be seen clearly because it is surrounded by air containing lung tissue.

The Production of the X-rays.—The production of the *x*-rays depends upon the passage of a high tension current through an *x*-ray tube. This high tension electric current may be generated from a static machine which is obsolete because impractical or from an induction coil, which for many years was used almost exclusively and is still used for small outfits, but the high tension transformer is more efficient and is now most generally employed. The high tension current used is equivalent to about 25,000 to 100,000 volts. In general, diagnostic work from 50 to 60,000 volts are used, and in deep treatment approximately 90,000 volts are generally used. In diagnostic work from 5 to 100 milliamperes of current are used, but generally about 30 milliamperes. In treatment work 5 milliamperes are used as a rule.

The *x*-ray tube consists of a glass bulb from which all but about one-millionth of the air has been exhausted. It contains at least two metal terminals, one called the cathode and the other the target or anode. There are two main types of tubes in existence and in use today; the gas tube and the Coolidge tube. The gas tube is approximately 6 to 7 inches in diameter, and from it all but about one-millionth of the atmospheric air or other gas has been removed. The remaining atoms of air in the tube are essential for the production of the *x*-rays. Under continued use these remaining atoms of gas become exhausted and it is then necessary to find some means for the introduction into this same bulb of other molecules or atoms of gas, and for this purpose is attached a regulator which is a device for introducing a small quantity of gas as needed. When a high tension current of electricity is passed through one of these tubes, the atoms of gas remaining in the tube are divided or separated into their corpuscles or electrons, and those electrons are propelled from the negative pole or cathode,

in straight lines from the surface of the cathode toward the target or anode of the tube. The cathode of the tube is usually cup-shaped, and therefore, as these electrons are propelled in straight lines from the surface, they become focused upon the target of the tube. This point of focusing is spoken of as the *focal point*, and the impact of these electrons upon this target is the cause of the production of these ethereal waves which are similar to light, but of much shorter length and are spoken of as the *x*-rays or the Röntgen rays. When the *x*-rays coming from one of these tubes have slight powers of penetration, they are said to be "soft," and the tube is said to be "low." When the rays have great penetrative power they are said to be "hard" and the tube is said to be "high." Between these two extremes we speak of "medium rays" and a "medium tube." Gas tubes are objectionable because of the difficulty in keeping the proper amount of gas in the tube, and thereby in keeping the penetrative value of the light constant. The impact of these electrons from the cathode terminal of the tube against the target produces great heat. This heat causes an expulsion of gas from the target of the tube and this increase in the amount of gas in the tube lowers the vacuum and produces softer rays. On account of the great difficulty in keeping the rays in a gas tube uniform in penetrative value the *hot cathode tube* was developed by W. D. Coolidge, and is now generally known as the Coolidge tube.

It was found that when a metal had been heated to a white heat electrons were given off. Therefore, Coolidge in the Research Laboratory of the General Electric Co. developed a tube from which approximately all of the gas had been removed, even the residual gas in the metal terminals. In order that there might be electrons in the tube for working purposes, he introduced a tungsten filament similar to the filament in the electric light bulbs. When this filament is heated to a white heat electrons are given off, and by regulating the amount of heat passing through this filament, just as the amount of electricity is regulated as it passes through the filament of the ordinary electric light bulb, by means of a rheostat, the degree of the heat of the filament is controlled and therefore the number of electrons given off are controlled. In this way one can compel this Coolidge tube to produce any kind of penetrative light continuously, and uniformly. Its chief disadvantage is the difficulty of bringing these converging electrons to a sharp focal point. The second disadvantage is that this tube produces more secondary radiation or vagrant rays than the gas tube. However, because of its convenience in handling, and its constant rays it is gradually replacing the gas tube in most work. It has entirely replaced the gas tube for therapeutic work. In therapeutic work the sharp focus is not essential and the vagrant rays are less objectionable.

Properties of the X=rays.—The four great properties of the *x*-rays which are of interest in surgery are, first, the effect on photographic plates; second, the fluorescence produced in certain substances; third, secondary radiation; fourth, the biological effect, or its curative properties in various diseases.

The photographic effects are very similar to those of light, excepting that the *x*-rays or Röntgen rays have the power of penetrating objects which are opaque to sunlight, and are recorded upon the plate, in inverse proportion to the density of the subject through which the rays are passing. This photographic effect is a record of the differentiations of the various densities of the object under examination. For instance, the greatest effect upon the photographic plate will be shown where the rays have to pass chiefly through air. The next greatest effect, or amount of photographic deposit, will be shown where the rays pass chiefly through soft tissues, and least effect of all through solid objects such as bone or metal. With great skill the finest kind of differentiations can be made in the tissues of the body, such as the tissues of the head, the details of bone, etc., and the soft tissues of the chest and abdomen. Any kind of photographic plates can be used but, usually, plates are specially prepared for this work, and are

generally doubly coated. They are developed in the ordinary manner. They must be protected, during the exposure to the Röntgen rays, from ordinary light and are therefore covered with a black envelope and then an orange envelope, or are placed in an aluminum or fiber casing, "Kassette."

Fluorescence.—The *x*-rays have the property of causing fluorescence in a number of substances, but those most commonly used are barium platinocyanide and tungstate of calcium. These two substances become fluorescent under the action of the rays but of course must be seen and studied in a dark room, or at least with all ordinary light shut out from the screen by means of a hood during the course of the examination. Upon this fluorescent screen the same sort of differentiation of tissues can be seen as is shown upon the photographic plate. For instance, with such a fluoroscope for use in a lighted room, or with a fluorescent screen in a dark room, one can see the movements of the heart, the movements of the chest, the movements of the lungs and diaphragm. One can also study the action of the stomach and the bowels. It is of especial use in the study of movable organs, though some valuable information can be obtained in the localization of foreign bodies, and in the setting of fractures. The use of the fluoroscope is, generally speaking, dangerous, and the beginner must be especially cautioned against burning the patient from too much exposure, but especially against burning his own hands and face. There is no sensation from the *x*-rays and one can do great damage to the skin of the patient or the operator without feeling any immediate effects. In order to do good fluoroscopic work, it is necessary for the observer to be in a dark room for approximately fifteen minutes before the examination, during which time the retina becomes sensitive to the faint light, for this fluorescent effect on the screen is not brilliant, and unless the retina is sensitive much detail is lost and accurate diagnosis is generally impossible. For this reason patients for fluoroscopic work should be sent in groups. Fluoroscopic examinations are generally unreliable in the diagnosis of fractures and "line" fractures or doubtful fractures are often overlooked. There should always be plates made when a fracture is suspected.

Secondary Radiation.—In the neighborhood of an *x*-ray tube all objects through which the rays pass give off secondary radiation. The secondary radiation is relatively feeble, probably not more than $\frac{1}{500}$th of the value of the primary radiation, but it is at least a very disturbing factor and we may learn later that it may also be a dangerous or harmful factor. The air, objects in the room, human bodies, every object through which the rays pass become radioactive, and give off these secondary radiations. Therefore, one may be thoroughly protected from direct radiation from the tube, and yet not sufficiently protected against the secondary radiation. Up to the present time, no ill effect has been observed from these secondary radiations, excepting that they tend to fog photographic plates and give or render more obscure the fluorescent image on the screen.

The biological effects of the Röntgen rays and radium are especially important from the standpoint of physiology and therapeutics. If used in like quantities and qualities the effects of the Röntgen rays and radium are very similar, and probably identical. The effect of the rays on the tissues of the human body depends first upon the quantities, secondly upon the quality of rays used, and thirdly upon the sensibility of the cells under exposure. In general, a small quantity of radiation has a stimulating effect upon the cells of the body and even upon the cells of growing plants (Albers-Schönberg) but very quickly the effect passes from one of stimulation to destruction, and in most instances, when the rays are used for therapeutic purposes, it is the inhibitory or destructive effect which is sought. In general the embryonic cell is the most sensitive to the rays, and this effect is due to the chemical or actinic action of the rays. In general, the glandular cells are the most sensitive of any in the body because they are most highly specialized, and of the glandular cells the

most active are the generative cells of the ovaries and testicles. Next to these are those of the spleen, the thyroid gland and thymus, the lymphatics and the liver. Next in order in sensibility are the tissues of the body, the protective covering of the skin and mucous membrane, the connective tissue, the lining of the blood-vessels, and probably most resistant of all in the body is the nervous tissue. It is because the carcinoma cell approaches the embryonic type that it is more sensitive than the surrounding tissues, and it is for this reason that the malignant cells in the body yield more readily and become effected by the rays even though the surrounding tissues show little or no effect. If it were not for this increased sensibility of the malignant cells, we would not be able to cause a disintegration or disappearance of a carcinoma excepting by destruction of the entire tissue. This specialized effect has been seen by almost every one who has had the opportunity of watching the therapeutic action of the rays. In an epithelioma of the skin, for example, one notices under the action of the rays, which are applied at intervals, that the tumor tissue is gradually absorbed sometimes without breaking down, or the tumor tissue undergoes degeneration and disappears, while the surrounding skin which had been exposed to an equal amount of radiation shows little or no effect. It must be borne in mind that the action of the rays is always greater on the surface of the skin excepting in so far as the tissues are influenced by the increased sensibility. Almost 50 per cent. of the rays are absorbed in the first cm. of tissues. It is therefore readily understood that the greatest effect will be shown on the surface, other things being equal, but because of the greater sensibility of certain tissues, such as the highly sensitive glandular organs, for example the testicles and ovaries, it is possible in these organs to produce a decided inhibitive or destructive effect without showing the slightest change in the overlying skin. The relative effect on the overlying as compared with that on the deeper tissues can be decreased by present-day filtration and cross-firing. This filtration was begun, so far as the *x*-rays are concerned, in 1906, at which time Pfahler argued that if the greater portion of the rays are absorbed in the first cm. of tissue, that if one introduce, between the skin and the tube, tissue resembling the skin that the greater portion of the rays, which would otherwise be absorbed by the skin, would be removed. Therefore, the skin would receive considerable protection. Experiments were carried out with the skin of a living rabbit. In this experiment he exposed an area on the back of the rabbit about 3 inches in diameter. One-half of this area was covered by a layer of sole leather. As a result of the exposure, which was given sufficiently long to produce a burn, the area unprotected by the sole leather developed a slough which involved the entire skin, while the area protected by the sole leather did not even remove the hair. This was very convincing as to the protective value of filtration. Since this time, however, the power of the Röntgen rays has been increased to such a considerable extent that Röntgenologists now use from 2 to 6 mm. of aluminum for filtration and thus increase the value of the deep radiation.

The amount of exposure or treatment that can be given over any area of skin is spoken of as a "*skin dose*," referring to the limit of toleration of the skin to a given amount of radiation. This limit of toleration is indicated by an erythema. Therefore, the dose is often spoken of as an "*erythema dose.*" An "erythema dose" not only produces erythema but when given over an area of the body covered by hair will produce epilation—"*epilation does.*" The amount of radiation that can be given to the deeper tissues, is of course greatly increased, probably four times, by means of filtration through 6 mm. of aluminum. It is advisable never to produce even an erythema of the skin because of the dangers which may develop a year or more after this exposure. Clinically the changes to be noticed as a result of excessive exposure to the Röntgen rays or radium may be divided into three or four phases. A so-called *x*-ray burn is not really a burn in the sense of a burn produced by fire, but it is a degeneration of the skin.

The *first degree* of an *x*-ray burn or dermatitis consists of an erythema indicated by general redness of the surface of the skin, with epilation in hairy areas, and generally this erythema comes on after a period of a few days to two or three weeks, depending upon the severity of the exposure. Generally the erythema may be looked for in about two weeks. It has the appearance of an ordinary sunburn, and disappears in about the same length of time as an ordinary sun burn. That is, the erythema disappears, and very commonly will leave behind a pigmentation or tanning, which is particularly likely in a dark subject Blondes show this erythema effect more readily than brunettes, and a slightly lesser dose can be given to blondes than to brunettes. A severe erythema may disappear completely at the end of ten days to two weeks, and nothing may appear again for a year or two, and for some reason not yet known some of these patients who have had an erythema will then develop a telangiectasis and an atrophic appearance of the skin over the area previously occupied by the erythema. This condition is due to an arteritis with secondary dilatation of the smaller blood-vessels, and in severe cases the whole area may be covered by a spiderweb-like distribution of fine blood-vessels through the skin.

The second-degree burn is the result of more excessive exposure than that necessary to produce the first degree burn, but less in extent than the third-degree burn. It is likely to make its appearance slightly earlier—at the end of a week or ten days—and shortly after the appearance of the erythema, vesicles, or bullæ make their appearance. The entire area then gradually desquamates and will require from four to six weeks for a complete healing process. These cases are very likely to be followed by an extensive telangiectasis after a year or two, and such *x*-ray burns should be avoided. They rarely occur in these days when filters are used for deep treatment, but even through any amount of filtration a burn of any degree can be produced if sufficient radiation be given.

A *third-degree burn* occurs as the result of very excessive exposure and in these days should not be produced on any account. They were seen in the early days of *x*-rays when instruments produced only a very soft radiation all of which was absorbed in the superficial skin. For instance, one patient whom Pfahler saw had been examined repeatedly for a stone in the kidney, the exposure had been excessive, and the radiation all absorbed in the superficial layers of the skin and subcutaneous tissues, and yet not sufficient radiation had passed through the body to produce a photograph of the kidney. This exposure was followed by a deep erythema and then extensive degeneration of the skin resulting in a gray ulcer, with indurated edge, extending entirely through the subcutaneous tissue and covering an area about four by six inches in diameter. This whole area sloughed profusely, but showed no tendency to heal. These third-degree burns are extremely painful, show little or no tendency to heal, develop into a foul, sluggish ulcer which may never heal, and which is apt to change from an ulcer into a malignant indurated carcinoma.

A *fourth type of radiodermatitis* consists of a degeneration in an area which has been treated repeatedly over a long period of time, say a year or more, after which there is a general sclerotic leather-like condition which may last for several years and later, as a result of deficiency in nutrient vessels, this area becomes necrotic, very painful, and like the third-degree burn, after a considerable period of time, extending over six months or a year, may degenerate into true carcinoma.

A *fifth type of radiodermatitis* is that found in *x*-ray workers, in those who are constantly exposed to radiation in the manufacture of *x*-ray tubes, or physicians or technicians who have been constantly exposing themselves to radiation in the course of examinations for medical purposes. This dermatitis found in the Röntgenologists and in the technicians is also varying in its effect. Pfahler has seen physicians who, from a single examination, have burned their hands so as to lose all the skin. For instance, a young physician with a portable outfit

attempted to set a broken leg. As a result the patient's leg was burned to the third degree, his own hands became enormously swollen so that the fingers were almost twice their normal size, all the skin became a mass of blood, and he was made absolutely helpless for a period of several months, during which time the skin desquamated and again healed. This is, of course, the acute dermatitis, such as can occur from any excessive exposure. Generally, the exposures to the Röntgen rays in the Röntgenologist produce no immediate effect, or at most only a slight erythema of the skin, which is passed over or given no particular attention. After several years the skin presents an atrophic aspect indicated by a glossy, smooth, lacquered appearance. There then develops a series of keratoses, or crusts, or small warts over different parts of the hand, or perhaps fissures. These warts, fissures or keratoses gradually degenerate into true epitheliomata and generally these epitheliomata are of the squamous-cell type, very malignant, tend to metastasize and to recur, and, in a number of instances, have led to the death of the Röntgenologist, through metastasis to the axilla and to the chest.

Another effect of the Röntgen rays and radium which is of interest to all operators is that of the production of sterility. This may be produced so gradually and without any knowledge on the part of the operator, that it must be especially guarded against. Just how much exposure of the testicles or ovaries is required to produce sterility has not yet been determined. It probably varies with the age. It does not produce impotence. This fact often deceives the operator as to the danger of this effect. Just as it is impossible to tell how much radiation is required to produce sterility, so too it is impossible to know when sterility has been produced or when it is complete, for it is well known that a number of cases which had been sterile for a time, again have become fertile, both in men and women. This fact can therefore serve as encouragement to those who may have been temporarily sterile, but it should not lessen, to any extent, the precaution that every beginner should take to provide protection against exposure to the rays by every means possible.

The Treatment of Radiodermatitis.—The treatment of radiodermatitis should, first of all, consist in its prevention by the application of all present knowledge used for protection. No one should undertake *x*-ray work unless he has learned to protect himself and his patients, and *x*-ray work should not be undertaken unless the means of protection have been provided. There should rarely be a dermatitis even of the first degree. Accidents will happen, however, and they happen in proportion to the intelligence and care used in the treatment or examination of a patient. We must keep in mind, however, that there are cases in which occasionally a patient will present an erythema even though only the normal amount of radiation has been used. For the *first-degree burn* or erythema Dodd's lotion, or "white wash," may be used.

Pulv. zinc oxid ..... dr. 4
Glycerin ..... fldr. 1
Phenolis ..... min. 30
Aq. calcis (fresh) ..... fl. oz. 8
Sig: Apply locally with a cotton sponge.

Pfahler uses this wash in practically all cases immediately after treatment, and then for a period of two weeks daily following the exposure. In place of Dodd's white wash, any soothing application such as is used for sunburn may be used. When itching and burning are troublesome, Engman ("Interstate Medical Journal," July, 1903) recommends the following preparation: 12 drams of boric acid, 1 ounce of zinc oxid, 1 ounce of chalk, 1 ounce subnitrate of bismuth, 1 ounce of olive oil, 3 ounces of lime water, 3 ounces of lanolin and 12 drams of rose-water. The powder is rubbed in a mortar, the lanolin is added, the olive oil and lime water are mixed, and are slowly added to the powder and lanolin. The mixture is stirred, the rose-water is added, the preparation is beaten into a creamy paste. If itching be severe 1 to 2 per cent. of carbolic

acid is added. The paste is spread on several thicknesses of gauze and the gauze should be covered with rubber dam.

The *second-degree burn* is treated very similarly, but by all means protection against the sun's rays or heat or further *x*-ray treatment, is to be considered first. The above-mentioned protective ointment is useful, or the white wash recommended by Dodd. Occasionally more relief is obtained by the constant application of normal saline.

A *third-degree burn* is a serious condition and is truly a dangerous process. Every means possible should be used to bring about local nourishment and comfort. Sometimes constant application of normal saline will give comfort enough to bring about separation of the sloughing mass. In the early stages, an outline of treatment such as follows, may give good results. A mixture composed of 2 drams each of zinc oxide and bismuth subnitrate, ½ dram each of liquor potassi and liquor plumbi subacetatis, 2 drams of glycerine and sufficient lime water to make 6 fluid ounces. This mixture may be applied twice daily and will relieve much itching and burning, and will control the exudate. It should be applied over a considerable area. Generally it is advisable to make the patient comfortable by whatever local applications will accomplish this, until there is a distinct limitation in the process and until there is neither an extension outward nor a contraction of the ulcer. In other words, when the process has reached a standstill, it is advisable, if at all possible, to excise the entire area, and then, if necessary, to do skin-grafting to close the wound. This excision at once relieves the excruciating pain, and also eliminates the tendency toward malignant degeneration, for if these cases are allowed to continue indefinitely they tend to become malignant. One must, therefore, not wait until such malignant degeneration has taken place, for we have then all the dangers involved in an operation upon a malignant process.

The treatment of the late degenerations, or the *fourth type of x-ray dermatitis*, is very similar to that of the third. One can coax the condition into a healing process as long as possible, but ultimately an excision is required, and if necessary skin-grafting should be done.

In the *fifth type*, or the radiodermatitis of the Röntgenologist, treatment should involve first of all a cessation of exposure to the Röntgen rays. As soon as warts, keratoses or fissures make their appearances they should be completely destroyed. Pfahler recommends very strongly the destruction of these areas by the high frequency spark or electrocoagulation. This destruction can be controlled most accurately, and the superficial layer only of the skin removed, or the area can be destroyed as deeply and as extensively as may be necessary. This destruction is followed by a pronounced reaction, with the formation of new blood-vessels, and healthy skin, or healthy scar. In many instances these lesions can be removed without even leaving a scar, and, if treated early, dozens of them can be removed without any damaging effect whatever. If they are allowed to continue, and especially if allowed to macerate by the application of ubber finger cots and rubber dam, which is used to keep the areas soft, they are likely to degenerate into squamous-cell carcinoma, the end of which no one can predict.

In these days, if all the principles of protection are applied, no more exposure to the naked tube or unfiltered rays should be necessary, and the radiodermatitis of the Röntgenologist should be a thing of the past. Unfortunately these precautions will not always be taken, for there are always men who consider themselves immune to the physical laws, and they will find out to their sorrow, when it is too late, that they have not used all the protection which science provides. If epitheliomas have developed, local destruction by electrocoagulation should be considered. Otherwise excision, amputation of the finger or the surgical removal of as much tissue as is necessary to eliminate the disease should be recommended, for unless this carcinomatous tissue be completely

removed from the hand there will likely be metastasis to the axilla, after which the chance of recovery will be very slim.

The Uses of the Röntgen Rays in Surgery.—This subject cannot be discussed fully in this work, and only such facts as are of special interest to the surgeons will be considered. Technical details will be omitted. Those who are interested in the practice of Röntgenology, even associated with surgery, should consult the special books written upon this subject, otherwise much harm will result. The object is to give the surgeon the essential facts so that he may make intelligent use of the Röntgenologist for the good of his patients. Not only is it impossible, in this short chapter, to discuss the technical side of the subject, but it is impractical even to consider all the variations at one time in connection with diagnosis and the treatment of the various diseases under consideration. The Röntgen rays are used for both diagnosis and treatment of surgical conditions, and in the hands of skilled and trained Röntgenologists great assistance can be given to the surgeon in all branches of surgery, in most of the chronic diseases, as well as in accidental conditions. In the hands of unskilled men, the Röntgen rays are capable of doing much harm by leading to false diagnosis, or to improper treatment. The general practitioner who has not been trained, or made a special study of the subject, can do himself and his patients a great deal of harm.

Diagnosis.—Diagnostic studies may be made either by means of the fluoroscope or by Röntgenograms (radiograph, skiagraph, *x*-ray plate). The Edison fluoroscope consisted of a four-sided box tapering from the top toward the screen, the top being open and arranged so that it will fit snugly over the eyes and nose, and the bottom of this box is covered by a fluorescent screen. The fluorescent screen consists of a layer of cardboard covered by barium platinocyanid crystals or by tungstate of calcium. In order to see an image on the fluorescent screen it is necessary that all daylight or ordinary light be eliminated from the observer's eyes and the screen. Therefore the above type of fluoroscope is essential when one attempts to make a fluoroscopic examination in a room from which the light cannot be completely excluded. In all modern hospitals and *x*-ray laboratories there is set aside a room which can be completely darkened, and used for fluoroscopic purposes. In this room there is usually a horizontal fluoroscope and a vertical fluoroscope. The horizontal fluoroscope consists of a table with a top which is transparent to the *x*-rays and underneath this table there is placed an *x*-ray tube properly attached and protected by means of lead glass, lead and opaque rubber, so that only the beam of rays which is essential for the fluoroscopic examination can be emitted, all other rays being excluded. This beam of rays is controlled by means of an adjustable diaphragm so that one can study a large or small field at will, the smaller the field under observation the sharper the detail, and the more satisfactory will be the results. In these fluoroscopic rooms there is supposed to be a vertical fluoroscope which consists of a similar apparatus or arrangement as the fluoroscopic table, excepting that it permits the patient to stand up and be examined in a vertical position. There are many modifications of these arrangements. The *fluoroscopic examinations* are especially useful in the study of movable organs. Therefore, this method is useful in the study of the movements of the lungs, the heart, the diaphragm, the stomach, the bowels, the liver, the spleen, and even of the kidney for mobility. The fluoroscope can also be used in the study of fractures, and may be used in the setting of fractures, but great caution should be used by a beginner or untrained operator in making an examination of this kind, because it is in the setting of fractures, or in the search for foreign bodies, that serious burns have most frequently been produced. The fluoroscope is also useful in the location of metallic foreign bodies, and it has been of the greatest service in this respect during the great war (see pages 1619 to 1628). Probably the greatest field of usefulness of fluoroscopy in civil practice is in the study of the gastrointestinal

tract. This subject, together with the localization of foreign bodies will be discussed in more detail under these headings. In making a fluoroscopic study of the hand, for example, it is placed between the tube and the screen. Usually the tube is about 25 inches from the screen. The hand is placed immediately back of the screen, and under the excitement of the tube, the screen becomes illuminated brilliantly outside of the object, and one can see clearly the outline of the bones as being distinct from the outlines of the flesh. One can see clearly through the joints, and in this same manner one can study the organs within the chest, and some of the organs within the abdomen. Röntgenograms are usually made in conjunction with the fluoroscopic examination, if a fluoroscopic examination be made, and in the great majority of surgical conditions the Röntgenogram alone is depended upon for the *x*-ray report.

Röntgenography.—The Röntgenogram primarily consists of a photographic plate which is protected from ordinary light by means of an envelope of black paper covered by another envelope of yellow paper, or is placed in an aluminum case which protects the plate thoroughly from light and through this covering, which is transparent to the *x*-rays, the object under examination is exposed to the *x*-rays. The plate is then developed, washed and dried as an ordinary photographic plate, after which it is studied by placing it over an illumination box or by holding it toward the northern sky, or by making use of the reflections of a sheet of white paper. It is not advisable to depend upon the light from an ordinary electric lamp, or candle, or gas light, for many delicate shadows and diagnostic points are overlooked in so doing. These Röntgenograms are essential in the study of most of the obscure conditions. Accurate diagnosis of fractures, of all lesions of the bones and of most of the gastrointestinal conditions demands the use of Röntgenograms, and fluoroscopic examinations alone cannot be depended upon. Röntgenographic studies are probably of even greater value than the fluoroscopic studies, but both should be used wherever it is necessary, and every laboratory should be equipped so that both forms of study in a case can be used at will. The Röntgenogram has the advantage of being a permanent record which can be studied by one or many, and can be compared with future pictures of the part under examination, gives much finer detail and in general gives much greater accuracy than fluoroscopic studies. Röntgenographic studies can be made today by the trained Röntgenologist without the slightest danger to either the patient or the operator. The time of exposure varies, of course, with the amount of energy introduced into the tube, but any part of the body can be recorded on the Röntgenogram in from $\frac{1}{10}$th to 10 seconds. Most exposures are made in from 1 to 5 seconds, and children can be Röntgenographed instantaneously, especially when one uses, in conjunction, the intensifying screen which increases the value of the exposure about five or six hundred per cent. The intensifying screen has the objection of giving less valuable detail, and shows some grains in the film, especially when rapid forced exposures are used, but when time is the important element it offers a wonderful advantage.

In *fractures* the rays enable us to determine the nature and extent of the injury, the amount of splintering, the degree of impaction, the relation of the fragments, the direction of the line or lines of fracture, the variety of the deformity, the existence of multiple fractures, the extent of epiphyseal separation or dislocation alone or with fracture, the existence of ununited fractures, the presence of callus and whether the callus is healthy or necrosis is taking place in the fragments. Probably the most valuable point in the study of fracture is the record of the position as shown in the dressings. There is some advantage in having Röntgenograms of all fractures before setting, but in cases in which the diagnosis of fracture is positive it is probably more economical of time, energy and money if the fractures are reduced, according to the well-known surgical principles, and placed in splints or dressings and then referred to the

Röntgenologist, and examined to determine whether the fragments are in satisfactory position or not. In some cases it will be found of great advantage to make the reduction of fractures under fluoroscopic observation. This reduction should be made by the surgeon and Röntgenologist conjointly, and the Röntgenologist should keep in mind continually the dangers both to the patient and to the operator involved in this procedure. Both the surgeon and the Röntgenologist should keep in mind the fact that they are only seeing the bone in one plane and that the observation must always be made in more than one plane in order to determine the actual position of the fragment. This great obstacle it is hoped will be overcome shortly by the use of stereo-fluoroscopy, so ably developed by the late Dr. E. W. Caldwell, and almost perfected by him at the time of his death. Patients to be examined for the position of the fragments should not be placed in a metallic splint unless the metallic splint be made of aluminum, for the examination through wire and other metallic splints is most unsatisfactory. These examinations for the position of fragments can easily be made through boards, cardboard, aluminum, a plaster cast, and celluloid casts. Adhesive plaster, leadwater and laudanum, and an ointment of mercury and belladonna, which are frequently applied over wounds, often interfere considerably with the diagnosis of doubtful or line fractures. All *doubtful* cases of fracture should be examined *before dressings* are applied. In these doubtful cases there is usually no deformity, and nothing can be lost in waiting for the application of permanent dressings or until after the *x*-ray examination has been made. All fractures should be examined from at least two angles, and when possible these examinations should be made at right angles. *Stereoscopic plates* are of advantage especially in the neighborhood of joints and about the head, and especially when the patient cannot be moved so as to get right-angle plates. Stereoscopic plates are of value in the diagnosis of fractures of the skull. Fractures of the spine should be studied if possible from both an anteroposterior direction and in a lateral direction. A lateral view of the spine cannot always be made satisfactorily, especially in very stout or muscular men, but, by the use of intensifying screens and careful technic, practically all can be demonstrated, and many fractures that were previously overlooked because they gave no characteristic symptoms of fracture, are now clearly demonstrable by the Röntgen rays.

Dislocations.—Dislocations of joints can generally be recognized by ordinary clinical signs, but it is important to have Röntgenograms of these dislocated joints to show the exact location of the dislocated bones and to demonstrate any associated fracture complicating the treatment and the results. It is also important to make Röntgenograms after the reduction to prove that the reduction has been complete.

Diseases of Bones.—In most diseases of the bones the lesions can be accurately demonstrated by the Röntgen rays and in most cases a definite diagnosis can be made by this means alone, but in all cases valuable assistance can be rendered to the surgeon in making a differential diagnosis. It should be remarked that in the earliest stages of *acute osteomyelitis* the diagnosis cannot be made by the Röntgen rays. Therefore, a negative report in a case suspected of being acute osteomyelitis should not be regarded as final and if the diagnosis cannot be made by clinical means, the examination should be repeated until the diagnosis is possible. In this brief chapter it is utterly impossible to give a complete description and illustration of the various diseases of bone. Whole books have been written on this subject alone. The leading characteristics of a few of the most common diseases of bone will be mentioned.

Tuberculosis is characterized by a general transparency extending outward from a joint due to a general absorption of the lime salts, and commonly associated with some destruction of the joint surfaces of the bone.

Myeloid sarcoma shows a central destruction of the bone extending outward

to the periphery, and sometimes develops to the extent of the disease breaking through the walls of the bones and extending into the surrounding tissues, with no definite line of demarkation and no bone sclerosis.

Periosteal sarcoma shows a destruction of the periphery of the bone with an elevation of the periosteum and a tumor formation which extends into the soft tissues.

Local gumma of the bone resembles somewhat periosteal sarcoma but it is associated with more actual destruction extending from the surface downward with less tumor formation, no elevation of the periosteum, and associated with bone sclerosis.

Periostitis is indicated by a slight thickening or elevation of the periosteum without other localized destruction of the bone.

Osteomyelitis is indicated by localized areas of destruction of the bone extending sometimes through the entire shaft, together with much bone sclerosis and small abscesses, marked thickening of the periosteum with a putty-like deposit over the periosteum, and frequently associated with sequestra.

All diseases of bone can be demonstrated.

Diseases of the Joints.—All diseases of the joints can be demonstrated by the Röntgen rays if there be change in the bony structure, exudate into the joint spaces, or thickening of the soft tissues about the joints.

Fractures of the Skull.—Fractures of the skull can be demonstrated but sometimes a number of negatives are required, and stereoscopic plates give a distinct advantage. There is some danger of diagnosing ordinary sutures and blood-vessel grooves as fractures, and this should always be kept in mind. When a number of negatives are made they should be made from different angles. Sometimes a fracture is found on the side opposite to the injury.

The nasal accessory sinuses and the mastoid cells can be clearly demonstrated, and the pathological processes in these sinuses and cells are usually demonstrated by an increased opacity due to exudate or tumor formation, or are indicated by an absorption or destruction of some of the septa or all of the various sinuses.

Intracranial Lesions and Diseases of the Bones of the Head.—The most common disease of the cranial bones is syphilis, indicated by an increased porosity and increased thickening of the tables of the skull, with a distinct disturbance in the diploë. *Tumors* are also found in these bones, as indicated by increased thickening, porosity, and more definite localization than in syphilis. *Osteomyelitis* is frequently observed, and is indicated by the usual characteristics of osteomyelitis. Intracranial tumors can be recognized if they are located superficially and cause pressure upon the bones of the skull so as to cause a thinning, or if the tumor is increased in density, such as Pfahler has seen in gumma and fibrosarcoma, but unless the tumor causes pressure on the inner table of the skull, or is of more dense structure than the cerebral tissues, it cannot be demonstrated. An associated sign of tumor is sometimes found and is indicated by dilatation of the meningeal vessels on the affected side. The most frequent location of tumors demonstrable by the rays is in the pituitary region, and these are indicated by a distinct increase in the size of the sella turcica and partial or complete destruction of the clinoid processes, or associated with the destruction there is a marked hypertrophy and elongation of the posterior clinoid processes. At times tumors in the pituitary region can be recognized by an increased density probably due to calcareous deposit. Just as these tumors cause pressure upon the clinoid processes, there may be pressure on the floor of the sella turcica and encroachment upon the sphenoid sinus. Stereoscopic plates are essential in all head examinations, and will give additional evidence in connection with the intracranial tumors, but in the study of the sella turcica it is always advisable to make a very small localized Röntgenogram of the sella turcica. This increased detail gives increased information. Internal hydrocephalus is indicated by deeply marked depressions, corresponding to the convolutions of the

brain, throughout the skull. When this condition is due to congenital syphilis, the skull sutures unite early. When it is due to internal hydrocephalus they are apt to be ununited or even separated. In external hydrocephalus the entire skull is deformed, the convolution markings are not nearly so prominent and may even be absent, and the skull sutures are separated.

Intrathoracic Surgical Conditions.—Patients suffering from intrathoracic conditions should be studied both fluoroscopically and Röntgenographically, and generally the examinations should be made both in the recumbent and vertical positions, but the vertical position is especially important. Pleural effusion is recognized by a general or homogeneous opacity with an upper level more or less clearly defined by the transparent lungs above, but this upper line is rarely a straight or horizontal line unless there be free air above it. The character of the fluid cannot be recognized definitely by the *x*-ray. One can form some estimate of the amount of fluid, its location and its mobility. Generally if the fluid does not change its position between the recumbent and vertical position it is encapsulated. The encapsulated empyema has been especially frequent during the recent epidemic of influenza. These encapsulated empyemas may be located anywhere in the chest, but a rather favorite location is that between the middle and lower lobe on the right side, and at the outer side of the base of the chest on both sides. If the pleural effusion be great, there will be associated a displacement of the mediastinal organs toward the opposite side. Pneumothorax is recognized by a clear, transparent area without lung markings, together with displacement of the lung tissue, and if the pneumothorax be great, displacement of the mediastinal tissues toward the opposite side. Hydropneumothorax and pyopneumothorax are recognized by the opaque fluid below, with displacement of the lung tissue and mediastinal tissues, and especially by the clear, transparent area above the level of the fluid, and if examined fluoroscopically, and if the patient be shaken, this fluid can be seen to splash.

Abscess of the lung is recognized by a localized area of opacity generally surrounded by more or less inflammatory or less dense tissue, but the positive diagnosis of abscess will depend upon its central location, or especially upon the finding of air above the level of fluid when the patient is in the standing position. *Gangrene of the lung* is recognized primarily by the odor, and its location is determined by the finding of a localized area of consolidation surrounded by more or less transparent lung tissue, and the central portion of the gangrenous area is more transparent, thereby giving the appearance of cavity formation.

Malignant Disease of the Lungs.—Primary carcinoma of the lungs is extremely rare, but when present is recognized by the tumor formation usually extending outward from the mediastinum, or root of the lungs.

Metastatic carcinoma or sarcoma of the lungs is quite common, and is especially common associated with carcinoma of the breast or sarcoma anywhere. It is my opinion that carcinoma of the lungs is often present preceding the operation on the breast, and for this reason a careful chest examination should always precede an amputation of the breast (see page 1592).

Hydatid cysts are recognized by the dense globular areas localized in the lungs and surrounded very definitely by clear lung tissue. The varying degrees of fixation of the diaphragm or displacement of the diaphragm from whatever cause, can be demonstrated by the *x*-rays.

Mediastinal Conditions.—Intrathoracic goiter can be demonstrated, and this is important preceding operation for goiter.

Enlarged thymus is especially demonstrable in children; an examination should precede operations. Fortunately enlarged thymus responds marvelously to *x*-ray treatment.

Mediastinal tumors of all varieties can be demonstrated as to their extent, their size, and their degree of pressure on the surrounding organs.

Aneurism of the arch of the aorta, its size, location, and degree of pulsation can be clearly demonstrated.

The heart, together with its variation in size, its pulsations or its position can be demonstrated.

Enlarged mediastinal and enlarged peribronchial glands can be demonstrated and are of importance in association with surgical conditions outside the chest. For example, in Hodgkin's disease at times the lymphatic glands may only be moderately enlarged externally, but may be much enlarged in the mediastinum, and will serve as a guide for or against operation.

The Alimentary Canal.—The alimentary canal is sometimes studied by means of the introduction of gas, either naturally or artificially introduced, but generally these studies are made by means of the use of an opaque meal consisting of two to four ounces of barium sulphate in buttermilk or gruel. There are many modifications of technic and this study in itself is so extensive that volumes have been written on this alone. (Carman and Miller, "The Röntgen Diagnosis of Diseases of the Alimentary Canal." W. B. Saunders Company.) Therefore only the most essential points of interest will be discussed. A barium meal or opaque capsules or pills are observed as they pass through the entire gastro-intestinal tract. The food can be clearly seen passing downward through the esophagus. The following surgical conditions can be recognized.

Diverticulum is recognized as a pouch on the side of the esophagus which becomes distended by the opaque fluid and encroaches upon the remainder of the esophagus, obliterating its lumen, thus interfering with the act of deglutition. The size, the position and the location of the orifice can be demonstrated, and this is of importance to the surgeon.

Strictures of the esophagus may be spasmodic or organic. A spasmodic stricture is complete, is usually smooth in outline, and is released suddenly allowing full and free passage of the fluid. The organic stricture is permanent usually presenting an irregular border. If benign the walls are generally smooth; if malignant the walls have a jagged appearance or there is a serrated outline of the opaque food. It is of importance to the surgeon to know the size of the lumen, the location of the tumor and the amount of esophageal dilatation above.

Cardiospasm is located at the point where the esophagus passes through the diaphragm, or at the cardiac end of the stomach. It is primarily a spasmodic stricture of the esophagus. It therefore presents a smooth lower border, the obstruction is complete even to fluid, and often presents enormous dilatation above; this condition may exist for many years without being recognized either by the patient or the physician. Pfahler has seen the esophagus sufficiently dilated to hold three or four pints of fluid, so that in two cases the patient was sent to him for an examination of the stomach because the attending physician obtained much fluid with the stomach tube, and yet could not obtain any free hydrochloric acid.

The Stomach.—By this method the size, outline, position, peristaltic movements, rate of emptying and general mobility of the stomach can be recognized.

Pfahler ("American Quarterly of Röntgenology," Feb., 1913) groups Röntgenological evidences of gastric ulcer under three headings, as follows:

"1. The evidence of perforation: (*a*) A projecting shadow outside the gastric shadow. (*b*) A gas bubble lying above this collection of bismuth. (*c*) Perigastric adhesions or involvement of other organs. (*d*) A palpable tumor connected with the stomach, but not affecting the lumen. (*e*) The above may be associated with either an organic or spasmodic hour-glass contraction of the stomach. (*f*) Retention of bismuth or barium in the ulcer after the remainder of the stomach has been emptied. (*g*) Resistance corresponding to the projecting shadow.

"2. The evidence of irritation, due either to a florid ulcer or to an irritable scar of an ulcer: (*a*) Spasmodic contraction. (*b*) Retention of food in the stom-

ach after six hours. (*c*) Painful pressure point corresponding to the location of the ulcer. (*d*) Normal outline of stomach.

"3. Secondary effects usually associated with a callous ulcer: (*a*) Pyloric stenosis and gastrectasis. (*b*) Fixation. (*c*) Organic contraction—hour-glass. (*d*) Interference with peristalsis. (*e*) Reversed peristalsis. (*f*) A contracted lesser curvature with retraction of the pylorus to the left."

Duodenal Ulcer—Ninty-five per cent. of duodenal ulcers occur in the first portion of the duodenum (Moynihan). These ulcers cause either deformity or spasm in this first portion of the duodenum, and since this portion of the duodenum can be clearly demonstrated, and presents a triangular appearance on the fluorescent screen and also on the *x*-ray plate, or an appearance which Cole has likened to a bishop's cap, it is therefore commonly spoken of as the "cap."

Fig. 1108.—Stomach showing perforating ulcer at the middle of the lesser curvature, with normal first portion of the duodenum. Outline of the bowel showing from a meal given twenty-four hours previously (Pfahler).

Fig. 1109.—Normal stomach. Duodenal ulcer shown by contractions in the outline of the first portion. Compare with Fig. 1108 (Pfahler).

When this first portion of the duodenum or cap is smooth in outline, having a definite smooth base resting on the pylorus, and the walls on all sides are smooth terminating in a cone, ulcer is considered to be absent, because there is no evidence of either indentation or deformity such as ulcer produces, nor contraction. We believe, therefore, that both the positive and negative diagnosis of duodenal ulcer can be made in approximately 95 per cent. of the cases when the work is done by a Röntgenologist skilled in this line of work. At times this ulcer is indicated by a nitch or projection outside the walls of the stomach which indicates perforation. At other times there is a retraction or slight filling defect on one or the other walls, and this filling defect persists throughout a prolonged fluoroscopic examination and is shown in many Röntgenograms made of this section. At times the entire duodenum is deformed and contracted. In all these cases the evidence presented by the Röntgenologist must be carefully co-related with the history and other clinical evidence.

Diverticuli of the duodenum are recognized by a pouching effect extending outward from the walls of the duodenum.

Adhesions of the duodenum can at times be recognized by their effect upon the stomach or duodenum in drawing them definitely out of place or in some instances by causing deformity in its outline.

The small bowel presents little Röntgenological evidence, and only in cases of obstruction or definite fixations can any thing abnormal be recognized. Obstruction can at times be recognized by the distention with gas above the point of obstruction.

The Appendix.—Unless the appendix be obliterated by exudate, it can usually be visualized by means of the opaque barium buttermilk meal. It is demonstrable best at the end of eight or twenty-four hours, but at times it can be seen for days, weeks, or even months after the barium meal has been given. An

Fig. 1110.—Normal stomach. Dilated duodenum. Adhesions drawing the duodenum upward and to the right. Gall-stones showing between the duodenum and the liver (Pfahler).

Fig. 1111.—Extensive carcinoma of the stomach, indicated by the filling defects and the general serrated edges (Pfahler).

acute appendicitis seldom demands an *x*-ray examination, and little or no evidence can be found in acute appendicitis aside from filling the colon and determining the point of localized tenderness and its relation to the bowel or other organs. In *chronic appendicitis*, the symptoms are often very obscure and very often point more strongly to the stomach than to the appendix. In these cases, the *x*-ray study is of most importance, and the evidence of chronic appendicitis is indicated by marked localized tenderness over the appendix. The appendix is only partially patulous. It is likely to be fixed. It may be distorted, or may be located retrocecally. It is often fixed by adhesions. The cecum is usually tender and more or less fixed. When the appendix is moveable, the localized tenderness moves with the appendix, and sometimes this tender point can be moved as much as six inches. In addition to determining the presence of chronic appendicitis the location of the appendix is very impor-

tant, for sometimes the appendix is found up at the liver, and in one case I found it surrounding the pyloric end of the stomach, and in other cases it may be located on the left side of the abdomen.

The Colon.—The opaque meal referred to above can be followed throughout the entire colon, and normally nearly or all of the opaque meal will have passed out of the intestines in about 24 hours. In intestinal stasis this opaque meal may remain in the colon for days or weeks. When the colon is outlined by the opaque meal it can be moved about, if not attached by adhesions, within a radius of a few inches in all directions. If bound by adhesions, it cannot be moved, and in this way one can determine such conditions as Jackson's membrane or any other similar condition which may be associated with extensive adhesions. *Obstruction of the colon* can be recognized by the stoppage of the barium at a certain point, but this does not occur unless the constriction be

FIG. 1112.—A case of chronic appendicitis. The appendix elongated, and attached in the gall-bladder region. Cecum directed upward. Symptoms were entirely referable to the stomach and gall-bladder (Pfahler).

very small. *Constrictions of the colon* are best recognized by an opaque enema consisting of two to four ounces of barium sulphate mixed with a tumblerful of kaolin, and two to three pints of water. This mixture is distinctly opaque to the *x*-rays and when injected into the rectum it can be traced throughout the entire colon. The outl ne of the bowel is clearly shown and if any constriction, indentations or filling defect be present, it will be clearly demonstrable. Many precautions must be taken to avoid error in interpretation. *Carcinoma of the colon* is best demonstrated by means of the opaque enema. If carcinoma be present a distinct filling defect will be shown and this filling defect is, I think, always associated with a considerable amount of serration in the region of the constriction, such as is produced in general by carcinoma. It is possible that an opaque meal may pass entirely through a constriction caused by a carcinoma and yet an opaque enema, even though it be very liquid, may not pass the constriction. The demonstration of carcinoma of the colon is important, not simply for the fact of diagnosis, but also to determine its size, its position, its adhesions to the surrounding structures, and at times even the evidence of

metastasis can be demonstrated, and thus an unnecessary exploratory operation may be avoided.

Diverticulitis sometimes gives rise to symptoms, resembling very strongly those of carcinoma. For instance, if there be a perforation present there may be a large inflammatory mass palpable in the abdomen through the abdominal wall, and there may be associated considerable pain, and nearly always a certain amount of constipation. There may also be a passage of blood and mucous. These point strongly toward carcinoma, but carcinoma and diverticulitis can be easily differentiated for with carcinoma there is a decided filling defect; with diverticulitis the lumen of the bowel is normal unless encroached upon by pressure of a mass on the outside, in which instance there will be an absence of the serration which is found in connection with carcinoma. In addition to this, one can generally demonstrate the opaque enema entering the pocket or pockets outside the line of the bowel wall. This can be demonstrated at times by the opaque enema, but at other times the demonstration can only be made positive after sufficient time has elapsed for the entire bowel to have emptied itself. This may require two or three days, or a week, and after this time, with the bowels empty of the general opaque enema, the little pockets of retained barium are opaque, making the diagnosis positive.

Each case must be studied according to the indications present, but routinely Pfahler (Jour. Am. Med. Assoc., Dec. 14, 1918, vol. 71, pp. 1951–1955) orders for the patient a purgative on the night before the examination. Then have him report at 9 o'clock in the morning, without breakfast, at which time about six or eight plates are made of the gall-bladder region. Then the esophagus, stomach and duodenum are studied carefully. If nothing be found abnormal in the stomach or duodenum, he is then allowed to eat his lunch, and then return at 5.30 for a second examination at which time the stomach is nearly empty, even of the second meal he has taken, and the opaque meal is in the cecum and ascending colon. At this time, some valuable information can be obtained with regard to the appendix, the mobility of the cecum, and any obstruction if it should be present in the ileum. Obstruction in the ileum is an extremely rare occurrence in Pfahler's experience. If there be any suggestion of gastric ulcer found in the first examinations, the patient is not allowed to have any food for a period of six hours, at the end of which time he is again examined. If the stomach at the end of six hours shows evidence of distinct retention and there be no marked ptosis or atony of the stomach present, one can conclude that the retention is due to a pylorospasm which is some evidence of gastric ulcer. In Pfahler's experience, this six-hour examination is rarely needed.

Examination of the gall-bladder is of value. According to Pfahler, Case, Cole and George, gall-stones can be recognized if the work be carefully and thoroughly done, and from eight to twelve plates are made, in approximately 50 per cent. of the cases in which gall-stones are present. In addition to these there is suggestive evidence of gall-stones in probably 25 per cent. more. This evidence may consist only of slight mottling, a pressure effect upon the duodenum in the gall-bladder region or just an increased density localized in the gall-bladder region, or evidence of adhesions indicated by a retraction of the stomach and duodenum to the right. These findings in themselves are insufficient to make a diagnosis, but when associated with clinical symptoms referring to the gall-bladder, and when by Röntgenological evidence the stomach, the duodenum, appendix and bowel are found normal, the doubtful evidence above referred to is of some distinct value.

The Urinary Organs.—In a study of the urinary organs the Röntgenologist should be able to determine the size and position of the kidneys in a normal subject weighing 160 pounds or less. In larger persons only the best skiagraphs will show the outline of the kidneys. In patients under 160 pounds renal calculi from the size of a No. 2 shot to the largest found, whether single or multiple, in

one kidney or both, and relatively their situation in the kidneys (except in stones composed of pure uric acid) can be determined in Röntgenographs of the best quality.

Ureteral calculi are subject to the same display as renal calculi. The course of the ureters is by no means constant, so that one cannot say that a shadow lies in the line of the ureter unless this line be determined by additional means. However, in the great majority of instances the history of renal colic; a point of tenderness on deep pressure; the presence of microscopical quantities of blood in the urine; the fact that ureteral calculi are almost never round, but oval or irregular, in contrast to the small round shadows cast by phleboliths, or calcareous deposits in the mucous membrane of the female genitalia; and, the mulberry appearance of calcified lymphatic glands, are sufficient to confirm a Röntgenographic diagnosis of ureteral calculus (see page 1457). Vesical calculi are more apt to escape notice since they are not infrequently composed entirely of uric acid. When they do contain more dense material the Röntgen diagnosis is usually positive as to size and number.

In the past few years great progress has been made in the Röntgenographic study of surgical conditions of the urinary organs with the aid of ureteral catheterization and injection of solution of colloidal silver, argyrol, potass iodid, sodium bromid. The study demands the assistance of one skilled in the use of the ureteral catheter, and this part of the subject is treated of in another section (see pages 1452 and 1455).

The part of the Rontgenologist is, to be prepared to make Röntgenographs at intervals during the injection and with the patient in both the recumbent and erect postures when desired. Manges has pointed out the advantages of making these examinations fluoroscopically.

The points of information gained by the Röntgen study of the kidney pelvis injected with collargol (*pyelography*) are: the position, shape, size, and the extent of mobility; also the relation of the kidney pelvis to calculi in the kidney, ureter, or gall-bladder.

The normal kidney pelvis will hold from 10 to 30 c.c. of the solution, and the calices are sharp in outline, branching at the apices, and well separated. The hydronephrotic kidney may hold any amount above this to 500 c.c. or more. The calices are less separated, the apices are rounded and smooth, and all the calices have much the same appearance. The pyonephrotic kidney may hold small or large quantities; one or more of the calices may be involved, and the outline is irregular, never smooth, as in hydronephrosis. Tumors involving the kidney produce distortion, but usually not marked enlargement of the pelvis and calices. One or more of the calices may be long, narrow, and irregular in outline. Abscess of the kidney when communicating with the renal pelvis permits of injection with collargol solution, and shows as a more or less large shadow external to the shadow of the renal pelvis.

The mobility of the kidney may be shown in some cases by skiagraphing the injected kidney before and after manual displacement of the organ, but when possible the exposures should be made with the patient recumbent one instant and erect the next. The change must be made quickly, as the collargol promptly leaves the unobstructed pelvis. A stone in any portion of the kidney pelvis will be included in the shadow of the injected pelvis; a point which not only serves to differentiate stone in the pelvis from stone external to the pelvis, but shows the necessity of preliminary Röntgen examination.

The study of the ureters by this method requires that the ureters be filled to their maximum capacity throughout their entire length at the time of exposure. The patient may be placed in the Trendelenburg position with the ureteral catheter inserted only a few centimeters, so that gravity will retain the collargol solution in the ureter and kidney. In this way the true line of the ureter and diameter of the lumen will be shown. In a case of hydro-

nephrosis due to ureteral kink associated with a movable kidney, to pressure from without, to constriction by adhesions, or to obstruction within the ureter, there will be shown a dilated ureter above the impediment and a narrow lumen below. If there be more than one point of interference the ureter will show a corresponding number of areas of dilatation. An almost completely obstructed ureter will be evidenced by the presence of only small areas of collargol shadow above the point of obstruction. Here again, as pointed out by Fowler and Stover ("American Quarterly of Röntgenology," Aug., 1912), skiagraphing the patient very promptly after putting him in the erect posture will often show the nature of the kink. Stone in the ureter may be positively diagnosticated by finding that collargol will enter the diverticulum occupied by the stone; by noting more or less distortion of the line of the ureter at this point and dilatation above, if the stone has been there for some time and caused obstruction. A stone acting as a "ball valve" in the ureter will be associated with dilatation including the stone shadow.

Kelly has used a water suspension of small quantities of bismuth subnitrate injected into the bladder and stereo-Röntgenographs to show the presence of and extent of tumors involving the bladder.

In addition to the above pathological findings, all sorts of anomalies and anatomical peculiarities of the urinary organs are plainly shown. Kelly and Lewis prefer an emulsion of silver iodid to collargol for pyelographic study, but the latter is more generally used.

The ureteral catheter containing lead shows the course of the ureter less accurately than proper injection of collargol, but does have the advantage of always being there at the time of exposure.

The proper preparation of the patient is an essential requirement in any *x*-ray study of the urinary organs. This consists of thorough purgation and abstinence from food or drink for at least six hours prior to the examination.

The Localization of Foreign Bodies.—This subject will only be discussed from the standpoint of the information needed by the surgeon, and not from the Röntgenologist's standpoint. Therefore, technical details will be omitted. Only the principles governing the various methods of localization can be discussed, so that the surgeon will understand the nature of the information which is presented to him by the Röntgenologist. The value of the localization will depend on the skill of the Röntgenologist and the clearness with which he can present the information to the surgeon.

Characters of Foreign Bodies.—Metallic bodies, such as bullets, pieces of steel or iron, pins, needles, tin, zinc, brass, etc., can be detected in any portion of the body, and accurately localized. Fragments of stone, granite, marble and lead glass can be localized except when very small and deeply situated. Drainage tubes and iodoform gauze if lost in a sinus or cavity can be demonstrated. Anthracite coal, glass (other than lead glass) or splinters of wood are difficult to detect unless they are of considerable thickness, are not superimposed by bone, and are imbedded in surface structures, so that the body can be brought close to the sensitive plate. Sometimes splinters of wood or other transparent bodies can be localized because of metallic dust or dirt that has been carried into the wound by the foreign body.

The Preparation of the Patient.—The clothes should always be removed from the part to be examined, and when at all possible, dressings should be removed. In fact, satisfactory localization cannot be made through dressing, and when a dressing is needed it should be at least no more than packing in an open, bleeding wound. When practical, the skin covering the part to be examined, should be cleansed, so that marks placed upon the skin by the Röntgenologist can remain there. The foreign body should be removed as soon after localization as is possible, not only because of infection which is likely to be carried into the wound by the foreign body, but because sharp-pointed foreign bodies, such as

needles or pieces of steel, are apt to be moved from their point of localization by the action of the muscles so that when operation is attempted, the foreign body cannot be found at the point at which it was originally localized. The manipulation of a part may displace the foreign body. For instance, needles have been forced out of the tissues of the foot merely during the process of scrubbing and preparing the foot for operation. When practical, the Röntgenologist should be present at the operation, but in all instances, there should be sufficient coöperation between the surgeon and the Röntgenologist to permit the surgeon to understand thoroughly the markings and information given by the Röntgenologist in each particular case.

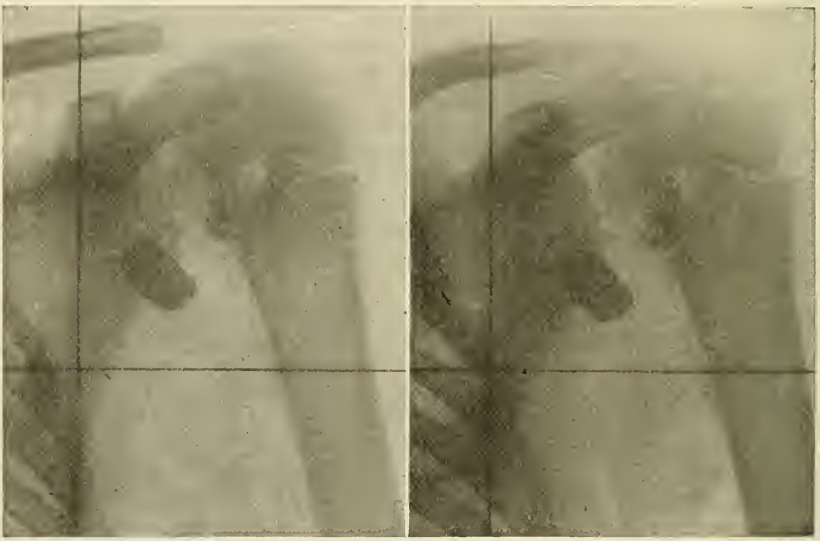

Fig. 1113.—Bullet localized by Manges by means of stereoscope. Removed by author.

Choice of Methods of Localization.—The method of choice for the localization of foreign bodies will depend first, upon the character of the equipment in any particular hospital; second, the form or character of the foreign body; third, upon its probable location, and fourth upon the opportunity that the Röntgenologist has had of perfecting his technic.

Preparation of the Patient.—The patient should always be examined with the part in the position in which it is likely to be placed during operation. That is, if the patient will require a general anesthetic he will likely be in a recumbent or supine position.

Principles of Localization of Foreign Bodies.—The *x*-rays move in a straight line from their source, and cannot be deflected. Therefore any opaque body in the path of these rays will project a shadow in a straight line between the source and the point of recording, whether the shadow be recorded on the photographic plate, or whether it be observed upon a fluorescent screen. Therefore, for purposes of localization of a foreign body, one must know the relation of the source of the rays on the target of the *x*-ray tube and the position of the shadow on the fluorescent screen or photographic plate in relation to the point of the object under observation. The central ray is a ray passing from the center of the target through the center of a foreign body. This central ray should if possible be made vertical to the plate or to the fluorescent screen in one position, and by closing the diaphragm until it is very small, under fluoroscopic study, this can easily be accomplished, by moving the tube until the foreign body is brought directly in the center of the small field upon the fluorescent screen. When the

central ray has been made to pass perpendicularly through the center of a foreign body we have at once localized the foreign body in the two vertical planes, but one must never judge the position of a foreign body from any single exposure on a plate or screen, for its depth can never be determined by such a single exposure. If the part under examination and the foreign body are kept in a fixed position and the tube be moved, the shadow of the foreign body will be projected at a different point. This second central ray also passes through the foreign body and at the point where these two central rays cross, the vertical ray and the ray of displacement will give the depth of the foreign body. All methods of localization, therefore, depend upon the determination of this depth point and the variation in the method is only a means of finding the point of crossing in these two central rays. The foreign body must be located with reference to some definite landmark placed upon the skin. This landmark is usually made by means of some indelible ink. If the photographic method of localization be used this landmark can be recorded by placing over the indelible mark on the skin an opaque body such as a pair of crossed pins, a ring or a definitely shaped metallic ball. The Röntgenologist determines the relation of the foreign body to the landmark on the skin. It is important, therefore, preceding the operation and during the operation that this landmark on the skin should be preserved. It is the duty of the Röntgenologist, so far as is practical, to localize the foreign body in relation to certain anatomical structures or landmarks so that if the skin mark be lost the surgeon can find the foreign body in its relation to the bones and anatomical structures.

Methods of Localization.—The methods of localization may be divided into two great groups; the fluoroscopic and the photographic. The fluoroscopic has the advantage of speed, and therefore during military operations in evacuation hospitals where patients must be examined in the shortest period of time, the fluoroscopic is the only practical method. It has the disadvantage of being less accurate and more dangerous to the operator and even to the patient if prolonged, though by modern technic there is practically no danger to the patient. No technic is described.

It is only in the hands of an amateur Röntgenologist, or of a surgeon who is assuming the rôle of a Röntgenologist, that the fluoroscopic localization of foreign bodies is a danger both to the patient and to himself. In this group of cases, however, extreme accuracy is not so important as speed, for in modern wars the projectiles are not small and the injuries are usually great. In connection with the Röntgenology in the recent world war, Col. Case very aptly says: "This war is not being fought with bird-shot, and the localizations as a rule to ½ centimeter will be entirely satisfactory." In the fluoroscopic methods of localization of foreign bodies every precaution for the protection of the operator, so far as is practical, should be observed, for constant exposure of the operator to the rays for many hours of every day is bound to do harm. In all fluoroscopic methods of localization the Röntgenologist should first make a general exploration of the injured portion of the body to determine the number of fragments or foreign bodies present, and their general location and size. He then centers the tube so that the central ray passing through the foreign body is vertical to the fluorescent screen. The diaphragm controlling the beam of rays is reduced to the smallest practical size. The tube is moved until the foreign body is brought exactly in the center of the fluorescent field. A mark is then made upon the skin of the patient directly over the point of exit of the central ray. This can usually best be accomplished by passing the pencil directly through a hole made in the screen after the screen has been so placed that said hole falls directly over the foreign body, or the Bowen marker may be used to advantage. We then know that in the position in which the patient is lying at that time, the foreign body is in a direct vertical line from the point marked on the skin. Its depth, however, has not been determined.

The tube is then moved a certain distance, according to the method used. The displacement of the shadow of a foreign body in relation to this vertical ray, and in relation to this mark on the skin is determined. By various methods the depth of a foreign body is then obtained. When dealing with the fingers or the extremities, one can sometimes mark the localization of the foreign body as indicated by the central ray in one position, then rotate the part of the extremity at right angles, and determine again the position of the foreign body by the vertical ray passed at right angles to the original vertical ray, and in this way the depth can be definitely determined. The fluoroscopic localization of foreign bodies is usually done in a darkened room with a tube under the table, the top of which is transparent to the *x*-rays. In the army, the ordinary army stretchers are usually employed. The tube under the table is capable of movement in at least two directions. There should be a diaphragm controlling the outlet of the rays so that they may be reduced to a minimum. The excitement of the tube should be usually controlled by a foot switch. In this way the amount of exposure can be reduced to a minimum. In the evacuation hospitals in many instances the localization of the foreign body was combined with the operation, the surgeon and the Röntgenologist working intermittently with ruby light for the surgeon, and with darkness for the Röntgenologist. When the stereoscopic fluoroscope is finally made practical for every-day use, the combined operation by the surgeon and Röntgenologist for the removal of foreign bodies will probably displace all other methods. The stereoscopic fluoroscope was developed by Caldwell almost to perfection.

The Röntgenographic method of localization has the advantage of accuracy and safety, at the expense of speed. The examinations are usually made in a well-lighted room with the patient lying on the Röntgenographic table with the tube over the top instead of underneath. The patient is fixed in a definite position, and an opaque marker is placed upon some part of the skin and the relation of the tube to this mark is recorded. Exposures are then made in two different positions. If the height of the opaque mark on the skin from the surface of the plate has been recorded, the positions of the tube can be determined by cross threads and then with the same cross threads leading from the positions of the tube to the shadows of the foreign body one can determine the depth and the exact location of the foreign body in its relation to the skin mark. By this method the patient is absolutely safe from any danger of exposure to the rays, and the operator is out of the field of the rays. The plates must be developed, washed, dried, and then the calculations made, after which the operation can take place. It is therefore not practical where the removal of a foreign body must be made within an hour or two after the patient reaches the hospital.

Methods of Localization Adopted by the Surgeon General's Office in the United States Army (U. S. Army *X*-ray Manual).—After receiving reports of both surgeons and Röntgenologists abroad, and after conference with Col. James Case, it was decided to adopt and provide apparatus for seven different methods. They are as follows:

These methods can only be described briefly so that the surgeon can understand the principles involved, and in a general way have an idea how localizations are made, but the space allotted to the subject will not permit a detailed discussion of technic.

The Nearest-point Method.—This method has the advantage of simplicity, great speed, with a fair degree of accuracy. The method consists in palpating under fluoroscopic observation the soft tissues surrounding the projectile. The instrument used for this palpation is a wooden rod about 10″ long with a wooden screw or some similar piece of metal at each end. Under the screen the wood is almost invisible, and the only clearly defined shadow is that cast by the metal. By the movement of the projectile under pressure on the tissues surrounding it, and the amount of pressure used, the operator is able, with care and ability,

to judge what point of the skin is nearest the projectile and also the depth of the latter. Obviously, palpation at a very near point will ordinarily cause much greater movement of the projectile than will palpation at a more remote point. Likewise, palpation will cause greater displacement in the very soft tissues than it will in the more firm. Skill in this method increases with continuous use, and a sense of pressure is developed that proves a valuable aid to speed and accuracy. To the beginner in this method it is recommended that he combine with palpation the principle of method B. by shifting his tube and observing relative displacement of the projectile and the palpating stick. The nearest-point method is applicable to localization of projectiles in the soft tissues, the extremities, the axilla, scrotum and buttocks, but not to the more vital and less palpable regions of the head, thorax and abdominal cavity. By practice, one becomes accustomed to palpating the soft tissues around the foreign body, and by what is termed light and deep palpation to determine the depth of the projectile from the nearest point on the skin surface. Even if the foreign body cannot be displaced by pressure with a palpating stick, this information is often of great value, showing the projectile must be in a joint, against a bone or imbedded in deep tissue. An indelible mark is, of course, placed upon the skin at this "nearest point," and a statement is given to the surgeon as to the probable depth at this point. This method is, in brief, adapted to localization in the extremities and soft parts of the body, under advanced hospital conditions where a rapid examination of the patient is a matter of great importance.

The other methods adapted for use in the army have been designated in the Army Manual by letters instead of by the names of those responsible for their development. This is not done with any idea of discrediting the author, or of indicating novelty, and for the sake of brevity the same idea will be carried out in these paragraphs. The more accurate methods are as follows:

A. Two-wire double tube shift method.
B. Parallax method.
C. Tube-shift method, with mechanical triangulation.
D. Profondometer.
E. Hirtz compass with accessory devices.
F. Cannula and trocar, with harpoon.

Method A (Strohl).—Briefly the method consists in fixing the hole in the screen directly over the central vertical ray. A mark is then made through the hole upon the skin. A diamond-shaped diaphragm or opening on the top of the tube box has a small wire stretched across each of two opposite corners. The tube is then moved either right or left in the line connecting these two corners, first in one direction until the shadow of the wire on the tube box coincides with the shadow of the foreign body. The tube is then moved in the opposite direction until the opposite cross wire coincides with the shadow of the foreign body. The distance between these two displacement shadows is then measured and the depth of the foreign body is then found according to a scale which is furnished with the outfit. In all fluoroscopic studies it is an advantage to mark the point of entrance and the point of exit of the vertical ray. This can be done by means of the skin marker, designed by Bowen, which can be pushed under the part of the body examined until the entrance of the vertical ray coincides with the shadow of the foreign body and similarly pushed under the screen until it coincides with the exit of the vertical ray.

Method B.—This method utilizes the optical principles of parallax and may be carried out with extremely simple apparatus, although a more elaborate device has been provided by Jordon and by Lane. If one observes the shadow of a projectile upon the fluoroscopic screen while the tube is moving and the projectile be very close to the screen, the shadow movement for a given tube-shift will be very slight, and the part of the body removed from the screen or

in other words, the greater the depth the greater will be the extent of the shadow motion. If we adjust a suitable opaque body outside of the patient until the shadow moves the same distance for a definite tube-shift as has been moved by the shadow of the projectile for the same tube displacement, the auxiliary body must then be in the same plane as the projectile whose depth is sought. For this purpose one may use the stick with the screw in the end, described under the nearest-point method, and, for example, if one is localizing a foreign body in the thigh, the screen is placed over the top of the thigh, the central ray found, and indelibly marked at its entrance under the thigh and on top of the thigh. The screw-head of the stick in the "nearest point method" is then held in the same vertical plain and moved upward and downward until it is found that the shadow of the screw-head moves equally with the shadow of the foreign body. This necessarily indicates the depth of the foreign body. The apparatus devised for this method of localization is provided with three horizontal arms, one of which passes under the patient and is fixed in the position of the entrance of the central ray; another arm is adjusted on top of the part under examination so that the opening in the end corresponds to the exit of the central ray; and the third arm, attached to a vertical post, is adjustable in this vertical plain so that when the depth of a foreign body has been determined its depth from above, below, or laterally can be read off from a scale marked on the rods and vertical posts.

Method C.—This is a single tube shift method with mechanical triangulation. Fluoroscopically one again locates the vertical ray, and marks its entrance and exit on the part under examination. The exact distance between the target of the tube and the fluorescent screen must be recorded. The tube is then moved a definite measured distance. The amount of movement of the shadow of the foreign body is then recorded. By means of two crossing straight lines drawn upon paper, or by means of two cross strings attached to the wall, or by a special apparatus with adjustable arms, one replaces the positions of the tube and the two shadows on the screen as above recorded, and at a point where these two lines cross is located the depth of the foreign body. This depth is then measured on the vertical post or vertical string. If the screen be not in direct contact with the skin, the amount of separation of the screen from the skin must be subtracted from the depth as above determined.

Method D.—The Profondometer (Flint). This method consists effectually in securing three lines of sight through the part under examination, each of which is to pass through the projectile. In other words, on the fluoroscopic table the vertical ray is marked at its point of entrance and exit as previously. The part of the body is then rotated, and another line of entrance and exit of the vertical ray is obtained in the same plane as before, and a third similar line, all of these lines to pass through the foreign body. Two pieces of flexible metal, such as tin, are hinged together in the middle and then moulded around the part of the body in the plane indicated by the skin marks and made to conform to the shape of this part of the body. The skin marks are transferred to this metallic band. After removing the latter from the body they may be laid down on a card or a sheet of paper, and by bringing the overlapping ends to the original position, a tracing with a pencil will show the outline of the body in the plane of examination. The skin mark positions are then transferred to the diagram, and we have an approximate duplicate of the shape of the body, and the location of the external skin markings. An atlas of cross-sections of various parts of the body is used conjointly.

Method E.—The Hirtz compass with accessory devices. Twenty-seven pages are devoted to the description of the Hirtz compass, its accessories and its use in the U. S. Army Manual, or the *x*-ray Manual, and a careful study of these twenty-seven pages is recommended to any who intend to use this method of localization. Briefly the method consists in finding the location of a foreign

body fluoroscopically by one of the first three methods previously described. The Hirtz compass consists of a central rod, to which is attached three adjustable arms standing on three adjustable legs, or rods used as legs. At the top of the central rod is attached an arch, and at the outer edge of this arch is attached an indicating rod, which is used to point to the foreign body. After the depth of the foreign body has been determined this central rod on the compass is adjusted in line with the vertical ray passing through the foreign body, and the three legs on this Hirtz compass are adjusted so as to conform to the shape of the body, and three marks are made to record the positions on the skin, or metallic washers are attached to the skin at the point where these legs touch. After careful adjustment, the compass is fixed in position and is sterilized to be replaced on the skin of the body at the time of the operation, and it gives the surgeon the advantage of using the arch at the top of the compass to move about the central axis through 360 degrees, and in an area measured by the extent of the length of the arch at the top of the central pin. It gives the surgeon the advantage of choosing many points for his incision, and always having the indicating pin directing to the foreign body and at the same time indicating its depth from his chosen point as measured by the indicating rod. The preparation of this record by the Röntgenologist is rather complicated. Its use by the surgeon is simple. If any of the adjustment screws become loosened or any of the arms displaced between the time of localization and the time of operation, all the work is lost, or must be repeated.

Method F. Cannula and Trocar with Harpoon.—This method is considered as the least desirable of all of the methods adopted, and it is urgently advised that it never be used excepting in the hands of an operator who will either work under the direct supervision of a competent surgeon or anatomist, or one who has acquired that degree of anatomical knowledge and surgical judgment which would permit of its use without danger to the patient. The method conists in finding the projectile as in the first three methods described. Then in direct line with the vertical ray, and never at an angle to this, a trocar is inserted through the skin. A cannula is then pushed down directly in the line of the vertical ray, until it touches the foreign body. A piece of piano-wire bent at one end in the form of a hook is then passed into the cannula until it passes through the opposite end against the foreign body. The hook then catches in the flesh, the cannula is withdrawn, the piano-wire is bent over and attached firmly to the skin. This serves as a guide to the surgeon in hunting for the foreign body. The method is considered dangerous and is very faulty unless the cannula be kept absolutely perpendicular and in direct line with the vertical ray passing through the projectile.

Fluoroscopic Assistance During Operation.—As soon as stereoscopic fluoroscopy (Caldwell) becomes practical, it is likely that most foreign bodies will be removed under the guidance of the stereoscopic fluoroscope. At present the removal of foreign bodies under the guidance of direct fluoroscopy by the surgeon is not usually satisfactory because it is rare that the surgeon has attained sufficient skill to make allowance for the distortion due to oblique rays, and unless the surgeon becomes a Röntgenologist, or the Röntgenologist a surgeon, the method will continue to have many objections. In all instances it involves considerable exposure of the hands, considerable work in the dark, and there is always the risk of damaging the anatomical structures.

The following methods may be used for combined work. *First.* The *x*-ray work may be done in the surgical operating room, thus affording the surgeon who operates special light, which may be extinguished when he desires to examine fluoroscopically. *Second.* The patient may be returned to the *x*-ray room when the surgeon requires further information. *Third.* The Röntgenologist may be called to the operating room for temporary assistance in pointing out the position of the projectile. *Fourth.* The operation may be performed with special forceps while using the fluoroscopic light as a guide.

Depth of Anatomical Landmarks Beneath the Skin.—Metcalf and Keys-Wells have published the following table[1] in the Lancet of May 27, 1916 for the purpose of giving surgeons assistance in determining the exact position of a foreign body in relation to points on the skeleton. By reference to this table the surgeon will better grasp the structure to which a certain depth will lead him when the depth is given to him by the Röntgenologist, as measured from the surface of the skin. These measurements have, of course, been calculated for the average soldier, and soldiers are generally neither very fat nor very thin. This fact must be borne in mind in considering these measurements.

HEAD: LATERALLY *Incision*	DEPTH OF ANATOMICAL POSITION
Just above zygoma	2.5 cm. to sphenosquamosal suture.
Just below zygoma	4 cm. to sphenoidal bone.
To coronoid process or condyle of mandible	2.5 cm.
NECK: ANTEROPOSTERIORLY	
Through center of larynx	5 cm. to body of vertebra.
3 cm. to side of center of larynx	4 cm. to transverse process of cervical vertebra.
3 cm. to side of center of larynx	7.4 cm. total depth of neck.
Through middle line of trachea just below cricoid	4 cm. to body of vertebra.
3 cm. to side of center of trachea	4 cm. to transverse process of vertebra.
From center of suprasternal notch	3 cm. to posterior border of manubrium.
NECK: LATERALLY	
From center of middle of neck	4 cm. to transverse process of vertebra.
From center of middle of neck	6 cm. to body of vertebra.
From just below tip of mastoid process	6 cm. to body of 1st cervical.
CHEST: SUPERIORLY	
From a point midway between root of neck and tip of acromion	5 cm. to apex of pleura, downward.
From a point midway between internal and external extremities and just behind posterior border of the clavicle	5 cm. to apex of pleura, downward.
CHEST: ANTERIORLY	
From center of lower border of clavicle backward to subscapular fossa just clear of ribs	7.5 cm.
From a point just over tip of coracoid to subscapular fossa backward	7.5 cm.
From a point 2.5 cm. external to sternoclavicular joint just below clavicle	3.5 cm. to 1st rib.
From a point 2.5 cm. external to sternoclavicular joint just below clavicle	2 cm. to pleura.
From a point 5 cm. external to sternoclavicular joint just below clavicle backward	3 cm. to 1st rib.
From a point 5 cm. external to sternoclavicular joint just below clavicle backward	4.5 cm. to pleura.
From a point 5 cm. below center of clavicle	5 cm. to pleura.
CHEST: POSTERIORLY	
To supraspinous fossa	2.5 cm.
To intraspinous fossa	2 cm.
To transverse process of 7th cervical vertebra	4 cm.
To pleura level of 7th cervical vertebra	5 cm.
To anterior level of body of 7th cervical	7.5 cm.
To transverse process of 12th dorsal vertebra	3.5 cm.
To pleura level of 12th dorsal vertebra	5 cm.
To anterior level of body of 12th dorsal vertebra	8.5 cm.

[1] These depths were given in inches in the original table but were converted into centimeters for publication in the United States Army *x*-ray Manual, from which this table has been copied.

ABDOMEN: THICKNESS OF WALL FROM FRONT	DEPTH OF ANATOMICAL POSITION
1 cm. to either side of middle line just above umbilicus	2.5 cm.
1 cm. to either side of middle line just below umbilicus	3 cm.
Just internal to anterior-superior spine to iliac fossa	7.5 cm.
Midway between anterior-superior spine and pubic crest to front of acetabulum	5 cm.
ABDOMEN: THICKNESS OF WALL FROM SIDE	
On level of tip of 12th rib in line upward from anterior-superior spine	2.5 cm.
ABDOMEN: THICKNESS OF WALL FROM BACK	
To transverse process 3d lumbar	4.5 cm.
To anterior level of body of 3d lumbar	11 cm.
To anterior level of psoas muscle	13 cm.
HIP AND THIGH FROM FRONT	
8 cm. below anterior-superior spine to head of femur	6 cm.
8 cm. below anterior-superior spine to neck of femur	5–7 cm.
15 cm. below anterior-superior spine (level of lesser trochanter) to front of femur	4 cm.
To greater trochanter	11 cm.
To lesser trochanter	9 cm.
Brim of pelvis 2.5 cm. in front of sacroiliac synchondrosis	9.5 cm.
To anterior-inferior spine	3 cm.
To spine of ischium	12.5 cm.
To ischial tuberosity	13 cm.
To anterior surface of line of junction of ascending ramus of ischium and descending, of pubis	7 cm.
HIP AND THIGH FROM BACK	
To ischial tuberosity	6 cm.
To spine of sacrum on level of posterior-superior spines of ilia	3 cm.
To sacral groove	5 cm.
To head of femur	5 cm.
To great trochanter	9 cm.
To lesser trochanter	7.5 cm.
To brim of pelvis 25 cm. in front of sacroiliac synchondrosis	10 cm.
To anterior-inferior spine	15 cm.
To spine of ischium	5 cm.
To posterior surface of junction of ascending ramus of ischium and descending ramus of pubis	11 cm.

Röntgenographic Methods of Localizing Foreign Bodies.—There are really a hundred or more methods of localizing foreign bodies, and many more modifications of methods. Only two or three of the simplest and most practical methods will be referred to, and these only briefly so that the surgeon or surgical student may understand the principles involved.

(1) *Röntgenographs at Right-angles.*—This method can usually apply to foreign bodies in the extremities, and the position of the foreign body is usually easily comprehended by the surgeon. An opaque marker, such as a pair of crossed pins, or a metallic ring, is placed upon the skin at the point of entrance, or near to the point at which the foreign body is likely to be found. With the patient lying upon his back, or the extremity lying in the position in which it is most likely to be operated upon, a plate is made with the anode or target centered directly above the opaque marker. The fingers or the extremity is then rotated at right angles, and another plate made in the same plane. Comparison of the two will usually give a fairly accurate idea of the location of the foreign body, and if a record has been made of the position of the tube in relation to the plate and opaque marker, exact measurements can be made by the Röntgenologist and the exact location given.

(2) *The Single Tube Shift Method.*—This is simply a reduction to photography of the fluoroscopic method described under "C." It consists in placing the

target of the tube directly above an opaque mark on the skin and above a known mark photographed directly on the plate. The tube must be placed at a definite height from the plate. A plate is then made in this position, or two exposures may be made on the same plate. Before the second exposure, the tube is shifted a certain distance. The two positions of the tube are then reproduced by cross strings leading to the shadow of the fixed marks, and a second pair of cross strings from the positions of the tube lead to the shadows of the foreign body, and at the point of crossing will be found the location of the foreign body in relation to the marks on the skin.

The Localization of Foreign Bodies in the Eye.—This involves the most accurate localization. A knowledge of the exact position of the foreign body is necessary for the ophthalmic surgeon to determine whether the eye can be saved or not. For this purpose the previously described methods of localization are too crude, and the use of the perfected Sweet localizer or the more simple Sweet-Bowen localizer is recommended, and for the use of these special skill is required of the Röntgenologist and a familiar knowledge of the detailed technic which can be found either in the United States Army *x*-ray Manual or in the articles written by Dr. Sweet or Bowen.

Röntgentherapy in Surgical Diseases.—The field of Röntgentherapy is very wide, but in this chapter will be considered only those diseases which are generally treated by the surgeon, and in which Röntgentherapy has been found beneficial. There will, therefore, be no reference made to skin diseases excepting epitheliomata. Reference to the paragraph of this chapter on the biological effect of the *x*-rays will give the reader an idea of the theory of the action of the rays on the various diseases under consideration and will help him to understand the effects produced.

Malignant Diseases.—Under this heading may be included, by far, the greater number of surgical diseases in which Röntgentherapy has been found beneficial. The Röntgen rays have their greatest effect upon the cells which approach the embryonic type, or those of recent origin or rapid growth, and least effect upon the normal tissue cells which usually make up the surroundings of the malignant tissue. Much experimental work and much microscopical study have been done upon malignant tissue to determine the effects of the Röntgen rays and radium rays.[1] Contamin did a number of experiments on the tumors growing upon mice. They were carcinoma of a granular type, and as a result of these observations Contamin drew the following conclusions: First, the action of the *x*-rays is the greater in younger and more actively growing tumors; secondly, the disappearance of a large tumor caused the death of the animal probably from intoxication. The disintegration products of the cells which have been injuriously affected by the rays are eventually absorbed by the body. When this absorption is excessive, it leads to a state of intoxication.

Nogier, Jaubert de Beaujeu and Contamin removed an adenocarcinoma from a mouse. It was then exposed to the *x*-rays, after which it was inoculated into normal mice to see whether it would grow. Under exposure to the soft rays, in which 50 per cent. of the rays were absorbed by the tumor, these inoculations gave no positives or "takes" and 15 negatives, while the controls gave 14 positive inoculations and one negative. The authors conclude from these, and similar observations, that the action of the rays is rather to hinder the subsequent growth of the tumors and to prevent their "taking" on inoculation. This is quite analogous to the effect of radium emanation upon the cells of rat sarcoma as shown by Jensen. In many cases where the histological features of the irradiated tumors were under investigation, only a small portion of the growth was exposed to the rays, the remainder being protected by a stout lead screen. In one tumor examined by Contamin only a small area, the size of a pea, was so exposed, the remainder of the neoplasm thus showing as a con-

[1] Radium, *X*-rays and the Living Cell, Colwell and Russ.

venient control. Two exposures of one hour were given on two consecutive days. Four days after the first irradiation the tumor was removed and prepared for histological examination. The non-irradiated part of the growth presented the character of a granular carcinoma, the cells having comparatively little cytoplasm, and the nuclei being round or oval. In the irradiated area the most marked change was the formation of cavities resembling cysts which originated in the center of cellular masses constituting the acini of the growth. Their walls were formed by the neoplastic cells themselves which in consequence of the pressure exerted upon them by the contents of the cysts had become flattened and otherwise more or less distorted. The cyst contents, after treatment with the usual histological fixing agent, presented a finely granulated appearance, while in the larger cysts hemorrhages were of frequent occurrence. In addition to this cystic stage, a commoner feature was the marked increase in the amount of stroma. The constituent fibers were densely packed together and in addition the nuclei of the connecting tissue cells were elongated and abnormal in contour. A considerable diminution in the number of neoplastic cells was observed and those which survived were more or less segregated into small groups by the greatly hypertrophied stroma. The cell groups were, however, observed not to be compact but, on the contrary, here and there were clear spaces and islands of degenerated cells. Another feature of the cell groups was that they were retracted from the stroma so that they did not come in contact with it, a condition of marked contrast to that obtained in non-irradiated areas, where the connection between the neoplastic cells and the stroma was remarkably close and intimate.

In the case of tumors removed eight days after the initial radiation, cysts were, generally speaking, absent; the main feature was the enormous increase in the stroma and the consequent subdivision of the cell masses into yet smaller islets, the section presenting an appearance as if the cells were undergoing strangulation by the fibrous tissue.

If the mouse bearing a tumor be exposed to *x*-rays, the tumor excised and subsequently grafted into normal mice, then after slight irradiation the grafts develop into tumors, but do not grow so quickly as the untreated tumor. With longer exposure the graft may remain in the animal for weeks without showing any signs of growth, and may then very slowly develop into a tumor. With still more prolonged exposure no growth at all takes place.

These observations become a strong factor in favor of anteoperative treatment. By that I mean treatment just preceding the operation, the *x*-ray treatment to be followed by operation in a few days. A tumor which has received a lethal dose shows no histological changes if it be examined at once. That is, a few hours after the exposure, but if it be left in the animal and portions be removed on succeeding days certain degenerative changes begin to make their appearance, and these changes are quite generally well established by the fifth and sixth days, the time depending upon the type of tumor and the amount of radiation.

Marie, Clunet and Raulot-Lapointe made a study of the effect upon the heredity of the characters imposed upon tumors when they are exposed to the *x*-rays. The mouse bearing the tumor (a sarcoma) was exposed to a strong dose (30 H) of unfiltered rays, and five days later the animal was killed and a portion of the tumor grafted into a number of mice. When this irradiated graft had grown to a suitable size, a mouse with the tumor was treated the same as the first, and this process was kept up for twenty months. The new characters imposed upon the tumors were found to consist mainly of, first, the reduction in the number or percentage of successful grafts; second, a reduction in the malignancy of the tumor; third, a slower rate of growth and certain histological features of which the following were the most important: (*a*) the presence of giant cells, some of the cells being as much as four or five times their original diame-

ter; (*b*) atypical mitosis; (*c*) basophile (giant) cells, having multiple nuclei. In order to determine whether these characteristics would be transmitted through a number of generations, even if entirely removed from the rays, they took one of these tumors and grafted it onto a mouse, and when it had attained sufficient size the mouse was killed and a section again grafted onto a new mouse, no rays being applied. It was found that there was a tendency on the part of the tumor gradually to return to its normal condition, but even in the sixth generation there were many cells showing the characteristic abnormalities, (*A*), (*B*), (*C*), produced in the tumor cells by the previous exposure to the *x*-rays.

Clunet and Raulot-Lapointe treated a number of cases of carcinomata and sarcomata, and at various stages of the treatment removed portions of the growth for histological study. As a result of observations of this nature upon nineteen cases of squamous cell carcinoma of Malpighian type in the human subject they state that before the ultimate disappearance of the growth, the cells passed through at least five successive phases, which have been characterized as follows: (1) The latent phase, which varies from six to fifteen days and during this time no cytological changes are to be seen; (2) the development of monstrous characters, (*a*) an enlargement of all parts of the cells which may be increased in diameter as much as two or three times, (*b*) an increased number of atypical mitosis, (*c*) the appearance of enlarged nuclei, markedly chromophile; (*d*) the appearance within the cells of forms having a pseudoparasitic character; (3) keratinization may be either disseminated, total or antipodal (if disseminated, each cell undergoes keratinization independently of its neighbor in contrast to those effects appearing to influence all cells alike); (4) disintegration and phagocytosis (the disintegration of the degenerating cells appears to be caused mainly by the polynuclear cells and the fibroblasts of the stroma which are in an active condition. Macrophages and plasma cells appear at a later stage and accumulate around the vessels, remaining in the vicinity long after the disappearance of the malignant cells. At the periphery of the keratinized masses plasmodia are sometimes found, simulating the type presented by the cells of the neoplasm, but they are rarely found in great numbers. The masses of degenerate cells, before becoming entirely destroyed, may cease to give color reactions of keratin, and remain encapsulated in the dermis for prolonged periods); (5) formation of the connective tissue scar (as a general rule this is not brought about by the formation of fibrous masses, but the tissues assume the structure of healthy skin, except for the absence of hair and of glands. The elastic fibres are also less numerous and more attenuated than they are normally. No neoplastic masses are to be found in these supple scars which appear to be quite healthy; on the other hand, at a depth below the skin, cells may be found which have been acted upon by the *x*-rays but are not yet destroyed; such cells remain in a latent condition and if the treatment be not continued they give rise to recurrences. They are distinguished by a very chromophilic nucleus, though not pyknotic, a reduced amount of protoplasm and an avidity for basic coloring material).

Sarcoma.—Clunet and Raulot-Lapointe[1] found when sarcomatous growths are exposed to *x*-rays that a somewhat similar transition in the cellular characteristics occurs, but the latent phase, during which no changes are observable, is very much shorter than in the other types of malignant growth considered; instead of being from six to ten days it is generally one or two days.

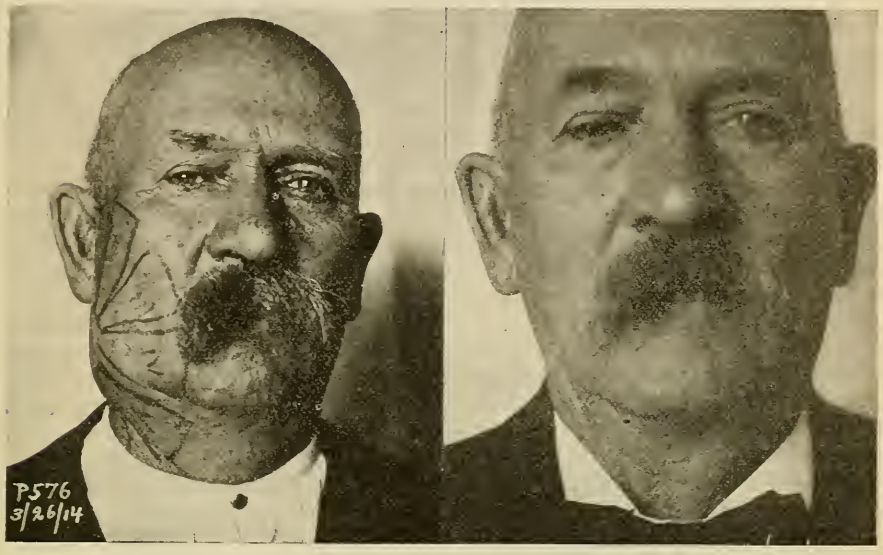
Of a spindle-cell sarcoma after having been exposed to a rather small quantity of unfiltered *x*-rays (9H), their description is as follows: "The fibrosarcomatous zone separating the granulation tissue from the normal dermis on one side and from the pure sarcoma on the other seems to show that at a certain depth the rays, although too feeble to destroy the neoplastic cells of the connective tissue, have nevertheless caused a profound alteration in the biological evolution of

[1] Radium, *X*-rays and the Living Cell, Colwell and Russ.

these cells; the rays have caused the cells to secrete collagen and to take on the morphological characters of a fibroma, a benign tumor." Dominici found similar changes in a fibro-sarcoma exposed to the gamma rays of radium (Dominici, Archives de Médecine Générale, 1909).

These and other experimental and pathological studies of the effects of the Röntgen rays upon malignant disease should convince the most skeptical of the value of the Röntgen rays in the treatment of malignant disease. The evidence is especially convincing when taken together with the mass of clinical observations made by various authors upon the disappearance of malignant disease.

Skill in the application of the Röntgen rays for therapeutic purposes is no less important than skill in the application of surgery in the treatment of dis-



a *b*

Fig. 1114.—(*a*) Sarcoma of the neck illustrating the manner of crossfiring upon this disease. Patient was considered inoperable. Treatment was begun March 26, 1914, and finished April 9, 1914. There has been no treatment since. The patient has remained well six years. (*b*) Photograph made October 23, 1915, showing complete disappearance of the tumor. No damage to the skin. No difference from the normal side (Pfahler, Jour. Am. Med. Assoc., May 1, 1915, Vol. lxiv, pp. 1477–1485).

ease and unless one keeps in mind continually the object to be obtained and pays the most careful attention to all details, the results are likely to be disappointing. All cases of malignant disease do not react in the same manner: there is some difference even in the same type as shown microscopically. The results obtained probably depend too, in part, upon the general resistance and power of reaction as shown in the individual patient. In a general way, sarcomata are more responsive to *x*-ray treatment than carcinomata. And of the epithelioma, those made up of the basal cells are more responsive than those made up of the spindle cells.

Lack of skill in the use of Röntgentherapy may do much harm. Harm may be done by insufficient treatment which will permit the disease to invade the surrounding tissues and extend to deeper tissues or harm may be done by destroying the surface of a growth and even the surrounding healthy skin without destroying the deep part of the tumors. At times, even under insufficient treatment the surface of an epithelioma, for example, may heal, the ulcer be closed, but the deeper lying cells remain, and if insufficiently treated will invade other tissues, and bring about a recurrence or metastasis. In

this respect Röntgentherapy resembles any other form of meddlesome or insufficient treatment of carcinoma.

Harm can result from too long treatment. In these cases, of which many have occurred, *x*-ray treatment has been applied with superficial effect, and, carried over a long period of time, leads to the development of telangiectasis, and a thick fibrous scar tissue with secondary degeneration into carcinoma. The treatment of epithelioma may produce a severe burn indistinguishable by the untrained from the original carcinoma, and thus treatment may be prolonged with the hope of controlling the carcinoma and conditions made worse. Harm can also result from the treatment of cases which are not suitable for *x*-ray treatment.

In most cases treatment can be combined to great advantage with other forms of treatment for malignant disease, of which we mention first surgical excision, second local destruction by electrocoagulation, and third the additional application of radium to the inside of cavities while the *x*-rays can be applied externally. Radium and *x*-rays should not be used at the same time or within the same month over any one area of skin or mucous membrane, for the action of the two agents is very similar, and overdosage is likely to result.

Epithelioma.—The epitheliomata involving the skin can nearly all be cured by skillful treatment with the Röntgen rays, and when combined with electrocoagulation (see page 1637) all can be cured if treated early. Most of this group of epitheliomata can also be cured by excision, and unless one has skill in the application of Röntgentherapy they had better be excised. Of the epitheliomata the basal-cell variety is much more respondent; the squamous or spindle-cell epitheliomata are much more resistant to the Röntgen rays, as well as to any other form of treatment. The majority of the epitheliomata occurring on the skin are of the basal-cell type. Those occurring on the mucous membrane and on the back of the hand, are more likely to be of the squamous-cell type, and are very resistant to treatment. Generally, in these cases, I believe radiotherapy alone cannot be depended upon, but should either be combined with surgical excision, or, better, electrocoagulation.

The advantages of the Röntgen rays in the treatment of epithelioma are first, the painless applications; second, the absence of deformity, and this is especially important when in the neighborhood of the eyelid or the side of the nose. The disadvantages of the treatment of these growths by radiotherapy alone are first, the slowness of the result to be obtained; second, the inability to examine the growth microscopically. In the treatment of recurrent or advanced epithelioma the keenest judgment and the greatest skill are required. In these cases generally the treatment should be combined with some other form of treatment, either with surgical excision or local destruction by electrocoagulation. The metastatic glands should be thoroughly excised. Surgical excision should also be used when the disease involves the neighborhood of vital organs or nerves, such as at the angle of the jaw in which the disease is liable to overlie the carotid vessels. In other cases where the disease involves areas, overlying structures which are less vital the disease can be destroyed by electrocoagulation first, and active deep Röntgentherapy applied immediately after.

Deep-seated Malignant Disease.—In the treatment of deep-seated malignant disease, the Röntgen rays can be thought of chiefly as an adjunct to surgical treatment. When, for some reason, surgical excision is impossible, skillful application of deep Röntgentherapy is undoubtedly the next best choice. In the treatment of deep-seated malignant disease surgical excision, when practical and when there is an opportunity, should always be followed by Röntgentherapy.

The Treatment of Recurrent and Metastatic Carcinoma.—There is a great variation in the results obtained from the treatment of recurrent metastatic carcinoma, and at present no one can decide which cases will respond to Röntgentherapy, and which will progress under treatment. In nearly all cases treated

there will be some improvement, and in many cases the local evidence of disease will disappear, at least so far as visible evidence is concerned. The patient may be free from local symptoms and in some of these cases they are free for a year or more when the disease recurs with more extensive distribution. Generally this second recurrence is uncontrollable. In some cases one may

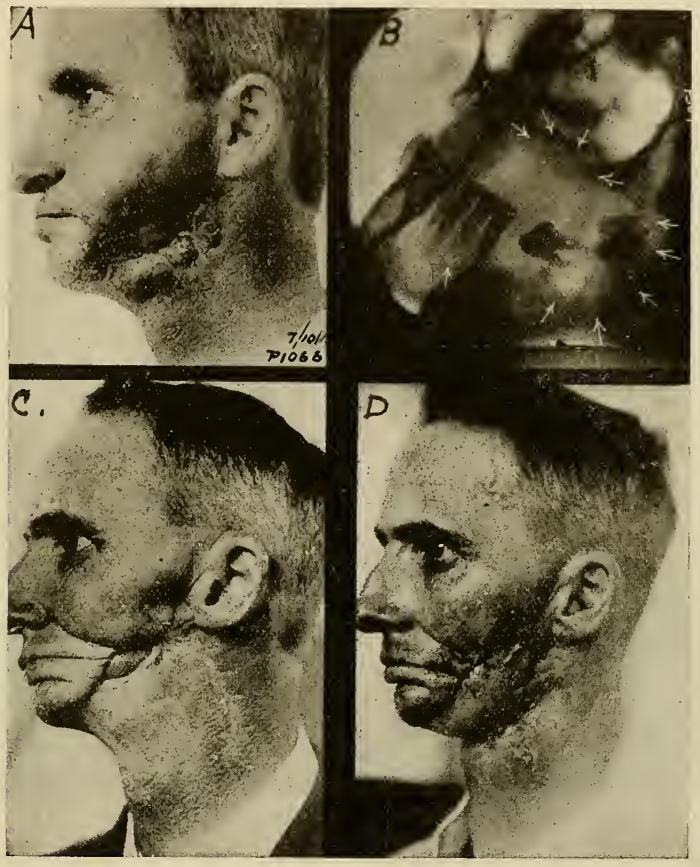


FIG. 1115.—A case of carcinoma involving the left cheek, the alveolar process in the left upper molar region, the anterior pillar of the fauces, the posterior two-thirds of the inferior maxilla, with a mass of metastatic lymph nodes the size of a small hen's egg. The disease in the mouth was destroyed by electrocoagulation, the metastatic glands were dissected out, and the left half of the inferior maxilla resected June 10, 1915. This was followed by radium applications inside the mouth and *x*-ray treatment externally. The patient is still well May 10, 1919 (Pfahler, Jour. Am. Med. Assoc., November 18, 1916).

(*A*) Shows area destroyed after the slough has separated.

(*C*) After first attempt to close the mouth.

(*D*) Showing mouth closed. The patient is a traveling salesman and is at work daily.

obtain a permanent disappearance or cure. In general, thorough skillful application of the Röntgen rays, or Röntgentherapy, according to modern technic, will give more satisfactory results in the treatment of recurrent carcinoma than any other known method. Metastatic carcinoma may be made to disappear in many instances, but here again there is some peculiarity in the nature of the disease which will cause some cases to yield to treatment while

others only show improvement for a time but do not get well. Pfahler has reported four cases in which metastatic carcinoma of the spine, secondary to carcinoma of the breast, showed a complete healing of the lesions which had caused total destruction of one or more of the vertebra, and the patients have remained free from symptoms for from one to two years. Metastatic carcinoma of the spine is, however, only a part of a general carcinomatosis, and sooner or later we believe that the patient must succumb to a general carcinomatosis, and this has been Pfahler's experience in all but one of these cases.

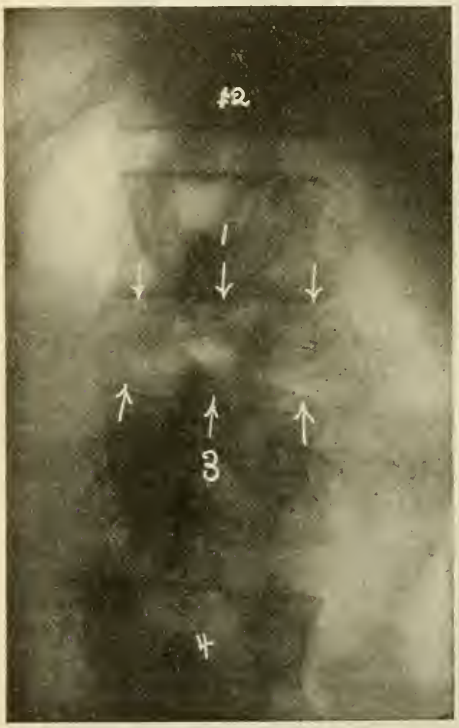

Fig. 1116.—Case of metastatic carcinoma, probably present before operation for carcinoma of the breast. Patient became bedfast three months after the amputation of the breast. Remained in bed fifteen weeks. Röntgenogram was made March 17, 1918. In four months the patient was able to attend to her housework with the support of a brace (Pfahler).

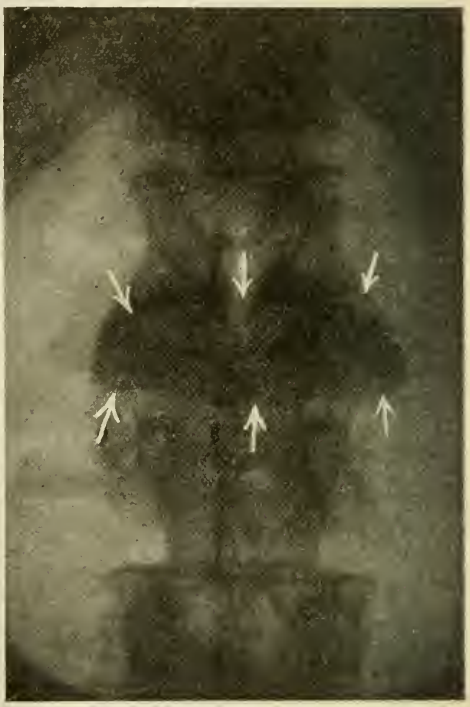

Fig. 1117.—Same case as Fig. 1116. Showing complete recalcification of the second lumbar vertebra. Röntgenogram made March 17, 1919, one year after the first, and one year after beginning treatment. Patient is doing all the general housework, including washing and ironing. Is wearing no brace, and is apparently well (Pfahler).

Ante-operative X-ray Treatment.—It has been shown in the preceding pages (see pages 1628 to 1631) that in experimental work done application of the Röntgen rays to a tumor reduces its malignancy, reduces the power of transplantation, and causes destruction especially of the more actively growing cells. This is accomplished when skillfully done without damage to the healthy tissues, because of the hypersensibility of the malignant cells. For this reason Pfahler recommends a thorough application of the rays preceding operation. Up to the present time no ill results have followed this ante-operative application. The wounds heal normally, and while we have only followed this method for about three years, and are therefore unable to draw definite conclusions, the results seem to justify this application.

Boggs and Pfahler have each recorded cases of inoperable carcinoma of the breast made operable by Röntgentherapy, but in these cases the treatment is given with a different object. It is given with the idea of destroying or sealing off the lymphatic extensions, and causing a shrinkage in the growth by the surrounding fibrous tissues as is indicated in the paragraph on experimental and pathological studies of carcinomatous growths. The operation is then done with the idea of removing the fibrous tissues including the encapsulated malignant cells. This prolonged ante-operative treatment requires much skill and good judgment, and it should not be used in an operable case. The ante-operative treatment which Pfahler believes can be applied to advantage in every case of deep-seated malignant disease requires only a few days during which a thorough course of treatment can be given with the Coolidge tube technic in which the disease is crossfired upon from every angle, and all the outlying lymphatic areas are included in the field of treatment. If the dose be carefully measured no harm can result. The post-operative treatment can then be started four weeks later.

Post-operative Röntgentherapy.—This should be applied in all cases of malignant disease. It should be applied with the object of reaching any cells which may have extended beyond the palpable growth even before the operation, and to devitalize any malignant cells that may have been transplanted or dissipated or disseminated during the operation. When practical it can be applied to advantage in the open wound immediately following the operation. This is generally not practical for various reasons. Therefore, this treatment should be given as soon after the operation as is found practical to move the patient to the Röntgen laboratory, but if ante-operative Röntgentherapy has been used, and full doses given, it must not be repeated in less than four weeks from the preceding treatment. This treatment should be given from every angle possible, and over every area to which the disease is likely to have extended, or is likely to extend. The amount of treatment required depends upon the amount of disease, the duration, the rate of growth, but generally, in a breast case for example, a single course or series of treatment will occupy two or three different days. Such a course of treatment, or series of treatment, should be repeated in a month, and repeated at intervals of a month or more from three to ten times, depending upon the stage of the disease and the degree of malignancy at the time of operation. In abdominal carcinoma more treatments are usually required, first, because the disease is more deeply situated, and secondly, because the lymphatic distribution of the disease is more likely to be extensive.

Sarcoma is more sensitive to the Röntgen rays than carcinoma, and unless one is quite sure that the disease can be completely excised it is better treated by Röntgentherapy than by excision, but it is likely that a combination of the two, ante-operative Röntgentherapy, excision and post-operative Röntgentherapy, will give the most satisfactory results. When the rays are depended upon alone, massive dose therapy and treatment from every angle possible cannot be urged too strongly.

Cervical Adenitis.—Cervical adenitis can be treated successfully by Röntgentherapy. These lymph nodes are more responsive the earlier the applications are made. According to modern technic, the applications are made from as many angles as possible, crossfiring upon the disease, and this is done once a month. If the treatment be begun after there is localized tenderness or softening, the softening process will be hastened. When any of the cells become softened they should either be excised or drained, or probably better aspirated and an injection of the following solution used, as has been recommended by Phender:

Olive Oil	70 parts
Ether	30 "
Creosote	3 "
Guaiacol	1 "
Iodoform	10 "

In some cases in which the disease has persisted for sometime, and in which there is much fibrous tissue, the nodes may not disappear completely under Röntgentherapy, but they may become calcified, so that one may obtain a complete chain of calcified lymph nodes as a result of this treatment. Therefore treatment should not be prolonged too much with the hope of causing a complete disappearance. This calcification shows the healing process for we well know that tubercular lesions heal in this manner. The quickest and best method, however, is complete excision, in which small and large lymph nodes are removed, and this should be followed by thorough deep Röntgentherapy. These applications should be made two or three times at intervals of a month. This is usually sufficient to prevent other glands from becoming enlarged as so frequently happens after an operation upon this area.

Enlarged lymphatic glands, from whatever cause, can be made to disappea- under skillful Röntgentherapy. In the treatment of cervical adenitis by Röntr gentherapy a dermatitis should always be avoided, and the treatment should never be carried to the point of producing a reaction in the skin nor continued too long. If this be done, there is very likely to result at some time later, possibly at the end of a year or two or three, a telangiectasis, together with an atrophic scar-like condition of the skin. A dermatitis is always hastened by the local application of other agents such as liniments, poultices, etc., so that when a patient is sent for Röntgentherapy, no other local application should be made at least within a month after Röntgentherapy. Röntgentherapy is usually chosen in these cases because it is supposed to produce better cosmetic results by preventing unsightly scars which sometimes follow surgical excision, but if a dermatitis be produced the end result may be worse than that produced by a surgical operation. The *x*-rays have been used in certain infections and George G. Ross reported a case of facial carbuncle treated by them (Annals of Surgery, July, 1917).

Exophthalmic Goiter or Graves' Disease.—The thyroid gland is especially sensitive to the Röntgen rays. In very small doses there is the possibility of stimulating the thyroid gland, but as the rays are applied in modern deep therapy technic, and in massive crossfiring doses there is an atrophic action upon the cells. The secretion of the glands is diminished, the secreting cells being the first to be affected. Then there is a gradual atrophy of the gland with consequent diminution in its size. By modern technic the gland is treated by massive doses, crossfiring from two to six different directions, or fields of entry, and this series is given about once a month. As a result there is first noticed a decrease in the nervous symptoms which can sometimes be seen at the end of a month, but almost certainly seen at the end of two months. With this there is a decrease in the pulse rate and increased weight, and gradually there is a reduction in the size of the gland although the disappearance of the thyroid enlargement and of the exophthalmus occurs last. It usually requires from six to twelve months to produce a cure. The pulse rate at times returns to normal, but generally it remains slightly above normal, either due to some permanent damage to the heart, or because the treatment has not been carried on long enough. Generally at the end of six months or a year the patient has been restored to normal so far as the patient can recognize. This treatment has the disadvantage of slow results because to produce results one must wait for an atrophy of the gland. It has the advantage, however, of avoiding the shock of an operation, and can be applied especially to inoperable cases, or it can be applied to those cases in which operation has not brought about sufficient results, or the treatment can be applied with the idea of reducing the secretion and preparing the patient for any later operation. By operation one reduces the size of the gland, thereby diminishing the secretion. By Röntgentherapy the amount of secretion is reduced by a reduction in the secreting surface or secreting area of the entire gland.

Simple goiter should not be treated by the Röntgen rays until after a careful study has been made as to the etiology of the enlargement, for in many cases the enlargenent of the thyroid is purely compensatory, and in such instances either operation for its removal or treatment by Röntgentherapy is in direct opposition to nature's efforts to relieve the patient of other more serious conditions. When there is a distinct hypertrophy of the thyroid gland, which cannot be accounted for by the theory of compensation, and operation is contraindicated it can often be treated successfully by the Röntgen rays, but the results obtained will be more satisfactory and more prompt, the earlier in the stage of the disease the applications are made. Cystic goiter is not likely to respond to Röntgentherapy and unless there be some contraindication the patient should be sent for operation at once.

Fibroids of the uterus can be successfully treated by Röntgentherapy, just as a hypoplasia or tumor formation anywhere in the body can be reduced by thorough application of Röntgentherapy. When the tumors are large or when there are no contra-indications they had better be removed surgically. Generally the cure of these cases is followed by an amenorrhea, but this is not always necessary. Pfahler and McGlinn reported a case in which, at exploratory operation, it was found that removal of the fibroid would mean sacrifice of the uterus—an operation not expedient under the circumstances. The exact position of the fibroid having been determined, the abdomen was closed, the *x*-rays were confined to the fibroid area, the ovaries being protected, and the tumor was removed completely. At no time did the patient cease menstruating or have any menstrual disturbance. At the proper time the patient was allowed to become pregnant, and gave birth to a full-term healthy, normal child. When the exact location of the fibroid is not known, or where it is so large that it overlaps the areas of the ovaries, this cannot be done, and an amenorrhea must be expected if the tumors are to be treated with success. The treatment extends over a period of from four to six months, and the series of doses crossfiring upon the diseased area are given once a month. During the first month there is little change. During the second month there is generally a diminution in the size of the tumor, and a marked reduction in the menstrual flow. Often the second period is absent. Generally the third is absent. The treatment is usually continued even after an amenorrhea has been produced for the purpose of destroying the tumor tissue. These results can be produced without placing the patient in the hospital, and generally she can be allowed to go about her duties.

ELECTROCOAGULATION IN THE TREATMENT OF MALIGNANT DISEASE[1]

This consists in the destruction of all of the malignant disease by means of the high frequency electric current, either of the Oudin or d'Arsonval type of current. It differs from the destruction of disease by the thermocautery in that this heat is generated in the tissues due to the resistance to the flow of the electricity through the tissues, instead of destruction by transmitted heat such as applies to the use of the thermocautery. It has the advantage, therefore, over the thermocautery of producing heat at a much greater depth, and in a more graded proportion. It applies the principle of the Percy cautery in producing a zone of tissue in which there is sufficient heat to destroy malignant cells

[1] Pfahler: Electrothermic Coagulation and Röntgentherapy in the Treatment of Malignant Disease. Surgery, Gynecology and Obstetrics, December, 1914, pp. 783 to 790; The Treatment of Malignant Disease About the Mouth by Combined Methods. Jour. Amer. Med. Assoc., Nov. 18, 1916, Vol. lxvii, pp. 1502–1508; The Treatment of Malignant Disease by Means of Deep Röntgentherapy and Electrothermic Coagulation. Surgery, Gynecology and Obstetrics, January, 1917, pp. 14–29; Deep Röntgentherapy and Electrocoagulation in the Treatment of Malignant Disease. Interstate Medical Journal, Vol. xxiv, No. 7; The Treatment of Malignant Disease by Combined Methods. Pennsylvania Medical Journal, February, 1919, Vol. xxii, p. 307.

but not normal tissue cells beyond the area of actual destruction of all tissues. In the area of coagulation all tissues are, of course, destroyed. The method, therefore, cannot be applied in the region of blood-vessels or nerves which must be saved by dissection.

Technic of electrocoagulation, according to Pfahler is somewhat similar to that described by Nagelschmidt and Clarke and in principle is identical. The d'Arsonval current is used, or the Oudin current may be used, or a combination of the two. When the d'Arsonval current is used an instrument is necessary which will generate from 1000 to 2000 milliamperes of current. The amount of current will, of course, vary with the amount of destruction of tissue desired. The two electrodes are used. Sometimes both electrodes are used locally for the destruction of the tissue. In many instances, or in most instances, however, the disease is destroyed by a pointed electrode and a pad is attached to some indifferent portion of the body and to the opposite pole. The pad is usually placed under the back or under the buttocks or over the abdomen. By means of the active point electrode one should first outline carefully the extent of the diseased tissue which is to be destroyed. If the growth be very large it is advisable to use both electrodes in the growth itself and the indifferent, or blunter electrode, or ball electrode, may be placed in the central portion of the disease, and the point electrode is used to surround the outside, coagulating the tissue toward the central electrode. If, as is usual, the area of disease be comparatively small, the indifferent electrode may consist of the pad placed under the buttocks or on the abdomen, and only the point be used for local destruction. The area to be destroyed is coagulated completely until it is entirely white. In this destruction one must realize that there is a tremendous heat developed and if the disease is destroyed within a cavity the steam from the cooking of the tissues is often sufficient to scald the surrounding mucous membrane. This must be especially considered when one is destroying disease in the mouth, in the pharynx, in the vagina or in the rectum. Caution in this respect will save the patient much suffering, and much unnecessary delay in the healing process. After the area is thoroughly coagulated, the destroyed tissue may be cut away by means of curved scissors or a knife, or it may be curretted away. One must always be as sure as is possible to destroy the entire diseased area, for there is danger of rapid extension from the periphery if all the disease be not destroyed—unless it be possible to control this tendency by deep Röntgentherapy. The tendency to the increased rate of growth in areas not removed by this process or by operation is probably due to the increased congestion which is brought about by the subsequent reaction.

Anesthetic.—The destruction of tissue by heat is, of course, always painful, and large lesions are more painful than others. The degree of pain also varies with the individual and with the location of the disease. When the area selected for destruction is large, the pain is, of course, intense, and some form of general anesthetic is always necessary. The operation is generally comparatively short, and if the lesion be not in the region of the mouth, nitrous oxid may be used, or a combination of nitrous oxid and ether. In mouth cases, however, some form of anesthetic must be used. Ether is objectionable because of some danger from explosion, no matter what portion of the body is being treated, because a spark may be drawn from any part of the body during this process. Therefore, ether, and the ether apparatus must be completely removed from the table or the patient during the process of actual destruction or electrocoagulation. In fact, the high frequency instruments should be completely detached from the table or they should be rendered inactive. Another objection to ether in mouth cases is the congestion of the mucous membrane, and the increased amount of mucus which accumulates during the process of etherization. This increased mucus and congestion of the mucous membrane interferes with vision, and the mucus carries away the current so that it cannot

be strictly confined to the area under treatment. When the condition of the patient will permit, anesthesia by means of morphin and hyoscin, or the combination of morphin, hyoscin and cactin (Abbott) may be used successfully. When necessary ether may be added to this and the mucus is less likely to collect in the mouth. Even when ether is depended upon as a general anesthetic, the preliminary administration of morphin and hyoscin has a distinct advantage, because of the local congestion. Small lesions, such as moles, warts, and epithelioma, may be removed usually by local anesthesia by the injection of novocain or any of the local anesthetics.

Cases Suitable for the Combined Form of Treatment.—(1) Those cases in which there is a considerable area of malignant tissue which can be removed en masse without danger of destroying blood-vessels or nerves, for it must always be kept in mind that all tissues are destroyed completely. It is especially valuable in the destruction of epithelioma, warts, moles and birth-marks. (2) Epithelioma involving the lip, cheek, tongue or alveolar process. The method seems to be especially useful in the treatment of malignant disease of the mucous membrane. (3) Old adherent scirrhous carcinomata of the breast in which there is no evidence of metastasis, and which are considered inoperable by surgical means because of the involvement of the intercostal muscles. At least, Pfahler has treated one such case successfully. Pfahler has treated approximately 50 cases of primary epithelioma of the lip by this method combined with deep Röntgentherapy without evidence of recurrence or metastasis.

Disadvantages of the Treatment.—(1) There is complete destruction of all the tissue between the two electrodes, when the two electrodes are used in the area diseased, and there is complete destruction of all tissues including blood-vessels and nerves, even when only a point electrode is used locally. Therefore, there is no chance of saving the blood-vessels or nerves which are in close proximity to the disease. In the destruction of disease of the floor of the mouth, and of the alveolar process of the lower jaw, there is danger of destruction of the periosteum and this is always followed by necrosis of the underlying bone. This very frequently involves destruction of the blood-vessels and nerves in the inferior dental canal, to be followed by necrosis of the entire body of the bone, very annoying later.

Because of this total destruction one can rarely destroy metastatic glands, especially in the region of the parotid vessels and in the axilla and supraclavicular regions. Here a careful dissection followed by deep Röntgentherapy must always be the method of choice. (2) It leaves an open area which is healed by granulation, but at times this healing must be followed by a surgical plastic operation to close the mouth or to correct some deformity. (3) A very serious objection to the patient, the friends, and other patients in the hospital, is the odor from the sloughing tissues, which, of necessity, follows such destruction. This can be partially diminished by careful removal of all the destroyed tissue after the operation. Such removal is not always possible and at best there must always remain a layer of tissue which must be left to slough away. Dichloramin-T may be used to control part of this disagreeable odor, but in the region of the mouth, or where there is much secretion, it seems at times that the combination of the secretion with the dichloramin-T produces marked irritation, and therefore must be eliminated. Thorough cleansing, together with deodorants such as permanganate of potash, must be used until the slough has come away. The duration of this sloughing process will, of course, vary with the extent of the tissue destroyed, but it generally requires from two to four weeks, after which the healing process begins, and at any stage during the healing process when healthy granulations are present skin grafting or skin transplantation may be done.

Advantages.—(1) There is complete destruction of the local malignant disease. (2) This is accomplished without opening the blood-vessels or the

lymphatics, and it is believed that this method of treatment is less likely to be followed by recurrence or metastasis. (3) The wound heals with a smooth, soft scar which resembles skin very closely. (4) It can be applied to surgically inoperable cases as, for instance, to the adherent scirrhus carcinoma of the breast (Pfahler, Surg., Gyn. and Obst., Dec., 1914, pp. 783–790).

Deep Röntgentherapy applied as an ante-operative measure, that is, immediately preceding the operation, and, after the proper interval, following the operation, has the same advantages as described previously in connection with surgical operations, and is always to be recommended when practical.

FINSEN LIGHT

It is known that below the spectrum of red light are heat rays, and above the spectrum of violet light are short violet, actinic, or chemical rays. The short violet, with the indigo rays and blue rays, constitute the Finsen light. Ultraviolet rays cause an electrified body to discharge, excite fluorescence in certain substances, affect a photographic plate, and are bactericidal, but have little power of penetrating tissues and, it is said, do not inflame tissues. Ultraviolet rays pass readily through rock salt or ice, which will not transmit heat rays.

Finsen taught us to use these rays therapeutically. He first obtained the rays from sunlight, intercepting the heat-rays by ice or rock crystal. Later he obtained them from the arc light.

Blood in part prevents the passage of the Finsen light, hence in using the light we must make the area on which the rays are to act nearly bloodless. This is done by pressing firmly upon the part with a rock crystal through which water passes. The rays pass through the crystal and the water absorbs the heat-rays. These rays are especially serviceable in lupus.

BECQUEREL'S RAYS

Becquerel discovered in 1896 that uranium and some of its compounds give off a radiation similar to but much weaker than the *x*-rays. Among these radiant substances are pitchblende, radium, and uranium. These rays are luminous, actinic, and skiagraphic (McFarland), and may produce, by prolonged action, dermatitis similar to *x*-ray dermatitis.

RADIUM RAYS

Monsieur and Madame Currie, after prolonged research, found that thorium and certain ores of thorium and uranium (pitchblende) are radio-active, pitchblende being more strongly so than uranium itself. The conclusion was that pitchblende contained a strongly radio-active element and that it was not uranium. In 1903 they discovered the sources of radio-activity to be two hitherto unknown elements, radium and polonium (Dawson Turner, in "Brit. Med. Jour.," Dec. 12, 1903).

Turner (Ibid.) tells us that radium gives off a radio-active emanation and three kinds of rays (alpha-rays, beta-rays, and gamma-rays). It also emits heat, and is itself at a higher temperature than the medium in which it rests. The emanation from radium is a luminous gas, which can be condensed by great cold, and which imparts radio-activity to certain bodies. It is to this gas that most of the curative effects of radium can be attributed.

Alpha-rays consist of a stream of positively charged gaseous particles. Turner points out that these particles are each about twice the size of a hydrogen atom, travel at a velocity of 20,000 miles a second, and have little power of penetration. In fact, the penetrating power of the alpha-rays is so slight that they do not pass through the glass of a tube (Robert Abbe, in "Med. Record," Oct. 12, 1907). The beta-rays consist of particles each being one one-thou-

sandth the size of a hydrogen atom and being strongly actinic. These rays are said by Turner to resemble cathode rays and to be far more penetrating than alpha-rays. Gamma-rays resemble *x*-rays and have great penetrating power (Dawson Turner, Loc. cit.). According to Abbe ("N. Y. Med. Jour.," Feb. 10, 1912), the soft beta-rays and the alpha-rays irritate and stimulate; the hard beta-rays and gamma-rays destroy. It is probable that radium also generates or helps to generate a gas called helium, which has no action on tissues.

The actions of radium are extraordinary. A man entirely blind cannot perceive light when radium is brought near him, but one not quite but almost blind can, and one quite blind to form but with retention of some light perception can actually see the shapes of objects near a screen rendered luminous by radium. Turner tells us that a man retaining vision, who covers his eyes, can detect radium held in a box behind his head. If dry seeds before planting are exposed to radium rays, sprouting will be retarded in proportion to the time of exposure. When meal worms are exposed to the rays "they go on living as meal worms, 'veritable Methuselahs,' as it has been said, while their sisters and brothers, unradiumized, progress for generations, completing several cycles of beetles, eggs, meal worms, etc." (Abbe, in "Med. Record," Oct. 12, 1907). Radium rays are germicidal, but act very slowly and feebly. Skiagraphs can be taken with the rays. Water and other materials may be rendered radio-active by exposure to radium rays. Probably certain natural waters have subtle powers due to radio-activity. On the tissues radium may act to produce a retrogressive effect; may increase self-digestion; may cause irritation and inflammation, and so block blood-vessels. Severe reaction may result in ulceration. On a tumor radium produces inflammation, first of the fibrous stroma, then of the tumor-cells, or a primary necrosis (Sticker, in "Presse Médicale," May 18, 1912). It seems to have a selective action on cancerous tissue. Sometimes a spreading eruption, like that of scarlet fever, follows overaction. Abbe says that when an ulcerated surface is treated or when a tube of radium is inserted in a wound for twenty-four hours, a "specific toxemia" frequently arises. "The symptoms will be headache, chill, general aching, coated tongue, fever up to from 103° to 106° F., and an occasional rash-like scarlatina." Some hold that radium acts similarly to the *x*-rays and that the *x*-rays can do anything radium can do. Other observers believe that the radium rays have a specific action and can accomplish some few things impossible to the *x*-rays.

Radium therapy is commanding profound and widespread public interest. How real its claims are and how great its future is to be we can only guess. Sir Frederick Treves bids us to be cautious in our estimates, although he thinks there may be a great future for radium therapy in surgery ("Brit. Med. Jour.," Jan. 30, 1909). It has cured many *surface* carcinomata and sarcomata, keloids, angeiomata, moles, pigmented moles, and warts. It is particularly valuable in lesions about the face when it is desirable to avoid scars; in lesions of the nostril, mouth, and other cavities. It has a very powerful action on angeiomata. So far radium has been used chiefly for inoperable cancer. It has been used most advantageously for epithelioma of the eyelid (see the striking cases reported by Abbe, in "Med. Record," Oct. 12, 1907). When treating a surface lesion the rays are obtained from radium bromid, which material is kept in a hermetically sealed platinum or lead tube. In a deep-seated tumor an incision may be made and a tube of radium bromid be inserted in the wound and allowed to remain for forty-eight hours. Attempts are being made to treat internal conditions by the inhalation of radium emanations or by the administration of materials which have been rendered radio-active and contain, so to speak, radium emanations in solution. Radio-active water has been tried for cancer of the stomach. Treatment by radium is called radium therapy; treatment by radio-active

substances, radiotherapy. It is extraordinary how even very brief applications of radium may be followed by notable changes. In one of Abbe's cases an epithelioma of the forehead disappeared after one exposure of an hour's duration. Another on the side of the nose disappeared in four weeks after one exposure of an hour's duration. A cancer involving one-third of the upper eyelid entirely disappeared in two weeks after three five-minute exposures. After an exposure no changes are apparent for several days or a week. The skin at the site of application then begins to burn and itch and becomes reddened. The irritation endures for about two weeks.

Confusion has arisen because of the varying strengths and amounts used by different operators. Bromid of radium is the salt usually employed. Abbe takes as a standard 10 mg. of bromid of radium and tests other specimens by this. He calls the 10 mg. of strong German bromid of radium "the working unit." In malignant disease the best results have followed one hour's exhibition of the "working unit" to small growths and three or four hours to large growths, "with an interval of one month for study of the effect" (Abbe, Ibid.). Ischemia favors powerful action of radium rays.

In order to obtain the best results from radium heavy "doses" seem to be necessary, and heavy "doses" are very apt to burn the skin. The penetrating rays are the gamma-rays, and in order to make them reach a deep growth in sufficient intensity to do good the superficial parts are endangered.

So far radium has found its chief use in inoperable cases and in superficial lesions. Abbe ("New York Med. Jour.," Feb. 10, 1912) says, we may suppress the short rays which burn, and yet use the deeply penetrating rays by placing a considerable amount of radium in lead which is from $\frac{1}{10}$ to 2 mm. in thickness.

Macdonald ("Brit. Med. Jour.," Dec. 9, 1911) uses for a deep growth at least 250 mg. of bromid of radium in platinum $2\frac{1}{2}$ mm. thick. He keeps the tube applied from twenty-four to forty-eight hours. In some cases he inserts the tube in the tumor and leaves it in place for forty-eight hours. A long application is not to be repeated for five or six weeks. For a superficial growth he uses radium in a glass tube every other day for a week.

It may develop that radium has decided power in preventing recurrence after operation. In some few cases of cancer radium may convert an inoperable into an operable case.

A serious bar to the extensive use of radium is its immense cost. The little there is in the world is in the hands of a few men and a few institutions. Altruistic persons in many lands are striving to give greater numbers access to the supposedly beneficient influence of that wonderful element. No process ever was so thoroughly and dramatically advertised as the radium treatment of cancer. There is a hideous cruelty in the newspaper exploitation of radium therapy, because great numbers of persons who are victims of cancer have been caused to believe that they could certainly be cured if they could gain access to radium. Such hopes cannot be realized. Any statement that an extensive cancer can *usually* or even *often* be cured by radium is a stupid mistake or a heartless deception. At the present time the real truth of the matter is being slowly and carefully studied out by earnest men who are not seeking profitable notoriety. There is little evidence at present that radium, unless it be in certain exceptional cases, has greater curative power than the *x*-rays, and the Coolidge *x*-ray tube may remove even these exceptional cases from the radium side of the scale (see pages 1628 to 1631).

Radium can be applied advantageously to carcinoma within cavities, such as the mouth, esophagus, bladder, rectum, and vagina, while *x*-rays are applied externally. Radium and the *x*-rays should not be used at the same time (see page 1632).

Radium has been found of value in the treatment of carcinoma of the uterus, of uterine fibroids, of uterine hemorrhage at the menopause and of simple hypertrophy of the prostate.

XLI. INJURIES BY ELECTRICITY

(Dr. William S. Wadsworth did me the kindness to rewrite the section on electricity.)

Electricity.—The surgeon meets four types of injury by electricity: (1) from currents applied for therapeutic purposes; (2) from industrial currents; (3) from lightning; (4) from radiant discharges—as *x*-ray burns.

To understand fully the effects one finds in the body would require not only a complete knowledge of the physics of electricity but an equally extensive knowledge of laboratory and clinical physiology. In the past both fields have been so crowded with controversy—in large measure due to the overvaluing of some minor part—that even at present it is hardly safe to express sane conclusions on the subject; but, as the surgeon cannot wait for the specialists to settle their disputes, he must accept conclusions as soon as they are sane.

While nothing is to be ignored there are certain things which must always be kept in mind. *Electric potential, or charge,* is produced by a vast number of processes in living bodies and *electric polarity* is found generally where metabolism is active. Whenever produced there is an equal amount of positive and negative electricity and these charges tend to go together and to neutralize each other.

In metals and other good conductors this reunion takes place readily but in organic tissues we find insulation preventing the equalization, in fact, most of the best insulating materials are organic bodies and this is not accidental.

We find then the body developing potential and polarity and at the same time insulation in the general tissue masses and we find specialized properties of insulation and conduction in the nervous system. We also find the blood acting as a good conductor.

All the active tissues of the body are converters or transformers of forces, and heat and electric potential are the indices we have for measuring metabolism.

We know that in any apparatus where electric potential is produced we can produce effects by passing in an artificial current in the direction opposed to that naturally produced.

We know that the action of the heart is accompanied by electric currents and we are not surprised that experimenters have been able to show conclusively that moderate currents passed into the heart disturb its action, causing it to cease its regular beat and pass into *fibrillation* and finally to stop entirely. We know that all muscular and nerve action is accompanied by electrical phenomena and are not surprised that common experience and laboratory tests show that electric currents produce profound effects on both nerves and muscles.

We know much about the effects of electricity on nerves and muscles, a little about its effects on the blood but almost nothing about its influence on the other tissues of the higher animals.

We are forced to limit our considerations largely to the effects on nerves, muscles and blood, not because such effects constitute the whole but because of the present limitations of science. Unfortunately, serious blunders have occurred in the surgical use of electricity because what was already known of normal and abnormal tissue potential and of the response to artificial potentials and currents by normal, abnormal, and repair tissues had not been utilized.

Specially sad have these blunders been in *x*-ray work. It should be remembered that the human body is a vast collection of histological units each of which is a sort of battery having its minute electric qualities of charge, resistance and effect.

While bodily currents and potentials are small, industrial currents are relatively very large, so that, aside from the great outside insulator (the skin), they readily overcome the internal resistances and, forming for themselves paths, cause very considerable damage to the tissues.

This damage becomes strikingly apparent when it affects some organ on which life immediately depends, as the heart and central nervous system. It is quite sensibly apparent when we get a shock. It is clinically important when we find the result of an apparently slight contact lasting as a painful and incapacitating neuritis, or as a large sloughing area about a slight burn. To understand the effect of artificial currents on the body we must clearly grasp the significance of the *skin as an insulator.* When the skin is dry it offers a high resistance, which is raised by natural or other oils. If, however, the skin becomes wet by water, or any other fluid of lower resistance, such as perspiration or saline solution, the power of resistance of the skin will be greatly diminished—so that very low currents will readily enter the body. This diminution in skin resistance is not so common after a superficial wetting as it is when the fluid has penetrated deeply into the cuticle. Denudation or wounding also aids in destroying insulation. Currents on entering the body find paths through the tissue or, more readily, along blood channels and along nerves. A few minutes' testing with a "medical" battery will give one much valuable insight into these matters. If the current finds a path through large veins to the heart it tends to produce marked disturbance leading to fibrillation or death by complete arrest of that organ. This is true of low voltage industrial currents whether direct or alternating.

Very high voltage direct and very rapidly alternating currents appear to have less effect on the heart—which explains why cases of survival after exposure to very high voltage as well as *deaths from low voltages* have been reported.

In general, *low voltage alternating currents* are more dangerous than direct currents of the same voltage, but as the rate of alternation increases the danger appears to become less until no fatal results follow when the rate of alternation mounts to the hundreds of thousands per second.

We have spoken of potential or charge and flow or current. There are two other very important groups of electric phenomena, those of *induction and radiant discharge.*

Wherever there is either stationary charge or current there is an influence capable of inducing in near objects secondary electric charges and currents.

Where the currents passing through the body are barely powerful enough to get through we may, as a rule, ignore the *induced currents* because these are less than the primary, but where the currents or charges are very large, as in lightning, the effects may be very great, in fact may result from currents which pass not through the body at all but only near it.

As a rule low currents find paths rather than make them, while high currents often make actual holes, not only in the skin but in the tissues, in the walls of blood-vessels and in the case of very high currents, as lightning bolts, through bones. Every current, no matter how small, tends to open the path so that it flows more readily after such path has been established.

Currents require substance along which to travel in their paths. They also carry substances along such paths. On this principle depends *cataphoresis* and we find that in serious industrial accidents there is, not rarely, a metallic impregnation of the tissues. This must be remembered in considering the burn which, in so far, becomes a poisoned one.

Currents produce heat but the burns are usually the result of the arc produced at the point of contact rather than by the heat directly resulting from the passage of the current. Currents also produce *electrolytic or chemical changes*—the direct current being regarded as most effective, but in the tissues there are changes which must be recognized even though we must wait for their explanation—such as are found in the blood.

The effects are, in general, proportional to the amount of current and, with qualifications, also proportional to the voltage. The time or duration of the flow is a very important factor in all electrical cases.

In considering electrical action it is necessary to magnify the time, for great results take place in such extremely short periods that we can hardly conceive of them as they occur unless we do so magnify them. Otherwise we will not properly realize the complex nature of an occurrence which takes but the minute fraction of a second, such as a stroke of lightning. Nor shall we properly appreciate that *electricity possesses no sense of geometry* but seeks its path under laws of attraction and repulsion as truly as does the trickle of water in a rain storm.

Injuries by therapeutic currents are generally to be studied by the damage done to the nerves and are usually of a trophic type—rarely we have severe thermal or mechanical injuries. Unfortunately we can say but little of the injuries to the tissues themselves owing to the dense ignorance of the whole subject. Very severe damage has been done by the substances forced into the tissues by the cataphoretic process—even fatal results have occurred; fortunately the recklessness in this matter has largely subsided.

Injuries by Artificial Currents.—During the past few years the enormous increase in the use of electricity for domestic and industrial purposes has brought with it a very large number of accidents which demand the attention of the surgeon. In spite of all precautions and safeguards this class of cases is still increasing. In the past they were added to by reason of the ignorance and stupid assurance of the so-called practical electricians; this is fortunately being corrected.

While these injuries are most frequent among those employed about electrical appliances they are not confined to this class. The private citizen in his bath may touch with his wet and soapy hand a charged metal light socket, the butcher in his refrigerator, the confectioner making ice cream, the lad at play, the pedestrian on the public highway, the domestic in the kitchen or laundry, the stenographer in the office. These and other similar cases have occurred with serious results in our own experience.

Most industrial currents are produced by dynamos and any metal or other conductor connected either purposely or through accident may become dangerously charged and cause serious or fatal accident. *Nearly all industrial currents are dangerous*, as no current of 50 volts or over is safe. Formerly it was supposed that the resistance of the human body was very high but, after a sad list of fatalities had occurred, it was concluded that under certain conditions the skin resistance rapidly disappeared. Then fatal cases from low currents were recorded as due to heart disease. If the charged metal be connected with the earth—"grounded"—the current will seldom leave it to enter the body; this suggests the procedure of grounding a charged wire where the current cannot be cut or the person removed from contact with it. It, however, should be remembered that this is a dangerous procedure. Usually the person receives the current in one of two ways, either he touches both wires, or conductors, and then makes a double contact or as is more usual, he is in contact with one wire and is grounded by touching some uncharged conducting material.

With low voltages full contact is necessary, as such currents will not overcome the resistance of the air; but with high voltages, the current may jump or spark.

Ordinarily, the skin resistance is sufficient to withstand currents up to 200 volts but with skin damp with perspiration or saline solutions the ordinary lighting currents of 110 volts are dangerous and it is surprising how little grounding is necessary to produce fatal results. We daily see the repair men on the trolley lines handling live wires but they are insulated from the ground. So too we know that firemen come in contact with live wires but their rubber boots save them from serious results, though they are frequently severely shocked. Fortunately the first effect of the current is to cause violent muscular contractions; at times these throw the man some distance, breaking the contact thus saving his life. Reports from the large industrial plants show that recovery is to be looked for

if first aid be promptly rendered and artificial respiration quickly instituted and persistently kept up.

At the point of contact one may find evidences of the passage of the current, such as minute punctures—holes or wounds—burns, or simply marks. The effect may vary from pallor due to vasomotor spasm to redness, from whiteness, as of cooking, to actual charring and, at times, may show a film from vaporized metal.

It is usually stated that constant or direct currents produce shock at opening and closing only but it should be remembered that, owing to muscular action and other factors, these currents often practically act differently and that burning and electrolysis may be severe. There is some debate as to the cause of respiratory failure resulting from severe electric shock but it is quite certain that asphyxia follows the arrest of respiratory action by reason of spasm of the muscles, also that this spasm produces fatigue which persists often for a considerable time, and that we actually do find true nervous respiratory paralysis in cases. It is therefore necessary in treating such cases to continue the artificial respiration long enough to allow for recovery of function in either case and to give over only when it becomes clear that such recovery is no longer to be hoped for. The hemolytic action of electric currents must be remembered, specially after prolonged contacts and the sequelæ of such hemolysis expected and treated when developed. The injury to the peripheral nerves may be very serious and may long resist treatment and must be considered as traumatic lesions. These so often complicate severe burns that they should be expected and the treatment should be adjusted accordingly. The path taken by the current cannot be readily diagnosed from the position of the contacts but something may be judged from these contacts. If both contacts are on the same leg one would expect the heart to escape, if the current passed from one hand to the other the chances are that the heart has suffered. In hand to leg contact there is uncertainty but from one hand to the leg of the opposite side the chances are less favorable. If one of the contacts is on the head the chances are usually bad. With higher voltage the danger to the central nervous system increases rapidly.

It must always be remembered that the person seldom receives the full charge from the wire or conductor—this is more apt to be the case if the skin be still intact after the exposure.

It must further be remembered that high-power currents may force a path through indifferent tissues avoiding the vital organs. Then we may hope for recovery but we must expect serious local effects along this path with delayed recovery of the part affected. Usually high-power currents acting continuously give fatal results and the exceptions which have been featured in the literature seldom show insuperable obstacles to careful analysis of cause and effect. The sequelæ depend on the duration, intensity, type and amount of current and on the location of its application and its path in the body. Usually the burns are slow to heal, tend to become infected and often show the trophic changes due to nerve lesions. The nerve lesions give rise to all degrees of anesthesia, paralysis and trophic changes. When of moderate degree we often find profuse local sweating, vasomotor disturbances, pain and various forms of paresthesia, such as tingling, formication, etc. Local effects naturally vary with the parts affected being unusually serious about the eye. The eye also suffers from the exceedingly bright light of the arc and "flash blindness" is quite common in electric plants.

Treatment.—If a person be in contact with a live wire, the first thing to do is, if possible, to shut off the current. If it be not possible to shut off the current, catch a portion of the clothing of the victim and pull him away from the wire, but do not touch his body with the bare hand. If a pair of rubber gloves can be obtained, the subject can be moved with impunity and the wires can be safely cut. If it be not possible to drag a person away from electric wires, an individual can wrap his hands in dry woolen material and safely lift the portion

of the body in contact with earth or wire, and thus break the circuit and permit removal of the body.[1] A dry cloth can be pushed between the body and the ground, and the body can then be removed from the wires. It may be possible to push the wires away by means of a dry piece of wood, or to cut them with shears which have wooden handles and which are perfectly dry, or to push or draw the body away from the wire by the employment of sticks of dry wood. Spitzka warns us to be careful in using shears "as the momentary arc formed between the separated ends may blind the rescuers." Treat the general condition in the manner set forth for Lightning-stroke (see page 1649). Raise the head a little, draw the tongue forward, and tickle the epiglottis. If the patient does not breathe, place him prone and make artificial respiration by Schäfer's method. Artificial respiration may be carried out with the patient supine by Meltzer's method of tracheal insufflation or by the pulmotor (see "Report of the Commission on Resuscitation from Electric Shock," June, 1913). Always apply external heat and massage over the cardiac region. If facilities are at hand and the victim is apparently dead, inject at once adrenalin and salt solution into a large artery (see page 538). While any heart action remains there is a chance of resuscitation. When heart action and respiration are present the prognosis is good. Very severe burns may be caused. The author has dressed many electric burns with hot fomentations of salt solution during the first few days. This facilitates the separation of the sloughs and seems to aid the weakened tissues in resisting microbic invasion; after sloughs separate, the part is dressed with dry sterile gauze. Antiseptic dressings can be used from the beginning, but they often fail entirely to arrest the sloughing. Iodoform produces much irritation and should not be employed. Ointments are very unsatisfactory. When the dressings are changed, the part should not be washed with corrosive sublimate, as this agent produces irritation; peroxid of hydrogen should be employed, followed by warm normal salt solution. Sharpe removes sloughs by applying the following mixture: 2 parts of scale pepsin, 1 part of hydrochloric acid, U. S. P., 120 parts of distilled water. This mixture is washed off after two hours with peroxid of hydrogen. The same surgeon treats necrosis of bone by injecting every few hours a 3 per cent. solution of hydrochloric acid, using every second day the pepsin solution, and when necrotic areas come away, packing with gauze. When repair begins, the raw surface should be covered with silver-leaf. Skin-grafting by Reverdin's method or Thiersch's method is rarely successful. In some regions it is possible to slide a large flap in place to cover a raw area which will not heal. In a very severe case amputation or resection may be necessary.

In New York, Pennsylvania, New Jersey, and several other states electricity is employed to execute criminals convicted of capital offenses. The infliction of death by electricity is popularly spoken of as *electrocution*. It is beyond doubt, in the words of Dr. Spitzka, "the most humane method of executing criminals." The first electrocution in New York was in Auburn Prison in 1890, and since then over 100 criminals have been executed by electricity in New York state alone. Dr. Spitzka has witnessed 36 electrocutions and made autopsies on 27 of the victims ("Jour. Med. Soc. of New Jersey," 1909). The apparatus used is "an alternating dynamo capable of generating 2000 volts, a 'death-chair' with adjustable head-rest, binding straps, and adjustable electrodes." (At Trenton a 2400-volt current is taken from the public service wire and lowered to the desired tension by a rheostat.) The notch to control the current is in the death-chamber and the dynamo is in another apartment, communication being had by electric signals. The prisoner (usually without fetters) walks in when everything is ready and sits down in the chair, and his arms, legs, head and chest are strapped to the chair. An electrode moist with salt solution is fastened to the head and another to the bare calf of the leg. The head need not be shaved.

[1] See the directions in "Med. Record," Dec. 28, 1895, from "Med. Press."

"The application of the current is usually as follows: The contact is made with a high potential—1800 volts—for five to seven seconds, reduced to 250 volts until a half-minute has elapsed; raised to high voltage for three to five seconds; again reduced to low voltage until one minute has elapsed, when it is again raised to the high voltage for a few seconds, and the contact is broken. The ammeter usually shows that from 7 to 10 amperes have passed through the criminal's body.

"A second or even a third brief contact is sometimes made, partly as a precautionary measure, but more to abolish completely reflexes in the dead body.

"The time consumed by the strapping-in process is usually about forty-five seconds and the first contact is made a few seconds later. In all, about sixty to seventy seconds elapse from the moment the convict leaves his cell until he is shocked to death" (Spitzka, Ibid.).

After electrocution the temperature of the body rises and may reach 129.5° F. Dr. Spitzka finds that after removing the brain the temperature in the vertebral canal is often over 120° F. The brain shows capillary hemorrhages, arterial anemia, and venous congestion. In some of Spitzka's cases sections of the pons, oblongata, and spinal cord showed areas resembling gaseous emphysema, which were perhaps caused by "electrolytic liberation of gas."

In electrocution there is no pain, consciousness is at once abolished, death is certain, and resuscitation is impossible. The lurid stories about criminals being killed by the necropsy and not by the electric current are nonsense.

Injuries by lightning occur mostly in the summer months and are more frequently met with in rural districts than in cities. The number of deaths varies from 2 to 20 a year per million of the total population. It is impossible to say how many are actually injured because no statistics are available but from such experiences as the great storm in Gettysburg during the militia encampment in 1908, when 3 were killed outright, 28 were reported as seriously shocked but recovered and scores were more or less seriously affected and from the records of many other instances giving similar proportion, we conclude that at least five are injured to one killed.

Lightning which is the discharge of atmospheric electricity varies enormously in phenomena and effects. We have little accurate knowledge regarding the amount of electricity contained in such discharges but we have every reason to believe it is very great as compared with all other forms of electricity. The discharge or "bolt," which passes from a cloud to the earth usually appears to be a direct disruptive spark like that from an induction coil of large capacity.

On closer study we find this simplicity is only apparent for it is highly complex, does not follow straight lines but seeks out a path with relation to conductors and the attraction of other primary and induced charges in many objects. Further the effects are not limited to the direct line or actual path of the discharge but extend to a very considerable distance by producing powerful induction effects in proportion to the enormous potential of the bolt. In order to understand the action of lightning we must recall how static charges not only accumulate on the surface of conductors but how they seem to sink into the substance of non-conductors or become occluded as if they spread over the multiple surfaces of the component particles, as they certainly do in such objects as hair, fur and clothing. The discharge is not over surfaces alone but goes through substance also.

We then can realize why animals become sources of danger during storms, for the dry hair offers an enormous surface for electrical accumulation and as soon as it becomes damp enough to conduct electricity the animal becomes more dangerous than an equal amount of metal. In a similar way masses of damp hay become conductors of electrical potential and are often struck.

Trees, with a corky bark, which offer an enormous surface become more dangerous when such bark becomes damp than smooth barked trees. This has given rise practically to a popular belief that the beech is safer than the oak in a storm.

We must not rest content with classing the variations of lightning as freak performances but must study the effects in the light of scientific accomplishment. Thus the effects on the clothing are often most startling, being often described as explosive in type; yet when we recall how vast is the surface of the component fibers and how hydroscopic such fibers are and how conduction increases with dampness and how partial conductors develop heat in proportion to the current, we are no longer surprised at the effects but are enabled to judge of the nature and path of the discharge with some degree of certainty. This will help us greatly in our diagnosis and prognosis of the injuries to the body. It will also help us to understand why two persons subjected to the induction effects of the same bolt will show very different markings.

We must never forget that electric discharges are extremely sensitive to the attractions and repulsions of electric charges and that they induce such charges. It must further be recalled that what we observe in the sky on a large scale takes place in the body on a small scale and that as one discharge is thick, intense and straight, another is notched or branched. So in the body we find markings corresponding to all the types seen in the sky. So, too, do we find the discharge from the body meeting that from the sky. In one case the mass of the discharge is so great that it is uninfluenced by minor object charges but crashes through all obstacles; in another case a smaller charge wanders about from object to object, entering a window or door and playing pranks of the greatest variety. So in the body the heavy charge smashes through skull, pulpifies brain, rushes straight down and out, while the milder bolt is influenced by conditions, wanders and may leave with only local effects. In this way cases of actual stroke have recovered. Usually, direct strokes are fatal when they pass through the body and only those passing through a part or those going over the surface or those passing near furnish the cases of recovery. When death occurs it is usually instantaneous so that when any sign of life remains there is hope, but, even in the apparently hopeless cases, treatment should be persisted in.

Persons struck while in open fields or on roads are apt to show burns indicating that the bolt passed from head to foot. Persons struck while under trees often show induction effects only but may show that the bolt or part of the bolt has jumped from the tree to the body. Arborescent markings are purely discharge phenomena and are generally due to induction charges.

What has been described as return stroke and has been supposed to be due to secondary or readjustment discharge, appears generally to be due to the discharge of induction charges immediately following the primary discharge. The cause of death, from its instantaneous nature, must necessarily be due to the effects on the nervous system, probably destructive effects and not unlike those produced by high voltage artificial currents. Tissue effects are found wherever the bolt has passed and these may be mechanical, consisting of various sized holes or considerable wounds or they may show the explosive type indicating the sudden production of gases or vapor. Very frequently we find burns, generally superficial but not rarely severe, and at times very severe. Often we find a combination of all types—burning, denudation, actual wounding and markings. The eyes often suffer, at times being burned and at others, the optic nerve being affected. Frequently we find only a temporary flash blindness.

The sequelæ include nerve lesions similar to those found after industrial injuries. The brain is more apt to be permanently injured but may exhibit anything from coma to intense excitement. Usually unconsciousness is only brief but may last for hours.

Treatment should be persisted in long after apparent death, for cases of late recovery are recorded. It is essentially the same as for injuries by industrial currents (see page 1647) and includes artificial respiration in the prone position with care to have the head bent well back so as to free the throat; maintenance of temperature; combating of shock and heart failure and the guarded use of electricity.
